ASM HANDBOOK®

VOLUME 13

Corrosion

ASM
INTERNATIONAL ®

Corrosion was published in 1987 as Volume 13 of the 9th Edition *Metals Handbook*. With the fourth printing (1992), the series title was changed to *ASM Handbook*. The Volume was prepared under the direction of the ASM International Handbook Committee.

Volume Chairmen

The Volume Chairmen were Lawrence J. Korb, Rockwell International and David L. Olson, Colorado School of Mines

Authors and Reviewers

- **H. Ackerman** Edco Products, Inc.
- **Donald R. Adolphson** Sandia Laboratories
- **D.C. Agarwal** Haynes International, Inc.
- **V.S. Agarwala** Naval Air Development Center
- **John D. Alkire** Amoco Corporation
- **John R. Ambrose** University of Florida
- **Albert A. Anctil** Department of the Army
- **Phillip J. Andersen** Zimmer
- **D.B. Anderson** National Bureau of Standards
- **Peter L. Andresen** General Electric Research and Development Center
- **Dennis M. Anliker** Champion International Corporation
- **Frank J. Ansuini** Consulting Engineer
- **A.J. Armini** Surface Alloys Corporation
- **William G. Ashbaugh** Cortest Engineering Services
- **Aziz I. Asphahani** Haynes International, Inc.
- **Terje Kr. Aune** Norsk Hydro (Norway)
- **Denise M. Aylor** David Taylor Naval Ship Research & Development Center
- **Robert Baboian** Texas Instruments, Inc.
- **C. Bagnall** Westinghouse Electric Corporation
- **V. Baltazar** Noranda Research Centre (Canada)
- **Edward N. Balko** Englehard Corporation
- **Calvin H. Baloun** Ohio University
- **R.C. Bates** Westinghouse Electric Corporation
- **Michael L. Bauccio** The Boeing Company
- **Charles Baumgartner** General Electric Company
- **Richard Baxter** Sealand Corrosion Control, Ltd.
- **R.P. Beatson** Pulp and Paper Research Institute of Canada
- **John A. Beavers** Battelle Columbus Division
- **T.R. Beck** Electrochemical Technology, Inc.
- **S. Belisle** Noranda Inc. (Canada)
- **Robert J. Bell** Heat Exchanger Systems, Inc.
- **B.W. Bennett** Bell Communications Reseach
- **David C. Bennett** Champion International Corporation
- **E.L. Bereczky** Unocal Corporation
- **Carl A. Bergmann** Westinghouse Electric Corporation
- **I.M. Bernstein** Carnegie-Mellon University
- **A.K. Bhambri** Morton Thiokol Inc.
- **Robert C. Bill** Lewis Research Center National Aeronautics & Space Administration
- **C.R. Bird** Stainless Foundry & Engineering, Inc.
- **Neil Birks** University of Pittsburgh

- **R. Ross Blackwood** Tenaxol, Inc.
- **Malcolm Blair** Delray Steel Casting, Inc.
- **A.J. Blazewicz** Babcock & Wilcox
- **J. Blough** Foster Wheeler Development Corporation
- **Michael E. Blum** FMC Corporation
- **Bennett P Boffardi** Calgon Corporation
- **P.W. Bolmer** Kaiser Aluminum & Chemical Corporation
- **Rodney R. Boyer** Boeing Commercial Airplane Company
- **Samuel A. Bradford** University of Alberta (Canada)
- **Robert W. Bradshaw** Sandia National Laboratories
- **J.W. Braithwaite** Sandia National Laboratories
- **W.F. Brehm** Westinghouse Hanford Company
- **P. Bro** Technical Consultant
- **R. Brock** Teledyne CAE
- **Alan P. Brown** Argonne National Laboratory
- **M. Browning** Technical Consultant
- **S.K. Brubaker** E.I. Du Pont de Nemours & Company, Inc.
- **John C. Bruno** J & L Specialty Products Corporation
- **James H. Bryson** Inland Steel Company
- **R.J. Bucci** Alcoa Laboratories
- **Charles D. Bulla** ICI Americas Inc.
- **Donald S. Burns** Spraymetal, Inc.
- **H.E. Bush** Corrosion Consultant
- **Dwight A. Burford** Colorado School of Mines
- **J. Butler** Platt Brothers & Company
- **W.S. Butterfield** Beloit Corporation
- **L.E. Cadle** Texas Eastern Products Pipeline Company
- **John Campbell** Quality Carbide, Inc.
- **L.W. Campbell** General Magnaplate Corporation
- **Thomas W. Cape** Chemfil Corporation
- **Bernie Carpenter** Colorado School of Mines
- **Allan P. Castillo** Sandusky Foundry & Machine Company
- **Victor Chaker** The Port Authority of New York and New Jersey
- **George D. Chappell** Nalco Chemical Company
- **Robert S. Charlton** B.H. Levelton & Associates, Ltd. (Canada)
- **G. Dale Cheever** General Motors Research Laboratories
- **Newton Chessin** Martin Marietta Aerospace
- **Robert John Chironna** Croll-Reynolds Company, Inc.
- **Omesh K. Chopra** Argonne National Laboratory
- **Wendy R. Cieslak** Sandia National Laboratories
- **Ken Clark** Fansteel--Wellman Dynamics
- **Clive R. Clayton** State University of New York at Stony Brook
- **S.K. Coburn** Corrosion Consultants, Inc.
- **Robert Coe** Public Service Company of Colorado
- **B. Cohen** Air Force Wright Aeronautical Laboratories
- **Roland L. Coit** Technical Consultant
- **L. Coker** Exxon Chemical Company
- **N.C. Cole** Combustion Engineering Inc.
- **E.L. Colvin** Aluminum Company of America
- **J.B. Condon** Martin Marietta Energy Systems, Inc.
- **B. Cooley** Hoffman Silo Inc.
- **Richard A. Corbett** Corrosion Testing Laboratories, Inc.
- **B. Cox** Atomic Energy of Canada Ltd.
- **W.M. Cox** Corrosion and Protection Centre University of Manchester (England)

- **Bruce Craig** Metallurgical Consultants, Inc.
- **K.R. Craig** Combustion Engineering Inc.
- **William R. Cress** Allegheny Power Service Corporation
- **Paul Crook** Haynes International, Inc.
- **Thomas W. Crooker** Naval Research Laboratory
- **Ronald D. Crooks** Hercules, Inc.
- **Carl E. Cross** Colorado School of Mines
- **Robert Crowe** Naval Research Laboratory
- **J.R. Crum** Inco Alloys International, Inc.
- **Daniel Cubicciotti** Electric Power Research Institute
- **William J. Curren** Cortronics, Inc.
- **Michael J. Cusick** Colorado School of Mines
- **Carl J. Czajkowski** Brookhaven National Laboratory
- **Brian Damkroger** Colorado School of Mines
- **P.L. Daniel** Babcock & Wilcox
- **Joseph C. Danko** American Welding Institute
- **Vani K. Dantam** General Motors Corporation
- **C.V. Darragh** The Timken Company
- **Ralph M. Davison** Avesta Stainless, Inc.
- **Sheldon W. Dean** Air Products and Chemicals, Inc.
- **Terry DeBold** Carpenter Technology Corporation
- **Thomas F. Degnan** Consultant
- **James E. Delargey** Detroit Edison
- **Stephen C. Dexter** University of Delaware
- **Ronald B. Diegle** Sandia National Laboratories
- **J.J. Dillon** Martin Marietta Energy Systems, Inc.
- **Bill Dobbs** Air Force Wright Aeronautical Laboratories
- **R.F. Doelling** The Witt Company
- **James E. Donham** Consultant
- **R.B. Dooley** Electric Power Research Institute
- **D.L. Douglass** University of California at Los Angeles
- **Donald E. Drake** Mobil Corporation
- **L.E. Drake** Stauffer Chemical Company
- **Carl W. Dralle** Ampco Metal
- **Edgar W. Dreyman** PCA Engineering, Inc.
- **Barry P. Dugan** St. Joe Resources Company
- **Arthur K. Dunlop** Corrosion Control Consultant
- **Walter B. Ebner** Honeywell Inc.
- **G.B. Elder** Union Carbide Corporation
- **Peter Elliott** Cortest Engineering Services Inc.
- **Edward Escalante** National Bureau of Standards
- **Charles L.L. Faust** Consultant
- **R. Fekete** Ford Motor Company
- **Ron Fiore** Sikorsky Aircraft
- **S. Fishman** Office of Naval Research
- **W.D. Fletcher** Westinghouse Electric Corporation
- **Mars G. Fontana** Materials Technology Institute
- **F. Peter Ford** General Electric Research & Development Center
- **Robert Foreman** Park Chemical Company
- **L.D. Fox** Tennessee Valley Authority
- **Anna C. Fraker** National Bureau of Standards
- **David Franklin** Electric Power Research Institute
- **Douglas B. Franklin** George C. Marshall Space Flight Center National Aeronautics & Space Administration

- **David N. French** David French Inc.
- **R.A. French** BASF Corporation
- **R.E. Frishmuth** Cortest Laboratories
- **Allan Froats** Chromasco/Timminco, Ltd. (Canada)
- **P. Fulford** Florida Power and Light Company
- **J.M. Galbraith** Arco Alaska Inc.
- **J.W. Gambrell** American Hot Dip Galvanizers Association
- **S. Ganesh** General Electric Company
- **Richard P. Gangloff** University of Virginia
- **Thomas W. Gardega** National Thermal Spray Company
- **Warren Gardner** Department of the Air Force
- **Andrew Garner** Pulp and Paper Research Institute of Canada
- **D. Gearey** Corrosion and Protection Centre University of Manchester (England)
- **George A. Gehring, Jr.** Ocean City Research Corporation
- **Floyd Gelhaus** Electric Power Research Institute
- **Randall M. German** Rensselaer Polytechnic Institute
- **William J. Gilbert** Croll-Reynolds Company, Inc.
- **Paul S. Gilman** Allied-Signal

Foreword

Volume 13 of the *Metals Handbook* series was compiled in response to the demand from our membership for a detailed work on the multibillion-dollar problem that confronts nearly every design engineer in every industry: corrosion. It represents the culmination of three years of intensive planning, writing, editing, and production. The hard work has paid off. *Corrosion* is the largest, most comprehensive volume on a single topic ever published by ASM.

We believe that our readers will find this Handbook useful, instructive, and enlightening. These pages cover every aspect of the subject: corrosion theory, forms of corrosion, testing and evaluation, design considerations, protection methods, and corrosion as it affects specific metals and alloys and specific industries. Our goal is to help you solve existing corrosion problems--and to help you prevent problems in the future.

ASM INTERNATIONAL is indebted to Lawrence J. Korb, Co-chairman of the Handbook and the driving force behind the project, and to Co-Chairman David L. Olson. Their task of planning and coordinating this volume has been a yeoman's one, and they have been equal to it. Both Larry and Dave are Fellows of ASM and have served in leadership roles within the Society for many years--Larry as a past Chairman of the Publications Council and the Handbook Committee, and Dave as a past Chairman of the Joining Division Council and as a member of the Handbook Committee since 1982. They epitomize the vast pool of talent and energy made available to the Sociey by its dedicated members, without whom we could not survive. Thanks also go to the ASM Handbook Committee and to the ASM editorial staff for their tireless efforts.

We are especially grateful to the nearly 500 authors and reviewers listed in the next several pages. Their generous commitment of time and expertise, their willingness to share their years of experience and knowledge, to write and rewrite, has made this Handbook a truly outstanding source of information.

- Raymond F. Decker

Preface

The cost of corrosion to U.S. industries and the American public is currently estimated at $170 billion per year. Although corrosion is only nature's method of recycling, or of returning a metal to its lowest energy form, it is an insidious enemy that destroys our cars, our plumbing, our buildings, our bridges, our engines, and our factories. Corrosion can often be predictable, such as the uniform corrosion of steel ship hulls or tanks, or it can be totally unpredictable and catastrophic, such as the hydrogen embrittlement or stress corrosion of critical structural members and pressure vessels in the aerospace and chemical processing industries. While corrosion obeys well-known laws of electrochemistry and thermodynamics, the

many variables that influence the behavior of a metal in its environment can result in accelerated corrosion or failure in one case and complete protection in another similar case. We can no longer think of materials and environments as monolithic. It makes no sense to ask whether stainless steel is compatible with sulfuric acid. Rather, the question we must ask is which alloy of stainless steel, with which microstructure, with which design detail, is compatible with which sulfuric acid. What is the acid's temperature, concentration, pH, impurity level, types of trace species, degree of aeration, flow velocity, etc.?

Avoiding detrimental corrosion requires the interdisciplinary approach of the designer, the metallurgist, and the chemist. Sooner or later, nearly everyone in these fields will be faced with major corrosion issues. It is necessary to learn to recognize the forms of corrosion and the parameters that must be controlled to avoid or mitigate corrosion. This Handbook was written with these three engineering disciplines in mind. We have attempted to put together a reference book that is well rounded and complete in its coverage--for we want this to be the first book you select when researching a corrosion problem. Each article is indexed to other appropriate sections of the Handbook, and each provides a road map to the thousands of individual bibliographical references that were used to compile the information.

The Handbook is organized into eight major Sections. The first is a Glossary of metallurgical and corrosion terms used throughout the Volume. Nearly 600 terms are defined, selected from more than 20 sources. Of course, one of the most difficult terms to get corrosion experts to agree upon is a definition for "corrosion" itself, for where does one draw the line? Is not the hydride, which precipitates in a stressed titanium weld, a form of corrosion just as the hydrogen embrittlement of steel? And where does corrosion stop--with a metal, or is the environmental reaction of a ceramic or polymer also a form of corrosion? In this Handbook we have limited our discussion of corrosion to metals, by and large, but have included reactions with external environments which may diffuse inside a metal, leading to its destruction as an "internal environment."

The second Section covers the theory of corrosion from the thermodynamic and kinetic points of view. It covers the principles of electrochemistry, diffusion, and dissolution as they apply to aqueous corrosion and high-temperature corrosion in salts, liquid metals, and gases. The effects of both metallurgical and environmental variables on corrosion in aqueous solutions are discussed in detail.

The third Section describes the various forms of corrosion, how to recognize them, and the driving conditions or parameters that influence each form of corrosion, for it is the control of these parameters which can minimize or eliminate corrosion. For convenience, this Section is divided into articles on general corrosion, localized corrosion, metallurgically influenced corrosion, mechanically assisted degradation, and environmentally induced cracking. More than 20 distinct corrosion mechanisms are discussed.

mIn the fourth Section, methods of corrosion testing and evaluation in the laboratory as well as in-place corrosion monitoring are discussed. For each major form of corrosion (pitting, stress-corrosion cracking, etc.), the existing techniques used in their evaluation are discussed along with the advantages and limitations of each particular test and the quality of the test data generated.

The fifth Section looks at corrosion from the design standpoint. Which materials and design details minimize corrosion? What are the corrosion problems with weldments and how can they be addressed? Finally, how do you place an economic value on your selection of alternate materials or coatings?

The next Section reviews the various methods used for corrosion protection. These include surface conversion coatings, anodizing, ceramic coatings, organic coatings, metallic coatings (both as barrier metals and as sacrificial coatings), thermal spray coatings, CVD/PVD coatings, and other methods of surface modification. It also discusses the principles of and the approaches to anodic and cathodic protection. Finally, the various types and uses of corrosion inhibitors are thoroughly discussed.

The seventh Section covers the corrosion of 27 different metal systems, including all major structural alloy systems and precious metals, and relates the latest information on such topics as powder metals, cemented carbides, amorphous metals, metal matrix composites, hard chromium plating, brazing alloys, and clad metals. In many areas, complete articles have been written where only a few paragraphs were available in existing corrosion texts. For each metal system, the authors discuss the alloys available, the nature of the corrosion resistance film that forms on the metal, and the mechanisms of corrosion, including the metallurgical factors or elements that inhibit or accelerate corrosion. Various forms of corrosion are discussed as well as various environmental effects. The behavior of these metal systems in

atmospheres (rural, marine, industrial), in waters (fresh water and seawater), and in alkalies, acids, salts, organic chemicals, and gases is discussed. Methods of corrosion protection most applicable to each metal system are reviewed.

The final Section of the Handbook is where all of this knowledge is put into practice. It vividly illustrates how far we've come in understanding and combating corrosion and how far we have yet to go. The corrosion experiences of experts from 20 major industries are covered in detail--from fossil fuels to nuclear power, from the chemical processing to the marine industries, from prosthetic devices to the space shuttle, from pharmaceuticals to electronics, from petroleum production and refining to heavy construction. The authors describe the corrosion problems they encounter, tell how they solve them, and present illustrated case histories.

We think you will find this Handbook a broad-based approach to understanding corrosion, with sufficient data and examples to solve many problems directly, and references to key literature for further research into highly complex corrosion issues. There is no cookbook for corrosion avoidance! We hope this Volume with its road map of references will lead you to a better understanding of your corrosion problems and assist you in their solutions.

This Handbook would not have been possible without the generous contributions of the nearly 500 leading corrosion experts who donated their expertise as authors and reviewers. They represent many of the leading industries and educational institutions in this country and abroad. The articles in this Handbook represent tremendous individual efforts. We are also grateful to the Handbook staff at ASM INTERNATIONAL and for the extremely valuable contributions of several technical societies and industrial associations, including the National Association of Corrosion Engineers, the American Society for Testing and Materials, the Electric Power Research Institute, the Pulp and Paper Research Institute of Canada, the Tin Research Institute, the Institute of Paper Chemistry, the American Hot Dip Galvanizers Association, and the Lead Industries Association. In addition, we particularly appreciate the efforts of those who took responsibility for coordinating authors and papers for many articles or entire Sections of this Volume: Dr. Miroslav Marek, Dr. Bruce Craig, Dr.Steven Pohlman, Mr. Donald Sprowls, Mr. James Lackey, Dr. Herbert Townsend, Dr. Thomas Cape, Mr. Kenneth Tator, Dr. Ralph Davison, Dr. Aziz Asphahani, Mr. R. Terrence Webster, Mr. Robert Charlton, Mr. James Hanck, and Mr. Fred Meyer, Jr.

This has truly been a collective venture of the technical community. We thank those who willingly have shared their knowledge with all of us.

Staff

ASM International staff who contributed to the development of the Volume included Joseph R. Davis, Senior Editor; James D. Destefani, Technical Editor; Heather J. Frissell, Editorial Supervisor; George M. Crankovic, Assistant Editor; Diane M. Jenkins, Word Processing Specialist; Robert L. Stedfeld, Director of Reference Publications; Kathleen M. Mills, Manager of Editorial Operations; with editorial assistance from J. Harold Johnson, Robert T. Kiepura, and Dorene A. Humphries

Conversion to Electronic Files

ASM Handbook, Volume 13, *Corrosion,* was converted to electronic files in 1997. The conversion was based on the Fourth Printing (December 1992). No substantive changes were made to the content of the Volume, but some minor corrections and clarifications were made as needed.

ASM International staff who contributed to the conversion of the Volume included Sally Fahrenholz-Mann, Bonnie Sanders, Scott Henry, Grace Davidson, Randall Boring, Robert Braddock, Kathleen Dragolich, and Audra Scott. The electronic version was prepared under the direction of William W. Scott, Jr., Technical Director, and Michael J. DeHaemer, Managing Director.

Introduction

PERHAPS THE MOST STRIKING FEATURE of corrosion is the immense variety of conditions under which it occurs and the large number of forms in which it appears. Numerous handbooks of corrosion data have been compiled that list the corrosion effects of specific material/environment combinations; still, the data cover only a small fraction of the possible situations and only for specific values of, for example, the temperature and composition of the substances involved. To prevent corrosion, to interpret corrosion phenomena, or to predict the outcome of a corrosion situation for conditions other than those for which an exact description can be found, the engineer must be able to apply the knowledge of corrosion fundamentals. These fundamentals include the mechanisms of the various forms of corrosion, applicable thermodynamic conditions and kinetic laws, and the effects of the major variables. Even with all of the available generalized knowledge of the principles, corrosion is in most cases a very complex process in which the interactions among many different reactions, conditions, and synergistic effects must be carefully considered.

All corrosion processes show some common features. Thermodynamic principles can be applied to determine which processes can occur and how strong the tendency is for the changes to take place. Kinetic laws then describe the rates of the reactions. There are, however, substantial differences in the fundamentals of corrosion in such environments as aqueous solutions, non-aqueous liquids, and gases that warrant a separate treatment in this Section.

Corrosion in Aqueous Solutions

Although atmospheric air is the most common environment, aqueous solutions, including natural waters, atmospheric moisture, and rain, as well as man-made solutions, are the environments most frequently associated with corrosion problems. Because of the ionic conductivity of the environment, corrosion is due to electrochemical reactions and is strongly affected by such factors as the electrode potential and acidity of the solution. As described in the article "Thermodynamics of Aqueous Corrosion," thermodynamic factors determine under what conditions the reactions are at an electrochemical equilibrium and, if there is a departure from equilibrium, in what directions the reactions can proceed and how strong the driving force is. The kinetic laws of the reactions are fundamentally related to the activation energies of the electrode processes, mass transport, and basic properties of the metal/environment interface, such as the resistance of the surface films (see the article "Kinetics of Aqueous Corrosion" in this volume).

The fundamental kinetics of aqueous corrosion have been thoroughly studied. The simultaneous occurrences of several electrochemical reactions responsible for corrosion have been analyzed on the basis of the mixed potential theory, which provides a general method of interpreting or predicting the corrosion potential and reaction rates. The actual corrosion rates are then strongly affected by the environmental and metallurgical variables, as discussed in the articles "Effects of Environmental Variables on Aqueous Corrosion" and "Effects of Metallurgical Variables on Aqueous Corrosion," respectively. Special conditions exist in natural order and some industrial systems where biological organisms are present in the environment and attach themselves to the structure. Corrosion is expected by the presence of the organisms and the biological films they produce, as well as the products of their metabolism, as described in the Appendix "Biological Effects" to the aforementioned article on environmental variables.

Corrosion in Molten Salts and Liquid Metals

These are more narrow but important areas of corrosion in liquid environments. Both have been strongly associated with the nuclear industry, for which much of the research has been performed, but there are numerous nonnuclear applications as well. In molten-salt corrosion, described in the article "Fundamentals of High-Temperature Corrosion in Molten Salts," the mechanisms of deterioration are more varied than in aqueous corrosion, but there are many similarities and some interesting parallels, such as the use of the E - pO^{2-} diagrams similar to the E - pH (Pourbaix) diagrams in aqueous corrosion. Preferential dissolution plays a stronger role in molten-salt corrosion than in aqueous corrosion. Corrosion testing presents special problems and is much more involved than the familiar aqueous testing, usually requiring

expensive circulation loops and purification of the salts. Although the literature on molten-salt corrosion is substantial, relatively few fundamental thermodynamic and kinetic data are available.

Liquid-metal corrosion, discussed in the article "Fundamentals of High-Temperature Corrosion in Liquid Metals," is of great interest in the design of fast fission nuclear reactors as well as of future fusion reactors, but is also industrially important in other areas, such as metal recovery, heat pipes, and various special cooling designs. Liquid-metal corrosion differs fundamentally from aqueous and molten-salt corrosion in that the medium, except for impurities, is in a nonionized state. The solubilities of the alloy components and their variation with temperature then play a dominant role in the process, and preferential dissolution is a major form of degradation. Mass transfer is another frequent consequence of the dissolution process. At the same time, the corrosion is strongly affected by the presence of nonmetallic impurities in both the alloys and the liquid metals.

Corrosion in Gases

In gaseous corrosion, the environment is nonconductive, and the ionic processes are restricted to the surface of the metal and the corrosion product layers (see the article "Fundamentals of Corrosion in Gases"). Because the reaction rates of industrial metals with common gases are low at room temperature, gaseous corrosion, generically called oxidation, is usually an industrial problem only at high temperatures when diffusion processes are dominant. Thermodynamic factors play the usual role of determining the driving force for the reactions, and free energy-temperature diagrams are commonly used to show the equilibria in simple systems, while equilibria in more complex environments as a function of compositional variables can be examined by using isothermal stability diagrams.

In the mechanism and kinetics of oxidation, the oxide/metal volume ratio gives some guidance of the likelihood that a protective film will be formed, but the major role belongs to conductivity and transport processes, which are strongly affected by the impurities and defect structures of the compounds. Together with conditions of surface film stability, the transport processes determine the reaction rates that are described in general form by the several kinetic rate laws, such as linear, logarithmic, and parabolic.

The most obvious result of oxidation at high temperatures is the formation of oxide scale. The properties of the scales and development of stresses determine whether the scale provides a continuous oxidation protection. In some cases of oxidation of alloys, however, reactions occur within the metal structure in the form of internal oxidation. Like corrosion in liquids, selective or preferential oxidation is frequently observed in alloys containing components of substantially different thermodynamic stability.

Thermodynamics of Aqueous Corrosion

CORROSION OF METALS in aqueous environments is almost always electrochemical in nature. It occurs when two or more electrochemical reactions take place on a metal surface. As a result, some of the elements of the metal or alloy change from a metallic state into a nonmetallic state. The products of corrosion may be dissolved species or solid corrosion products; in either case, the energy of the system is lowered as the metal converts to a lower-energy form. Rusting of steel is the best known example of conversion of a metal (iron) into a nonmetallic corrosion product (rust). The change in the energy of the system is the driving force for the corrosion process and is a subject of thermodynamics. Thermodynamics examines and quantifies the tendency for corrosion and its partial processes to occur; it does not predict if the changes actually will occur and at what rate. Thermodynamics can predict, however, under what conditions the metal is stable and corrosion cannot occur.

The electrochemical reactions occur uniformly or nonuniformly on the surface of the metal, which is called an electrode. The ionically conducting liquid is called an electrolyte. As a result of the reaction, the electrode/electrolyte interface acquires a special structure, in which such factors as the separation of charges between electrons in the metal and ions in the solution, interaction of ions with water molecules, adsorption of ions on the electrode, and diffusion of species all play important roles. The structure of this so-called double layer at the electrified interface, as related to corrosion reactions, will be described in the section "Electrode Processes" in this article.

One of the important features of the electrified interface between the electrode and the electrolyte is the appearance of a potential difference across the double layer, which allows the definition of the electrode potential. The electrode potential becomes one of the most important parameters in both the thermodynamics and the kinetics of corrosion. The fundamentals will be discussed in the section "Electrode Potentials," and some examples of the calculations of the potential from thermodynamic data are show in the section "Potential Versus pH (Pourbaix) Diagrams."

The electrode potentials are used in corrosion calculations and are measured both in the laboratory and in the field. In actual measurements, standard reference electrodes are extensively used to provide fixed reference points on the scale of relative potential values. The use of suitable reference electrodes and appropriate methods of measurement will be discussed in the section "Potential Measurements With Reference Electrodes."

One of the most important steps in the science of electrochemical corrosion was the development of diagrams showing thermodynamic conditions as a function of electrode potential and concentration of hydrogen ions. These potential versus pH diagrams, often called Pourbaix diagrams, graphically express the thermodynamic relationships in metal/water systems and show at a glance the regions of the thermodynamic stability of the various phases that can exist in the system. Their construction and application in corrosion, as well as their limitations, will be discussed in the section "Potential Versus pH (Pourbaix) Diagrams."

Thermodynamics of Aqueous Corrosion

Electrode Processes

Charles A. Natalie, Department of Metallurgical Engineering, Colorado School of Mines

---

In the discussion of chemical reactions and valence, the topic of electrochemical reactions is usually treated as a special case. Electrochemical reactions are usually discussed in terms of the change in valence that occurs between the reacting elements, that is, oxidation and reduction. Oxidation and reduction are commonly defined as follows. Oxidation is the removal of electrons from atoms or groups of atoms, resulting in an increase in valence, and reduction is the addition of electrons to an atom or group of atoms, resulting in the decrease in valence (Ref 1).

Because electrochemical reactions or oxidation-reduction reactions can be represented in terms of an electrochemical cell with oxidation reactions occurring at one electrode and reduction occurring at the other electrode, electrochemical reactions are often further defined as cathodic reactions and anodic reactions. By definition, cathodic reactions are those types of reactions that result in reduction, such as:

$$\mathrm{M(aq)}^{2+} + 2e^{-} \rightarrow \mathrm{M(s)} \qquad \textbf{(Eq 1)}$$

Anodic reactions are those types of reactions that result in oxidation, such as:

$$\mathrm{M(s)} \rightarrow \mathrm{M(aq)}^{2+} + 2e^{-} \qquad \textbf{(Eq 2)}$$

Because of the production of electrons during oxidation and the consumption of electrons during reduction, oxidation and reduction are coupled events. If the ability to store large amounts of electrons does not exist, equivalent processes of oxidation and reduction will occur together during the course of normal electrochemical reactions. The oxidized species provide the electrons for the reduced species.

The example stated above, like many aqueous corrosion situations, involves the reaction of aqueous metal species at a metal electrode surface. This metal/aqueous interface is complex, as is the mechanism by which the reactions take place across the interface. Because the reduction-oxidation reactions involve species in the electrolyte reacting at or near the metal interface, the electrode surface is charged relative to the solution, and the reactions are associated with specific electrode potentials.

The charged interface results in an electric field that extends into the solution. This electric field has a dramatic effect on the solution near the metal.

A solution that contains water as the primary solvent is affected by an electrical field because of its structure. The primary solvent--water--is polar and can be visualized as dipolar molecules that have a positive side (hydrogen atoms) and a negative side (oxygen atoms). In the electric field caused by the charged interface, the water molecules act as small dipoles and align themselves in the direction of the electric field.

Ions that are present in the solution are also charged because of the loss or gain of electrons. The positive charged ions (cations) and negative charged ions (anions) also have an electric field associated with them. The solvent (water) molecules act as small dipoles; therefore, they are also attracted to the charged ions and align themselves in the electric field established by the charge of the ion. Because the electric field is strongest close to the ion, some water molecules reside very close to an ionic species in solution. The attraction is great enough that these water molecules travel with the ion as it moves through the solvent. The tightly bound water molecules are referred to as the primary water sheath of the ion. The electric field is weaker at distances outside the primary water sheath, but it still disturbs the polar water molecules as the ion passes through the solution. The water molecules that are disturbed as the ion passes, but do not move with the ion, are usually referred to as the secondary water sheath. Figure 1 shows a representation of the primary and secondary solvent molecules for a cation in water. Because of their smaller size relative to anions, cations have a stronger electric field close to the ion, and more water molecules are associated in their primary water sheath. However, anodic species have few, if any, primary water molecules. A detailed description of the hydration of ions in solution is given in Ref 2.

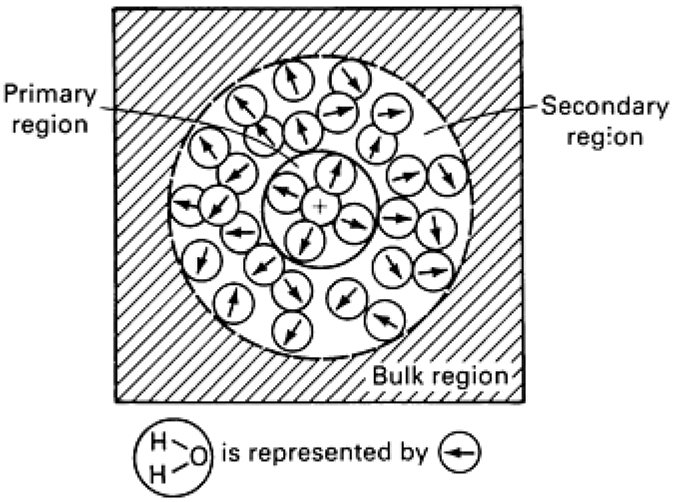

Fig. 1 Schematic of the primary and secondary solvent molecules for a cation in water

Because of the potential and charge established at the metal/aqueous interface of an electrode, ions and polar water molecules are also attracted to the interface because of the strong electric field close to the interface. Water molecules form a first row at the metal/aqueous interface. This row of water molecules limits the distance that hydrated ions can approach the interface. Figure 2 shows a schematic diagram of a charged interface and the locations of cations at the surface. Also, the primary water molecules associated with the ionic species limit the distance the ions can approach. For example, the plane of positive charge of the cations that reside near the surface of a negatively charged interface is a fixed distance from the metal due to the water molecules that are between the surface and the ions. This plane of charge is referred to as the Outer-Heimholz Plane (OHP).

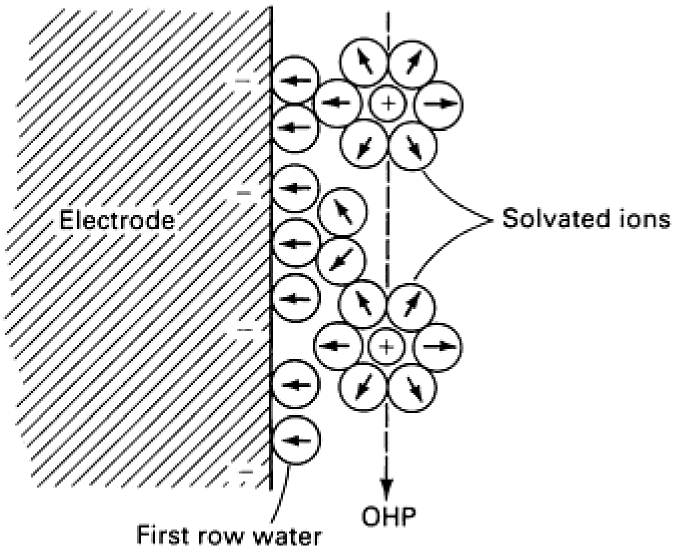

Fig. 2 Schematic of a charged interface and the locations of cations at the electrode surface

Because of the structure of the charged interface described above, it is often represented (Ref 2) as a charged capacitor (Fig. 3). The potential drop across the interface is also often simplified as a linear change in potential from the metal surface to the OHP.

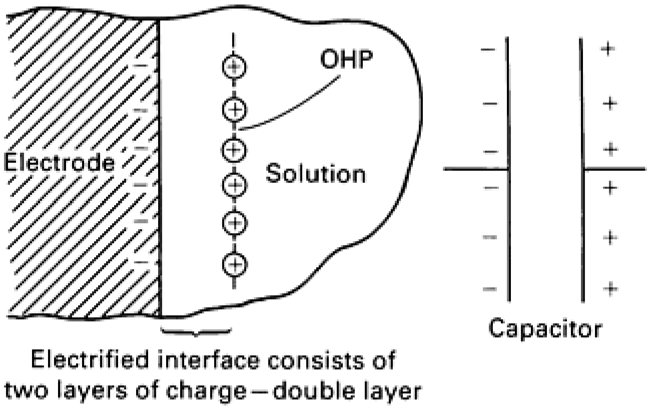

Fig. 3 Simplified double layer at a metal aqueous interface

The significance of the electronic double layer is that it provides a barrier to the transfer of electrons. If there were no difficulty in the transfer of electrons across the interface, the only resistance to electron flow would be the diffusion of aqueous species to and from the electrode. The surface would be nonpolarizable, and the potential would not be changed until the solution was deficient in electron acceptors and/or donors.

This is of particular interest when dealing with the kinetics at the interface (see the article "Kinetics of Aqueous Corrosion" in this Volume). The double layer results in an energy barrier that must be overcome. Thus, reactions at the interface are often dominated by activated processes, and activation polarization plays a significant role in corrosion. The key to controlling corrosion usually consists of minimizing the kinetics; this slows the reaction rates sufficiently that corrosion appears to be stopped.

Electrode Potentials

Charles A. Natalie, Department of Metallurgical Engineering, Colorado School of Mines

The object of chemical thermodynamics is to develop a mathematical treatment of the chemical equilibrium and the driving forces behind chemical reactions. The desire is to catalog known quantitative data concerning equilibrium that can be later used to predict equilibria (perhaps even equilibria that has never been investigated by experimentation).

The driving force for chemical reactions has been expressed in thermodynamic treatments as the balance between the effect of energy (enthalpy) and the effect of probability. The thermodynamic property that relates to probability is called entropy.

The idea of entropy has been expressed as thermodynamic probability and is defined as the number of ways in which microscopic particles can be distributed among states accessible to them (Ref 3). The thermodynamic probability is an extensive quantity and is not the mathematical probability that ranges between 0 and 1.

Free Energy

The driving force for chemical reactions depends not only on chemical formulas of species involved but also on the activities of the reactants and products. Free energy is the thermodynamic property that has been assigned to express the resultant enthalpy of a substance and its inherent probability. At constant temperature, free energy can be expressed as:

$$\Delta G = \Delta H - T\Delta S \qquad \textbf{(Eq 3)}$$

where ΔG is the change in free energy (Gibbs free energy), ΔH is the change in enthalpy, T is the absolute temperature, and ΔS is the change in entropy.

When reactions are at equilibrium and there is no apparent tendency for a reaction to proceed either forward or backward, it has been shown that (Ref 4):

$$\Delta G^\circ = -RT \ln \mathrm{K_{eq}} \qquad \textbf{(Eq 4)}$$

where ΔG° is the free energy change under the special conditions when all reactants and products are in a preselected standard state, R is the gas constant, and $\mathrm{K_{eq}}$ is the equilibrium constant. The standard free energy of formations for an extensive number of compounds as a function of temperature have been cataloged; this allows the prediction of equilibrium constants over a wide range of conditions. It is necessary only to determine the standard free energy change for a reaction (ΔG°, Eq 4) by subtracting the sum of the free energy of formations of the products at constant temperature.

If an electrochemical cell is constructed that can operate under thermodynamic reversible conditions (the concept of reversibility is described in more detail in the section) "Potential Measurements With Reference Electrodes" in this article and in Ref 4) and if the extent of reaction is small enough not to change the activities of reactants and products, the potential remains constant, and the energy dissipated by an infinitesimal passage of charge is given by:

$$|\Delta G| = \text{charge passed} \cdot \text{potential difference}$$

or

$$|\Delta G| = nF \cdot |E| \qquad \textbf{(Eq 5)}$$

where n is the number of electrons per atom of the species involved in the reaction, F is the charge of 1 mol of electrons, and E is the cell potential. Because free energy has a sign that denotes the direction of the reaction, a thermodynamic sign convention must be selected. The common U.S. convention is to associate a positive potential with spontaneous reactions; thus, the reaction becomes:

$$\Delta G = -nFE \qquad \textbf{(Eq 6)}$$

If the reaction occurs under conditions in which the reactants and products are in their standard states, the equation becomes:

$$\Delta G^\circ = -nFE^\circ \qquad \textbf{(Eq 7)}$$

Combination with Eq 4 results in:

$$\ln K_{eq} = \frac{-nFE^\circ}{RT} \qquad \textbf{(Eq 8)}$$

thus allowing the prediction of equilibrium data for electrochemical reactions.

Cell Potentials and the Electromotive Force Series

If a strip of zinc metal is placed in water, some zinc ions will be converted to aqueous zinc ions because of the relatively large tendency for zinc to oxidize. Because of the electrons remaining in the metal, the positively charged zinc ions will remain very close to the negatively charged zinc strip and thus will establish a double layer, as described in the section "Electrode Potentials" in this article (Fig. 1). The potential difference established between the solution and the zinc is of the order of 1 V, but because the double layer is very small, the potential gradient (change in potential with respect to distance) can be very high.

A negative electrode potetial (with respect to the standard hydrogen electrode discussed below) exists for a zinc electrode in a solution of zinc ions. However, if a copper strip is placed in a solution containing copper ions, a positive potential is established between the more noble copper strip and the solution.

If, however, a metal is placed in a solution containing metal ions of a different nature, the first metal may dissolve, while the second metal deposits from its ions. A common example of this is the metal displacement reaction between zinc metal and copper ions, for which the complete oxidation-reduction reaction is:

$$Zn(s) + Cu(aq)^{2+} \rightarrow Zn(aq)^{2+} + Cu(s) \qquad \textbf{(Eq 9)}$$

If the reverse procedure is tried, that is, copper metal placed in a solution containing zinc ions, no reaction will take place to any measurable extent. For example, if the solution containing zinc ions has no copper ions present initially, the reaction will occur to a very small extent, with the reaction stopping when a certain very small concentration of copper ions has been produced. In the opposite case, zinc metal will react with copper ions almost to completion; the reaction will stop only when the concentration of copper ions is very small.

The above experiment can be repeated with many combinations of metals, and the ability of one metal to replace another ion from solution can be used as a basis for tabulating the metals in a series. The table formed would show the abilities of metals to reduce other metal ions from solution. This electromotive force (emf) series for some common metals is shown in Table 1. The potentials listed in Table 1 are measured values, which will be described below as well as in the section "Potential Measurements With Reference Electrodes" in this article.

Table 1 Electromotive force series

See also Fig. 4, which shows a schematic of an electrochemical cell used to determine the potential difference between copper and zinc electrodes.

Electrode reaction	**Standard potential at 25 °C (77 °F), volts versus SHE**
$Au^{3+} + 3e^- \longrightarrow Au$	1.50
$Pd^{2+} + 2e^- \longrightarrow Pd$	0.987
$Hg^{2+} + 2e^- \longrightarrow Hg$	0.854
$Ag^{+} + e^- \longrightarrow Ag$	0.800
$Hg_2^{2+} + 2e^- \longrightarrow 2Hg$	0.789
$Cu^{+} + e^- \longrightarrow Cu$	0.521
$Cu^{2+} + 2e^- \longrightarrow Cu$	0.337
$2H^{+} + 2e^- \longrightarrow H_2$	(Reference)

$K^{+} + e^- \longrightarrow K$	-2.93
$Li^{+} + e^- \longrightarrow Li$	-3.05

The reactions described in establishing an emf series are referred to as electrochemical reactions. Electrochemical reactions are those reactions that involve oxidation (increase in valence) and reduction (decrease in valence), as described in the section "Electrode Processes" in this article.

For the example of copper metal deposition using zinc metal, the oxidation reaction for producing electrons is:

$$Zn(s) = Zn(aq)^{2+} + 2e^- \qquad \textbf{(Eq 10)}$$

Electrons are consumed by copper ion according to the following reduction reaction:

$$Cu(aq)^{2+} + 2e^- \rightarrow Cu(s) \quad \textbf{(Eq 11)}$$

To study the reactions discussed above (Eq 9, 10, 11), an electrochemical cell, such as the one shown and described in Fig. 4, can be constructed by using a copper electrode in a solution of copper sulfate as one electrode and a zinc electrode in a solution of zinc sulfate as the other electrode. If the external conduction path is short circuited, electrons will flow from the zinc electrode (anode) as zinc dissolves to the copper electrode (cathode); this causes the deposition of copper metal. This type of arrangement would demonstrate how some electrochemical reactions can take place with the reactants and products physically separated and how the overall process can be visualized as two separate reactions that occur together.

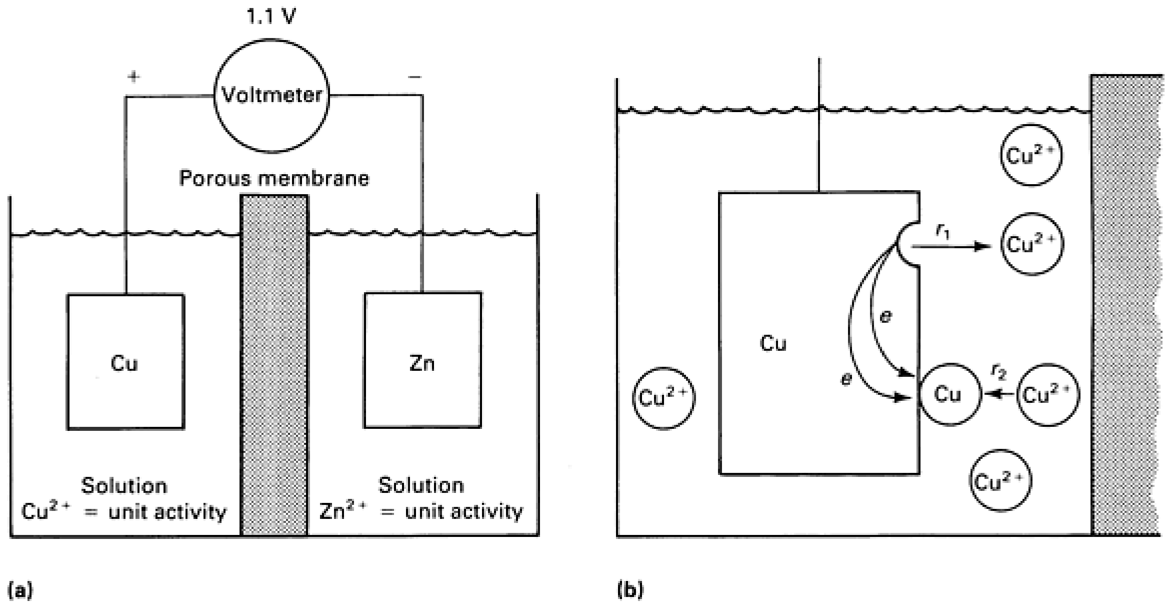

Fig. 4 Typical electrochemical cell (a) used to study the free energy change that accompanies electrochemical or corrosion reactions. In this example, the cell contains copper and zinc electrodes in equilibrium, with their ions separated by a porous membrane to mitigate mixing. For purposes of simplicity, the concentration of metal ions is maintained at unit activity; that is, each solution contains about 1 g atomic weight of metal ion per liter. The reactions taking place on each side of the cell are represented by Eq 10, and 11, and the half-cell reactions for copper and zinc electrodes are given in Table 1. The rates of metal dissolution and deposition must be the same as shown in (b), which illustrates copper atoms being oxidized to cupric ions and, at other areas, cupric ions being reduced to metallic copper. Equilibrium conditions dictate that the reaction rates r_1 and r_2 be equal. Source: Ref 5

The two reactions listed in Eq 10, and 11, and shown schematically in Fig. 4 are often referred to as half-cell reactions. This nomenclature is due to the requirement that oxidation and reduction occur simultaneously under equilibrium conditions. Therefore, the reaction given in Eq 10 is defined as an oxidation half-cell reaction, and the reaction given in Eq 11 is a reduction half-cell reaction. The reaction in Eq 9 can be referred to as the overall electrochemical reaction and is the sum of the half-cell reactions given in Eq 10 and 11.

Because specific, or absolute, potentials of electrodes cannot be measured directly, an arbitrary half-cell reaction is used as a reference by defining its potential as 0. All other half-cell potentials can then be calculated with respect to this zero reference. As described in the following section "Potential Measurements With Reference Electrodes," the hydrogen ion reaction $2H^+ + 2e \rightarrow H_2$ (Table 1) is used as the standard reference point. It is not possible to make an electrode from hydrogen gas; therefore, the standard hydrogen electrode (SHE) potential is measured by using an inert electrode, such as platinum, immersed in a solution saturated hydrogen gas at 1 atm. All values of electrode potential, therefore, are with reference to SHE.

The potentials given in Table 1 are specifically the potentials measured relative to an SHE at 25 °C (77 °F) when all concentrations of ions are 1 molal, gases are at 1 atm of pressure, and solid phases are pure. This specific electrode

potential is referred to as the standard electrode potential and is denoted by $E°$. The standard electrode potential for zinc--the accepted value for which is -0.763 (Table 1)--can be calculated by measuring the emf of a cell made up, for example, of a zinc and a hydrogen electrode in a zinc salt solution of known activity Zn^{2+} and H^+ (Fig. 5). This procedure could be repeated by exchanging the zinc electrode with any other metal and by assigning the half-cell electrode potentials measured for the electrochemical cells to the proper reactions in Table 1. Changes in concentration, temperature, and partial pressure will change the electrode potentials and the position of a particular metal in the emf series. In a particular, the change in electrode potential as a function of concentration is given by the Nernst equation:

$$E = E° - \frac{RT}{nF} \ln \frac{(ox)}{(red)} \quad \textbf{(Eq 12)}$$

where E is the electrode potential, $E°$ is the standard electrode potential, R is the gas constant (1.987 cal/K mol), T is the absolute temperature (in degrees Kelvin), n is the number of moles of electrons transferred in the half-cell reaction, F is the Faraday constant (F = 23,060 cal/volt equivalent), and (ox) and (red) are the activities of the oxidized and reduced species, respectively.

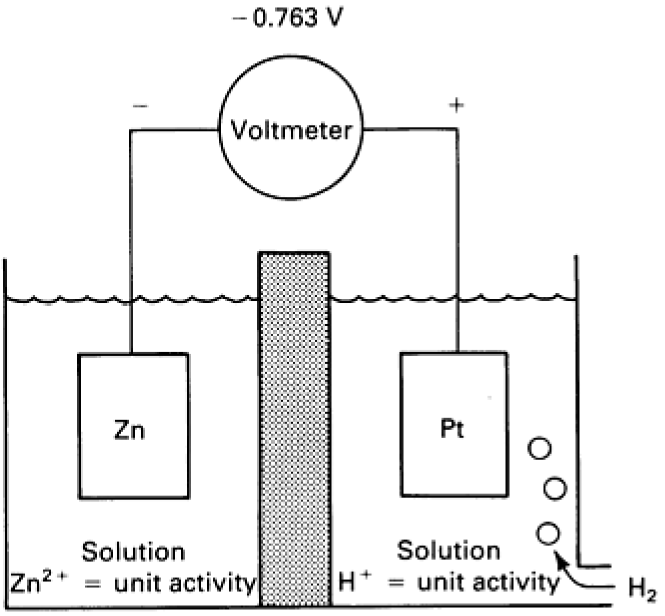

Fig. 5 Electrochemical cell containing a zinc electrode and hydrogen electrode

Electrode potentials, as described above, are always measured when zero current is flowing between the electrode and the SHE. The potential is thus a reversible measurement of the maximum potential that exists and an indication of the tendency for the particular reaction to occur. For example, metals listed in Table 1 above molecular hydrogen are more noble and less resistant to oxidation than the metals listed below hydrogen when standard-state conditions exist. This tendency is a thermodynamic quantity and does not take into account the kinetic factors that may limit a reaction because of such physical factors as protection by corrosion product layers.

Care should be taken when using an emf series such as that shown in Table 1. These values are for a very specific condition (standard state) and may not apply to a specific corrosion environment. More complete emf series (Ref 6, 7) and potentials in other environments (Ref 8) are available.

Returning to the example of an electrochemical cell with copper and zinc electrodes, it is apparent that the chemical energy that exists between the copper and zinc electrodes can be converted to electrical energy (as occurs in a battery). However, the external circuit can be replaced with a direct current (dc) power supply, which can be used to force electrons to go in a direction opposite to the direction they tend to go naturally. Both concepts are useful when dealing with corrosion because the oxidation of a metal will always be coupled to a cathodic reaction and because corrosion

reactions are similar to the galvanic-type cell. Also, application of external potentials can be used to protect metals, as in cathodic protection (see article "Cathodic Protection" in this Volume).

Corrosion processes are often viewed as the partial processes of oxidation and reduction previously described. The oxidation reaction (anodic reaction) constitutes the corrosion of the metallic phase, and the reduction reaction (cathodic reaction) is the result of the environment. Several different cathodic reactions are encountered in metallic corrosion in aqueous systems. The most common are:

$$2H^+ + 2e^- \rightarrow H_2$$
Hydrogen ion reduction

$$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O$$
Reduction of dissolved oxygen (acid media)

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^-$$
Reduction of dissolved oxygen (basic media)

$$M^{3+} + e^- \rightarrow M^{2+}$$
Metal ion reduction

$$M^{2+} + 2e^- \rightarrow M$$
Metal deposition

Hydrogen ion reduction is very common because acidic media is so often encountered, and oxygen reduction is very common because of the fact that aqueous solutions in contact with air will contain significant amounts of dissolved oxygen. Metal ion reduction and metal deposition are less common and are encountered most often in chemical process streams (Ref 9). All of the above reactions, however, share one attribute: they consume electrons.

Potential Measurements With Reference Electrodes

D.L. Piron, Department of Metallurgical Engineering, École Polytechnique de Montreal

Electrode potential measurement is an important aspect of corrosion prevention. It includes determination of the corrosion rate of metals and alloys in various environments and control of the potential in cathodic and anodic protection. Many errors and problems can be avoided by intelligently applying electrochemical principles in the use of reference electrodes. Among the problems are the selection of the best reference for a specific case and selection of an adequate method of obtaining meaningful results.

It is important to note that many different reference electrodes are available, and others can be designed by the users themselves for particular problems. Each electrode has its characteristic rest potential value, which can be used to convert the results obtained into numbers expressed with respect to other references. These conversions are frequently required for comparison and discussion, and this involves use of *E*-pH (Pourbaix) diagrams, which will be discussed later in this article. The electrode selected must than be properly used, taking into account the stability of its potential value and the problem of resistance (*IR*) drop.

Thermodynamics of Aqueous Corrosion

Electrode Potential Conventions

The use of reference electrodes is based on two fundamental conventions. One of these conventions sets a zero reference point in the potential scale, and the other gives a meaningful sign to potential values.

The Zero Convention. The potential of an electrode can be determined only with respect to another electrode, the reference electrode. As discussed previously in the section "Electrode Potentials" in this article, only the potential difference between two electrodes, each with its own specific potential, is measured.

The absolute value of the potential of a particular electrode cannot be obtained experimentally. One electrode, therefore, must be selected as 0 in the potential scale. By convention, the standard hydrogen electrode (SHE) was chosen, that is, the standard electrode potential for the reaction $2H^+ + 2e^- \rightarrow H_2$ is made to equal 0. This zero convention makes it possible to assign numbers to electrode potentials on the scale of electrode potentials. The SHE is arbitrarily fixed as the zero level, and all other potentials are expressed with respect to this reference. Practical measurements are performed with various reference electrodes having known values with respect to the SHE. For example, the saturated calomel electrode potential is +240 mV versus SHE, and the copper sulfate/copper ($CuSO_4$/Cu) electrode potential is +310 mV versus SHE.

The Sign Convention (The Reduction or Stockholm Convention). Electrode reactions may proceed in two opposite directions. For example, the Fe^{2+}/Fe system may undergo oxidation ($Fe \rightarrow Fe^{2+} + 2e^-$) or reduction ($Fe^{2+} + 2e^- \rightarrow Fe$).

The potential of this iron electrode is expressed with respect to the SHE = 0. The coupling of these two systems (Fe^{2+}/Fe and H^+/H_2), however, brings about the spontaneous oxidation of iron. The situation is entirely different with a Cu^{2+}/Cu system. In this case, the reduction is spontaneous in an electrochemical cell with a hydrogen electrode.

This difference in the spontaneous reaction direction with respect to hydrogen can be represented by a sign. This sign is also very useful in computing cell potentials from single electrode values.

The choice of a conventional direction for the reaction imposes a sign to the free energy. For the oxidation of Fe^{2+}/Fe, the $\Delta G_{\mathrm{ox}}^{\mathrm{Fe}}$ is negative, because a spontaneous reaction liberates energy. The $\Delta G_{\mathrm{red}}^{\mathrm{Fe}}$ would be positive for the reduction reaction. In the case of copper, however, thereduction of Cu^{2+}/Cu is spontaneous, and $\Delta G_{\mathrm{red}}^{\mathrm{Cu}}$ is therefore negative.

At the International Union of Pure and Applied Chemistry meeting held in Stockholm in 1953, it was decided to choose as the conventional direction the reduction reaction:

$$\mathrm{ox} + ne^- \rightarrow \mathrm{red}$$

where ox represents the oxidized species, n is the number of electrons e^-, and red is the reduced species.

The sign of the electrode can be determined by using the following reaction, which was discussed previously (see Eq 6):

$$\Delta G = -nFE$$

As a result, the Fe^{2+}/Fe system has a negative sign, and Cu^{2+}/Cu has a positive sign.

In this reduction convention, a negative sign indicates a trend toward corrosion in the presence of H^+ ions. The ferrous cations have a greater tendency to exist in aqueous solution than the H^+ cations. A positive sign indicates, on the contrary, that the H^+ ion is more stable than Cu^{2+}, for example.

The reduction convention selects a conventional direction reduction for electrochemical reactions. It is because this conventional direction is not necessarily the natural spontaneous direction that a sign can be given to the electrode potential.

Example of Potential Conversion. The need to be consistent in expressing electrode potentials versus references in a specific problem (regardless of the actual reference used in the measurement) is illustrated in the following example.

The electrode potential of buried steel pipe is measured with respect to a $CuSO_4$/Cu electrode, and the value is 650 mV for a pH 4 environment. If that value is mistakenly placed in the iron *E*-pH diagram, it could be concluded that corrosion is not going to take place. This conclusion would, however, be incorrect, because the *E*-pH diagrams are always computed with respect to the SHE. It is then necessary to express the result of the measurement with respect to that electrode before consulting the *E*-pH diagram. The measured electrode potential then has to be expressed with respect to the SHE.

Because the $CuSO_4$/Cu electrode potential is +310 mV versus SHE, the number that expresses the measured potential is 310 mV higher with the $CuSO_4$/Cu electrode than with the SHE. As a result, V_{SHE} should be -340 mV. The principle of this conversion is illustrated in Fig. 6 in an electrode potential reference conversion schematic.

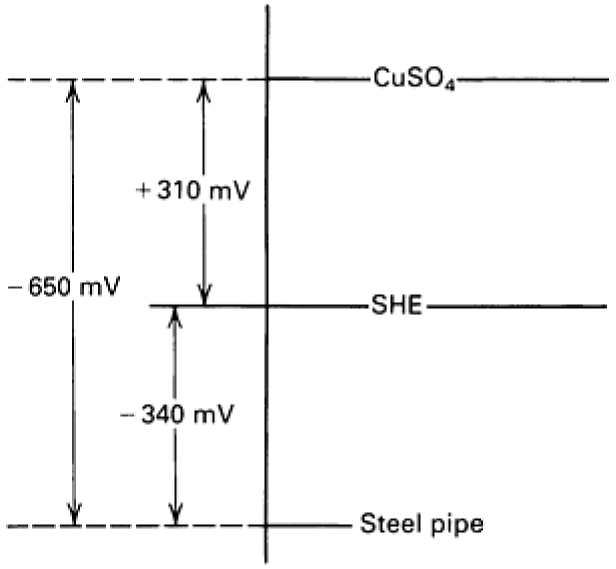

Fig. 6 Electrode potential conversion diagram

The value of -340 mV placed in the *E*-pH diagram at a pH 4 clearly indicates a corrosion region for iron (Fig. 7). It would then be definitely necessary to consider the cost benefit of a protection system for the steel pipe.

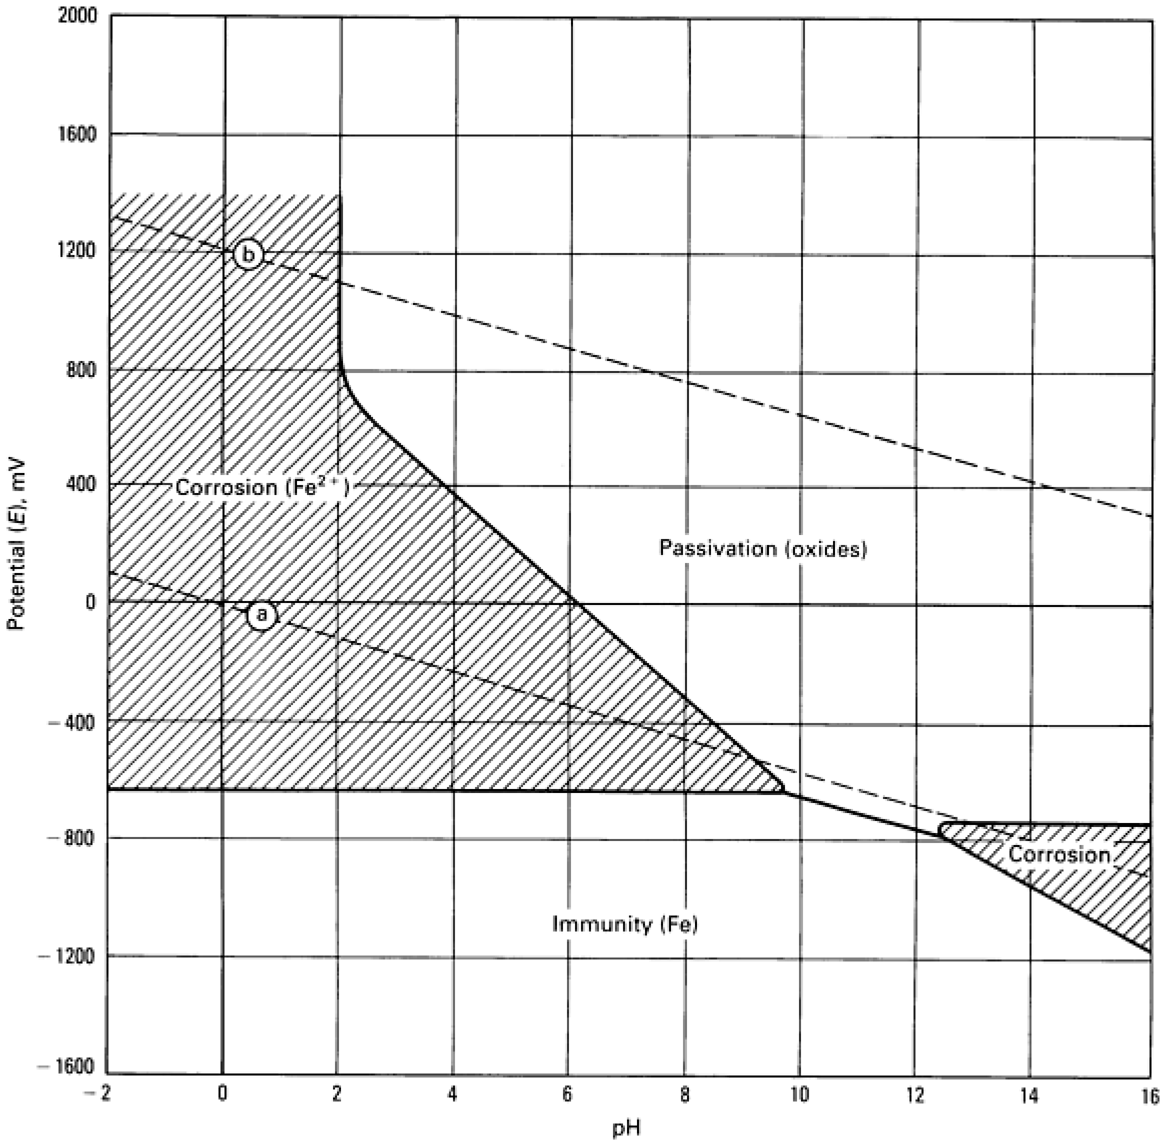

Fig. 7 Iron *E*-pH diagram. Dashed lines a and b are explained in Fig. 18 and in the corresponding text.

The Three-Electrode System

When a system is at rest and no significant current is flowing, the use of only one other electrode as a reference is sufficient to measure the test electrode potential. When a current is flowing spontaneously in a galvanic cell or is impressed to an electrolytic cell, reactions at both electrodes are not at equilibrium, and there is consequently an overpotential on each of them. The potential difference measured between these two electrodes then includes the value of the two overpotentials. The potential of only the test electrode cannot be determined from this measurement.

To obtain this value, a third electrode, the auxiliary electrode, must be used (Fig. 8). In this way, the current flows only between the test and the auxiliary electrodes. A high-impedance voltmeter placed between the test and the reference prevents any significant current flow through the reference electrode, which then does not show any overpotential. Its potential remains at its rest value. The test electrode potential and its changes under electric current flow can then be measured with respect to a fixed reference potential (most references are not made to be polarized by a current flow). The three-electrode system is widely used in the laboratory and in field potential measurement.

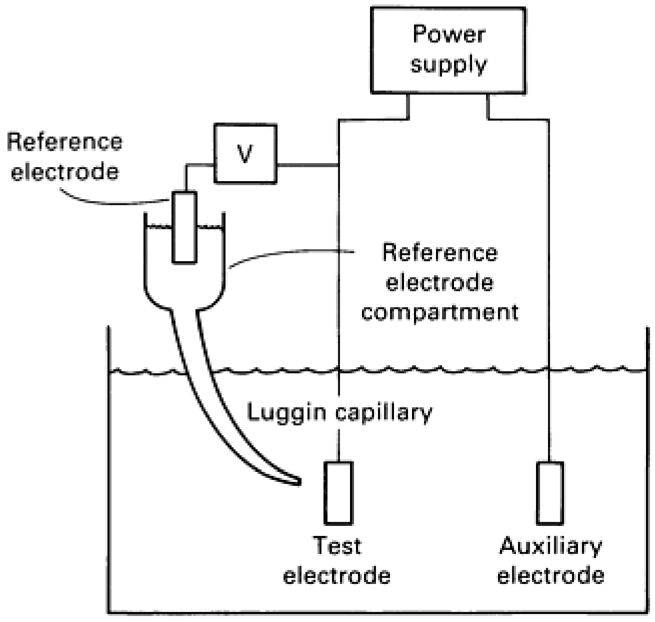

Fig. 8 Potential measurement with a luggin capillary. V, voltmeter

Electrode Selection Characteristics

Stable and Reproducible Potential. Electrodes used as references should offer an acceptably stable and reproducible potential that is free of significant fluctuations. To obtain these characteristics, it is advantageous, whenever possible, to use reversible electrodes, which can be easily made.

The $CuSO_4$/Cu electrode is an excellent example of a good reversible electrochemical system; it is widely used as a reference electrode in the corrosion field. It can be easily made by immersing a copper rod in a saturated $CuSO_4$ aqueous solution, as shown in Fig. 9.

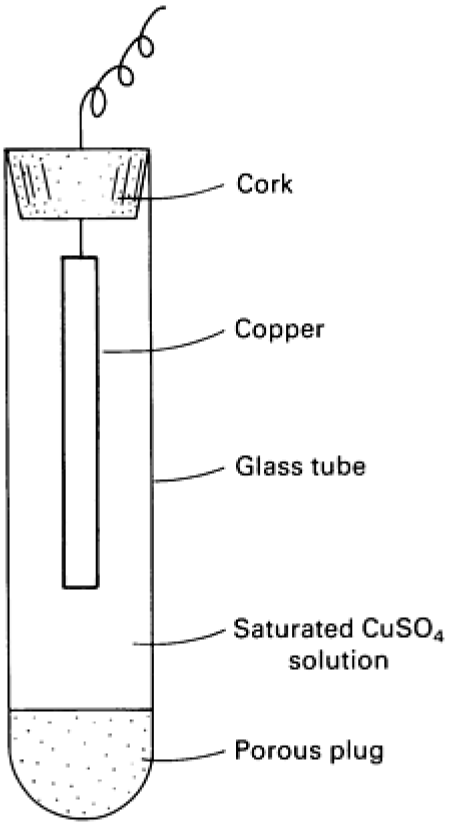

Fig. 9 Schematic of a $CuSO_4$/Cu reference electrode

This electrode is reversible, because a small cathodic current produces the reduction reaction ($Cu^{2+} + 2e^- \rightarrow Cu$), while an anodic current brings about the oxidation reaction ($Cu \rightarrow Cu^{2+} + 2e^-$). This is not a corroding system like that of immersed iron, which dissolves anodically into Fe^{2+}, because the immersed copper system produces the hydrogen evolution reaction under a cathodic current.

In the case of the $CuSO_4$/Cu electrode, the rest potential is the equilibrium potential that can be $E_{Cu^{2+}/Cu}$ computed by the Nernst equation (Eq. 12). At 25 °C (77 °F), it would be:

$$E_{Cu^{2+}/Cu} = +0.34 + \frac{0.059}{2} \log a_{Cu^{2+}}$$

where $E_{Cu^{2+}/Cu}$ is the Cu^{2+}/Cu equilibrium potential, 0.34 is the standard potential, and $a_{Cu^{2+}}$ is the activity of Cu^{2+} in the aqueous solution. This system then provides a well-defined reversible system that is reliable and easy to build.

In some practical cases, however, nonreversible electrodes are used. Although not as well defined, their potential stability in a particular environment is considered sufficient in certain applications. In the selection of reference electrodes, their durability, life expectancy, and price must also be considered.

Low Polarizability. The polarization of reference electrodes introduces an error in the potential measurement. The potential versus current density response, called a polarization curve, should show a low overpotential and a high exchange current, i_{ex}, as can be seen in Fig. 10 (line a). More detailed information on polarization curves can be found in the article "Kinetics of Aqueous Corrosion" and in the section "Electrochemical Methods of Corrosion Testing" of the article "Laboratory Testing" in this Volume.

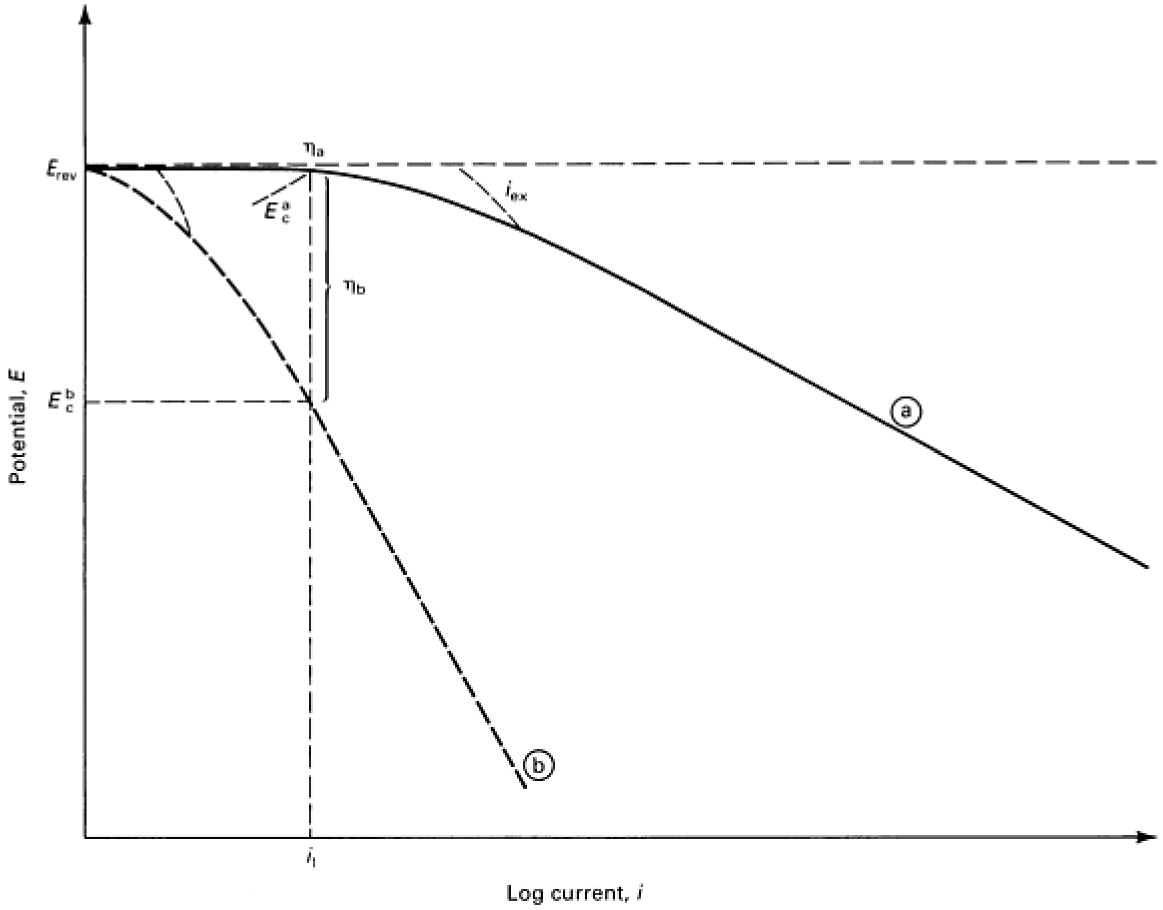

Fig. 10 Polarization curve for a good reference electrode (line a) and a poor reference electrode (line b)

A poor polarization characteristics for a reference electrode is represented by the dashed line (b) in Fig. 10. In this case, a small current density i_1 produces a significant potential change from E_{rev} to E_c^b. This results in a large change in the overpotential η_b. The electrode represented by line (a) offers much better polarization characteristics. Under the same current density i_1, the observed electrode potential E_c^a remains very close to the reversible value. The resulting overpotential η_a is then negligible.

It is a question of judgment as to how polarizable the reference electrode can be. The answer depends on the precision required and on the impedance of the voltmeter used. A high-impedance voltmeter may provide acceptable results with a more polarizable electrode than a less expensive measuring instrument.

The Liquid Junction Potential. Reference electrodes are usually made of metal immersed in a well-defined electrolyte. In the case of $CuSO_4$/Cu electrode, the electrolyte is a saturated $CuSO_4$ aqueous solution; for the saturated calomel electrode, it is a saturated potassium chloride (KCl) solution. This electrolyte that characterizes the reference electrode comes into contact with the liquid environment of the test electrode (Fig. 11). There is then direct contact between different aqueous media. The difference in chemical composition produces a phenomenon of interdiffusion. In this process, except for a few cases such as KCl, the cations and anions move at different speeds. However, for hydrogen chloride (HCl) solution in contact with another media, the H^+ ions move faster than the Cl^- ions. As a result, a charge separation appears at the limit between the two liquids (the liquid junction); this produces a potential difference called the liquid junction potential. This liquid junction potential is included in the measured potential, as expressed in:

$$V = V_T - V_R + V_{LJP}$$

where V_T is the unknown voltage to be measured, V_R is the reference electrode potential, and V_{LJP} is the unknown liquid junction potential.

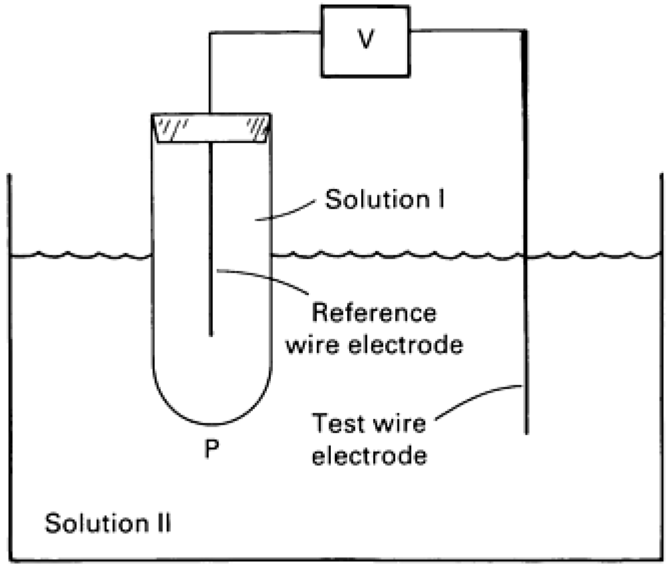

Fig. 11 Schematic of an electrochemical cell with liquid junction potential. P, interface

In order to determine V_T, the liquid junction potential has to be eliminated or minimized. The best way, when it is possible, is to design a reference electrode using electrolyte (Fig. 11) identical to the solution in which the test electrode is immersed. This can be done in some cases, for example, in overpotential measurement in a copper electrowinning cell. The reference electrode can be a copper wire in a glass tube simply immersed in $CuSO_4$ cell electrolyte. A simple $CuSO_4$/Cu reference electrode can be made in this way.

Most of the time, however, this ideal solution is not possible, and the best approach is to minimize the liquid junction potential by using a reference electrolyte with a chemical composition as close as possible to the corrosion environment. In some cases, the use of a solution of KCl (such as in the calomel electrode) offers a partial answer. The diffusion rates of potassium (K^+) and chloride (Cl^-) ions are similar. In contact with another electrolyte, a KCl solution does not produce much charge separation and, consequently, no significant liquid junction potential. The ions present in the other solution, however, also diffuse, and they may do so at different rates, thus producing some separation of charge at the interface P (Fig. 11).

The remaining liquid potential, after minimization, constitutes an error that is frequently accepted in electrode potential measurements, especially when compared with results determined under similar experimental conditions. Liquid junction potentials have to be minimized as much as possible. There is no general solution for this; each individual case has to be well thought out.

Operating Conditions for Reference Electrodes

When a reference has been selected for a particular application, its proper use requires caution, as well as measurement methods based on the same electrochemical principles. In a measurement of the potential of a polarized electrode, it is important not to polarize the reference electrode and to keep its reference value.

Very Low Current Density. It is important to use a reference electrode that operates at its known open-circuit potential and to avoid any significant overpotential. This is achieved by using a high-impedance voltmeter that has a negligible input current and, for polarized test electrodes, by using an auxiliary electrode in a three-electrode system.

The requirement is shown in Fig. 10 on curve a. The current must be maintained lower than i_1 to avoid a significant overpotential η_a. The value tolerated for η_a is a matter of judgment that depends on the accepted magnitude of error in the

particular case under investigation. The use of an electrometer or a high-impedance voltmeter usually fulfills this requirement. The existence of an overpotential η_a could result, however, when less expensive equipment is used, and in this case, electrodes similar to electrode b in Fig. 10 should be avoided.

The *IR* Drop and Its Mitigation. The *IR* drop is an ohmic voltage that results from the electric current flow in ionic solutions. Electrolytes have an ohmic resistance, and when a current passes through them, an *IR* voltage can be observed between two distinct points.

When the reference electrode is immersed at some distance from a working test electrode, it is in the electric field somewhere along the current line. An electrolyte resistance exists along the line between the test and the reference electrode. Because a current flows through that resistance, an *IR* voltage appears in the potential measurement according to:

$$V = V_T - V_R + IR$$

where V_T is the test potential to be measured, V_R is the reference electrode potential, and *IR* is the ohmic drop. In this case, the liquid junction potential has been neglected. The *IR* drop constitutes a second unknown value in a single equation. It must be eliminated or minimized.

The Luggin capillary is a tube, usually made of glass, that has been narrowed by elongation at one end. The narrow end is placed as close as possible to the test electrode surface (Fig. 8), and the other end of the tube goes to the reference electrode compartment.

The Luggin capillary is filled with cell electrolyte, which provides as electric link between the reference and the test electrode. The use of a high-impedance voltmeter prevents the current from flowing into the reference electrode and consequently into the capillary tube between the test electrode and the reference electrode department (Fig. 8). This absence of current eliminates the *IR* drop, and the measurement of V_T is then possible. A residual *IR* drop may, however, exist between the tip of the Luggin capillary and the test. This is usually negligible, however, especially in high-conductivity media.

The remote electrode technique can be used only for measurement in an electrolyte with very low resistivity, usually in the laboratory. It is applicable, for example, in a molten salt solution, in which the ohmic resistance *R* is very small. In such a case, the reference electrode can be placed a few centimeters away from the test electrode because the product *IR* remains negligible. In other electrolytes (for example, in measurements in soils) the ohmic resistance is rather large, and the *IR* drop cannot be eliminated in this manner.

The Current Interruption Technique. In this case, when the current is flowing the *IR* drop is included in the measurement. A recording of the potential is shown in Fig. 12. At time t_1, the current is interrupted so that $I = 0$ and $IR = 0$.

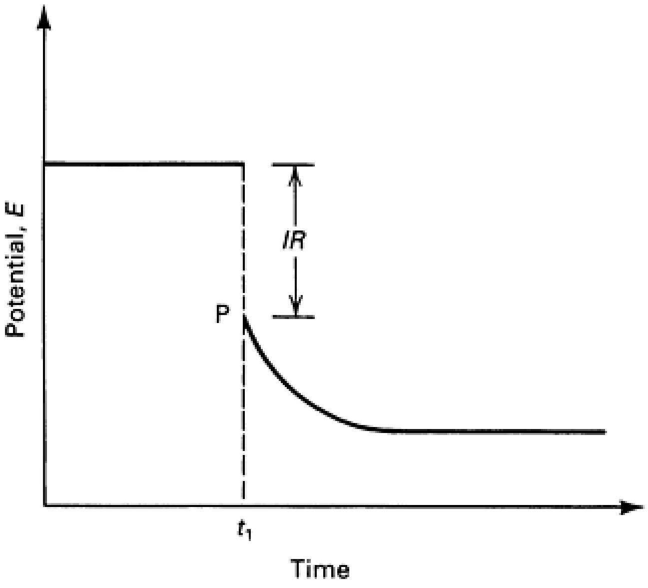

Fig. 12 The potential decay at current interruption. See text for discussion.

At the moment of the interruption, however, the electrode is still polarized, as can be seen at point P in Fig. 12. The progressive capacitance discharge and depolarization of the test electrode takes some time. The potential measured at the instant of interruption then represents the test electrode potential corrected for the *IR* drop. Precise measurements of the potential of P are obtained with an oscilloscope.

Potential Versus pH (Pourbaix) Diagrams

D. L. Piron, Department of Metallurgical Engineering, École Polytechnique de Montreal

Potential -pH diagrams are graphical representations of the domain of stability of metal ions, oxides, and other species in solution. The lines that show the limits between two domains express the value of the equilibrium potential between two species as a function of pH. They are computed from thermodynamic data, such as standard chemical potentials, by using the Nernst equation (Eq. 12). Potential -pH diagrams then provide a graphical expression of Nernst's law.

These diagrams also give the equilibrium of acid-base reactions independent of the potentials. These equilibria are represented by vertical lines at specific pHs. Potential -pH diagrams organize many important types of information that are useful in corrosion and in other fields of practice. They make it possible to discern at a glance the stable species for specific conditions of potential and pH.

When applied to a metal, the equilibrium potential line gives the limit between the domains of stability of the metal and its ions. For conditions of potential and pH corresponding to metal stability, corrosion cannot take place, and the system is in a region of immunity. However, when the potential and pH correspond to the stability of ions, such as Fe^{2+}, the metal is not stable, and it tends to oxidize into Fe^{2+}. The system is then in a corrosion region of the diagram.

In the case of iron, corrosion is deaerated water is expressed by the electrochemical reaction $Fe \rightarrow Fe^{2+} + 2e^-$, and the species Fe^{2+} and Fe are considered. The Nernst equation (Eq. 12) makes it possible to compute the equilibrium potential for the system Fe^{2+}/Fe:

$$E_{eq}^{Fe} = E^\circ + \frac{RT}{nF} \ln (Fe^{2+})$$

This equilibrium potential can be represented as a horizontal line in a partial *E*-pH diagram (see, for example, Fig. 7).

The line indicates the potential at which Fe and Fe^{2+} of a given concentration are in equilibrium and can coexist with no net tendency to transform into the other. Above the line is a domain of stability for Fe^{2+}; iron metal is not stable at these potentials and tends to dissolve as Fe^{2+} and thus increase the Fe^{2+} concentration. Below the equilibrium line, the stability of the metallic iron increases, and the equilibrium concentration of Fe^{2+} decreases; that is, the metal becomes immune. When the reaction of the metal with water produces an oxide that protects it, the metal is said to be passivated.

Diagrams such as Fig. 7 were first made by M. Pourbaix (Ref 10, 11) and have proved to be very useful in corrosion as well as in many other fields, such as industrial electrolysis, plating, electro-winning and electrorefining of metals, primary and secondary electric cells, water treatment, and hydrometallurgy. It is very important to emphasize that these diagrams are based on thermodynamic computations for a number of selected chemical species and the possible equilibria between them. It is then possible to predict from an *E*-pH diagram if a metal will corrode or not. It is, however, not possible to determine from these diagrams alone how long a metal will resist perforation.

Pourbaix diagrams offer a framework for kinetic interpretation, but they do not provide precise information on corrosion rates (Ref 12). Moreover, they are not a substitute for kinetic studies. Because each diagram is computed for a selected number of chemical species, the addition of one or more species to the system will introduce several new equilibria. Their representation in the *E*-pH diagram will produce a new diagram that is different from the previous one. For example, the simple diagram of gold in water does not show any possible solubility for that metal. The addition of cyanide ions to the system, however, makes possible the formation of a gold complex soluble in water. Gold that does not corrode in water can dissolve in the presence of cyanide. This property is the basis of gold plating and of the hydrometallurgy of that metal.

Computation and Construction of *E*-pH Diagrams

As discussed in the introduction to this article, *E*-pH diagrams are based on thermodynamic computations. The equilibrium potentials and the pH lines that set the limits between the various stability domains are determined from the chemical equilibria between the chemical species considered.

It is interesting and practical to realize here that there are three types of reactions to be considered.

- Electrochemical reactions of pure charge transfer
- Electrochemical reactions involving both electrons and H^+
- Pure acid-base reactions

As will be shown, graphical expressions at the Nernst equation (Eq 12) can be constructed from each of these reactions.

Reactions of Pure Charge Transfer. These electrochemical reactions involve only electrons and the reduced and oxidized species. They do not have protons (H^+) as reacting particles; consequently, they are not influenced by pH. An example of a reaction of this type is:

$$Ni^{2+} + 2e^- \rightarrow Ni$$

The equilibrium potential is given by the Nernst equation (Eq 12). In the case of the nickel reaction given above, it can be written:

$$E = E^\circ + \frac{RT}{nF} \ln (Ni^{2+}) \qquad \textbf{(Eq 13)}$$

where *E* is the equilibrium potential for Ni^{2+}/Ni; *E*° is the standard potential for Ni^{2+}/Ni; *R, T, F,* and *n* are defined in Eq 12; and (Ni^{2+}) is the Ni^{2+} activity in the solution.

The value of the potential obtained depends on the Fe^{2+} activity, but not on H^+ ions, which do not participate in the electrochemical reaction. The result is then independent of the pH, and it can be represented by the horizontal line in an *E*-pH diagram.

In order to obtain this result, it is necessary to compute the value of the standard potential, given by:

$$E^\circ = \frac{\Delta G^\circ}{nF} = \frac{\Sigma \nu_{ox}\, \mu^\circ_{ox} - \Sigma \nu_{red}\, \mu^\circ_{red}}{2F} \qquad \textbf{(Eq 14)}$$

where ν is the stoichiometric coefficients of oxidizing and reducing species and μ is given below. In this case under consideration:

$$E^\circ = \frac{\mu_{Ni^{2+}} - \mu_{Ni}}{2F}$$

where $\mu^\circ_{Ni^{2+}}$ and μ°_{Ni} are standard chemical potentials. By convention, the standard potential of a chemical element is 0. This gives $\mu^\circ_{Ni} = 0$, and simplifies the above equation:

$$E^\circ = \frac{\mu^\circ_{Ni^{2+}}}{2F}$$

The value of $\mu^\circ_{Ni^{2+}}$, which can be found in the *Atlas of Electrochemical Equilibria* (Ref 13), is 11,530 cal. Consequently:

$$E^\circ = \frac{11\ 530\ \text{cal}}{2\ \text{equiv.} \times 23\ 060\ \text{cal/V equiv.}} = -0.25\ \text{V}$$

This result can be introduced into Eq 13 as follows:

$$E_{Ni^{2+}/Ni} = -0.25\ \text{V} + \frac{2.3\ RT}{2F} \log\ (Ni^{2+})$$

where 2.3 *R* = 4.57 at a temperature of 25 °C (77 °F) or 298 °K. If 2.3 *RT*/*F* = 0.059 V, the equilibrium potential for Ni^{2+}/Ni will be:

$$E = -0.25 + 0.03 \log\ (Ni^{2+})$$

As previously stated for this case, the potential depends only on the activity of (Ni^{2+}), not on the pH. It is customary here to select four activities: 1 or 10^0, 10^{-2}, 10^{-4}, and 10^{-6} g ion/L. This will provide four horizontal lines, as shown in Fig. 13:

- At a concentration of 10° g ion/L, $E^{Ni^{2+}/Ni} = E^\circ = -0.25$ V
- With 10^{-2} g ion/L, $E^{Ni^{2+}/Ni} = -0.25 + 0.03 \log 10^{-2} = -0.31$ V
- With 10^{-4} g ion/L, $E^{Ni^{2+}/Ni} = -0.37$ V
- With 10^{-6} g ion/L, $E^{Ni^{2+}/Ni} = -0.43$ V

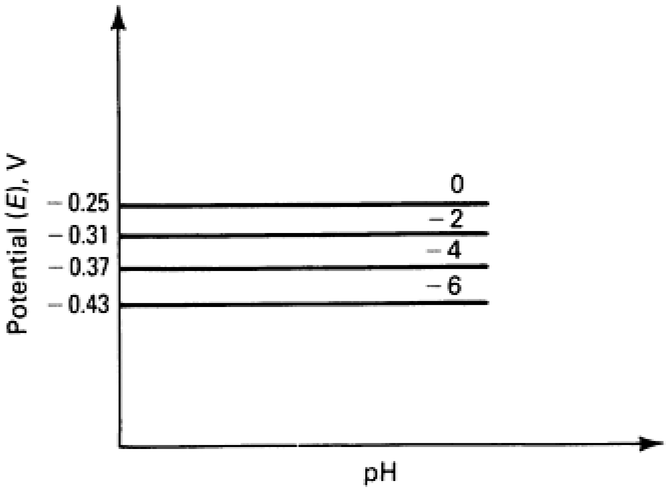

Fig. 13 Partial *E*-pH diagram for the $Ni^{2+} + 2e^- \rightarrow Ni$ reaction

For any activity of Ni^{2+} in the solution, a horizontal line represents the equilibrium potential, that is, the potential at which Ni^{2+} ions and Ni metal can coexist. Above the line is the region of stability of Ni^{2+} ions; nickel metal at these potentials will tend to corrode and produce Ni^{2+}, the stable species. Below the line, metallic nickel is stable, and nickel in these conditions will not corrode.

Reactions Involving Both Electrons and H^+. Nickel can also react with water to form an oxide, according to the electrochemical reaction:

$$Ni + H_2O \rightarrow NiO + 2H^+ + 2e^-$$

The standard potential $E°$ is given by:

$$E° = \frac{\mu^{\circ}_{NiO} - \mu^{\circ}_{Ni} - \mu^{\circ}_{H_2O}}{2F}$$

$$= \frac{-51\ 610 - 0 + 56\ 690}{2 \times 23\ 060} = 0.11\ V$$

The Nernst equation (Eq 12) can in this case be written as follows:

$$E_{eq} = +0.11 + \frac{0.06}{2} \log \frac{(NiO)(H^+)^2}{(Ni)(H_2O)} \quad \textbf{(Eq 15)}$$

The NiO and Ni are solid phases, and they are considered to be pure; their activity is therefore 1. The activity of water in aqueous solutions is also assumed to be 1. Equation 15 can then be simplified to:

$$E_{eq} = +0.11 + 0.03 \log (H^+)^2$$

Because pH = -log (H^+), it is possible to write:

$$E_{eq}^{NiO} = 0.11 - 0.06\ \text{pH} \qquad \textbf{(Eq 16)}$$

In this case, the equilibrium potential is a decreasing function of pH, as represented in a partial *E*-pH diagram (Fig. 14).

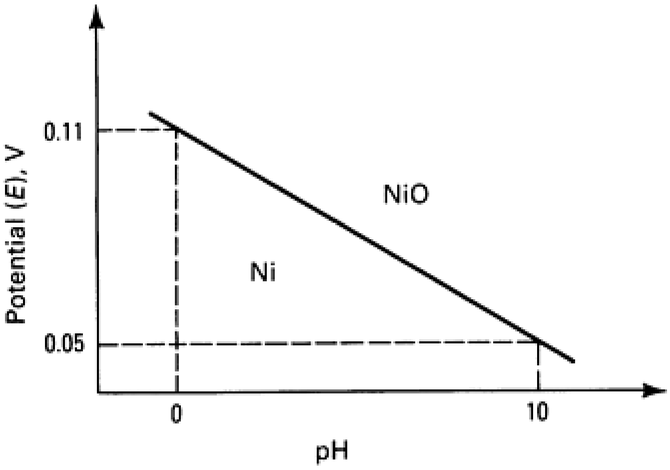

Fig. 14 Partial *E*-pH diagram for the Ni + H_2O $\rightarrow$ NiO + $2H^+$ + $2e^-$ reaction

The diagonal line in Fig. 14 gives the value of the equilibrium potential for Ni and NiO at all pH values. Above the line, NiO is stable, and below it, nickel metal is stable.

Potential-pH diagrams are very general and can also be applied to electrochemical reactions involving nonmetallic chemicals. An example involving the reduction of nitrite (NO_2^-) in ammonia (NH_4^+) will be given here. In this case, the metal of the electrode supports the reaction by giving or taking away electrons as follows:

$$NO_2^- + 8H^+ + 6e^- \rightarrow NH_4^+ + 2H_2O$$

It is only a supporting electrode. The Nernst equation (Eq 12) can then be written:

$$E = E^\circ + \frac{RT}{6F} \ln \frac{(NO_2^-)(H^+)^8}{(NH_4^+)(H_2O)^2} \qquad \textbf{(Eq 17)}$$

where $(H_2O) = 1$.

the equation for the standard potential is:

$$E^\circ = \frac{\mu^\circ_{NiO_2} + 8\mu^\circ_{H^+} - \mu^\circ_{NH_4^+} - 2\mu^\circ_{H_2O}}{2F}$$

$$= \frac{-8250 - (-19\ 000) - 2(-56\ 690)}{6 \times 23\ 060}$$

$$= +0.897$$

The equilibrium potential is then given by:

$$E = 0.897 + 0.01 \log \frac{(NO_2)}{(NH_4^+)} - 0.08 \text{ pH}$$

It can be represented in an *E*-pH diagram for equal activity in NO_2^- and NH_4^+ by a decreasing line in Fig. 15.

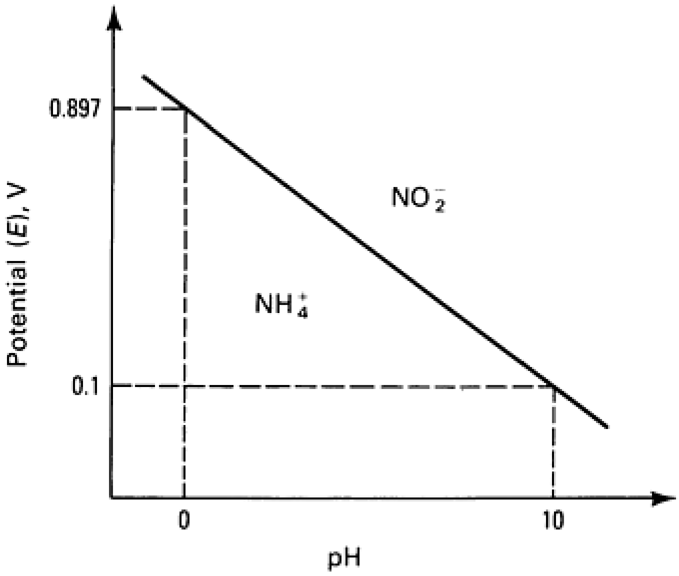

Fig. 15 Partial *E*-pH diagram for the NO_2^- + $8H^+$ + $6e^-$ $\rightarrow NH_4^+$ + $2H_2O$ reaction

Above the line, there is a region in which NO_2^- is predominantly stable but in equilibrium with smaller activities of NH_4^+. Below the line, NH_4^+ is predominantly stable, with smaller quantities of NO_2^-.

Pure Acid-Base Reactions. The previous computations showed that there are possible equilibria between the metal and its ions (such as Ni^{2+}/Ni) and between the metal and its oxide (NiO/Ni). In the case of cobalt it is possible, as shown in Fig. 16, to determine the equilibria for Co^{2+}/Co and for CoO/Co. The two equilibrium potential lines meet at some point P, and above them are two domains of stability for Co^{2+} and CoO. These two species are submitted to an acid-base chemical reaction:

$$Co^{2+} + H_2O \rightleftharpoons CoO + 2H^+ \qquad \textbf{(Eq 18)}$$

which does not involve electrons. It does not depend, then, on the potential, and it will be represented by a vertical line. Point P in Fig. 16 is one point on that line located at a pH 6.3 for an activity of 1 in Co^{2+} ions.

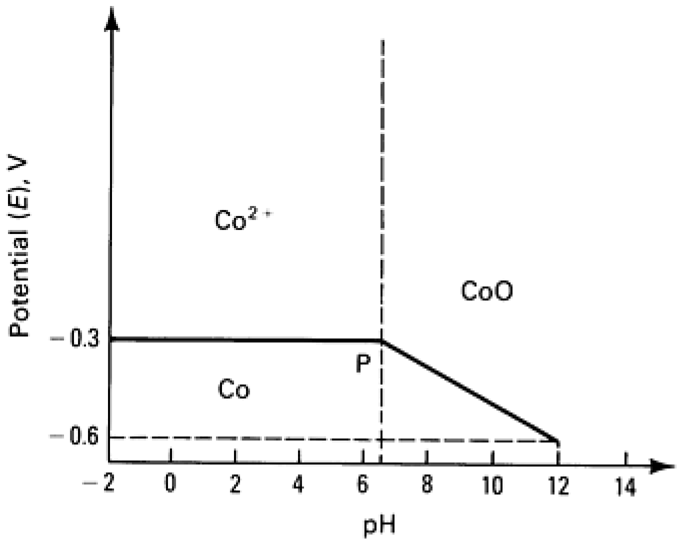

Fig. 16 Partial *E* -pH diagram for Co^{2+}/Co and CoO/Co

The pH value of that line can also be computed from the chemical equilibrium, with the general equation:

$$\Delta G° = -RT \ln K$$

or

$$\log K = \frac{\Sigma \nu_R \mu^\circ_R - \Sigma \nu_P \mu^\circ_P}{2.3\, RT} \quad \textbf{(Eq 19)}$$

where K is a constant, ν_R is the stoichiometric coefficient of the reactants, ν_P is the stoichiometric coefficient of the product, $\mu°_R$ is the standard chemical potential of the reactant, and $\mu°_p$ is the standard chemical potential of the product. In this case, the equilibrium as given in Eq 18 can be written:

$$\log \frac{(CoO)(H^+)^2}{(Co^{2+})(H_2O)} = \frac{\mu^\circ_{Co^{2+}} + \mu^\circ_{H_2O} - \mu^\circ_{CoO}}{2.3\, RT}$$

By assuming that (CoO) and (H_2O) both have activities of 1 and by replacing the standard chemical potentials by their values given in the *Atlas of Electrochemical Equilibria* (Ref 13), it is possible to write:

$$\log \frac{(H^+)^2}{(Co^{2+})} = \frac{-12\,800 - 56\,690 - (-52\,310)}{2.3 \times 1.987 \times 298} = -12.6 \quad \textbf{(Eq 20)}$$

and finally:

$$\log (Co^{2+}) = 12.6 - 2\ \text{pH} \quad \textbf{(Eq 21)}$$

for (Co^{2+}) = 1 or pH = 6.3. This verifies the value obtained by tracing the two equilibrium lines.

Figure 17(a) shows a partial *E*-pH diagram in which only three chemical species--Co, Co^{2+}, and CoO--are considered. There are, however, other possible chemical species, such as CoO_2 and $HCoO_2^-$, that must be considered. This introduces new equilibria that modify the diagram to give Fig. 17(b).

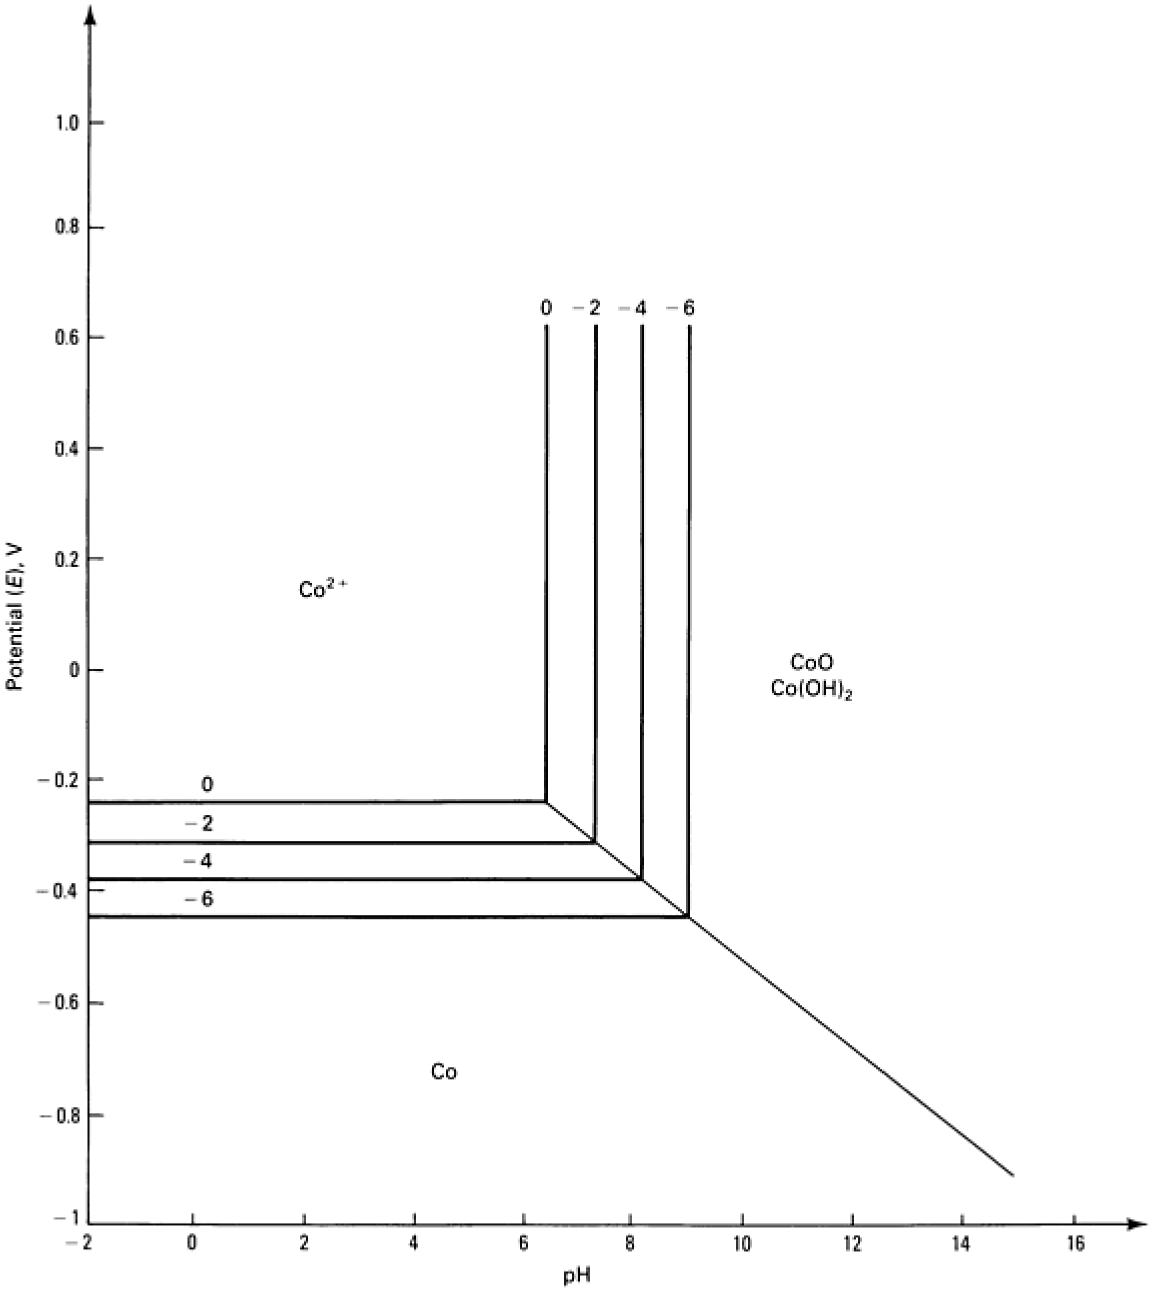

Fig. 17(a) Partial *E*-pH diagram for cobalt

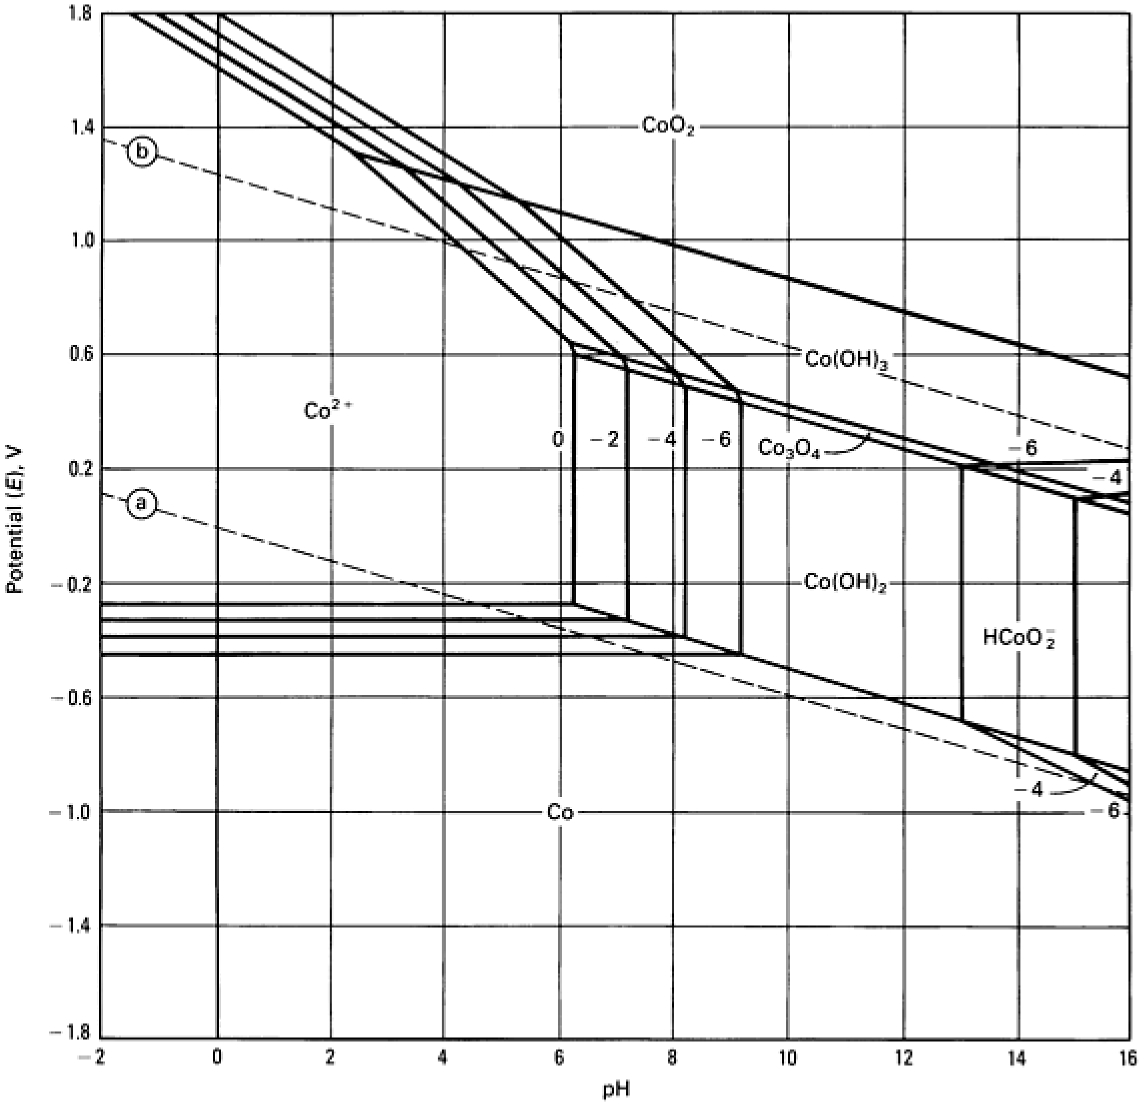

Fig. 17(b) *E*-pH diagram for cobalt

The Water *E*-pH Diagram. Pourbaix diagrams are traced for equilibrium reactions taking place in water; consequently, the water *E*-pH diagram always must be considered at the same time as the system under investigation. Water can be decomposed into oxygen and hydrogen, according to the following reactions:

$$2H^+ + 2e^- \rightarrow H_2$$

and

$$H_2O \rightarrow \frac{1}{2} O_2 + 2H^+ + 2e^-$$

There are then two possible electrochemical equilibria for which the equilibrium potential can be determined by using the Nernst equation (Eq 12). For hydrogen:

$$E_{H^+/H_2} = E^\circ_{H^+/H_2} + \frac{0.059}{2} \log \frac{(H^+)^2}{p_{H_2}}$$

where (H^+) is the activity of H^+ in water, and pH^2 is the pressure of hydrogen near the electrode. Because, by convention, $E^\circ H^+/H^2$ = O, the above equation can be rewritten as follows:

$$E_{H^+/H_2} = -0.059 \text{ pH} - \frac{0.059}{2} \log p_{H_2} \quad \textbf{(Eq 22)}$$

The equilibrium potential for the system H_2/H_2O can be represented in Fig. 18 by line a, which decreases with the pH.

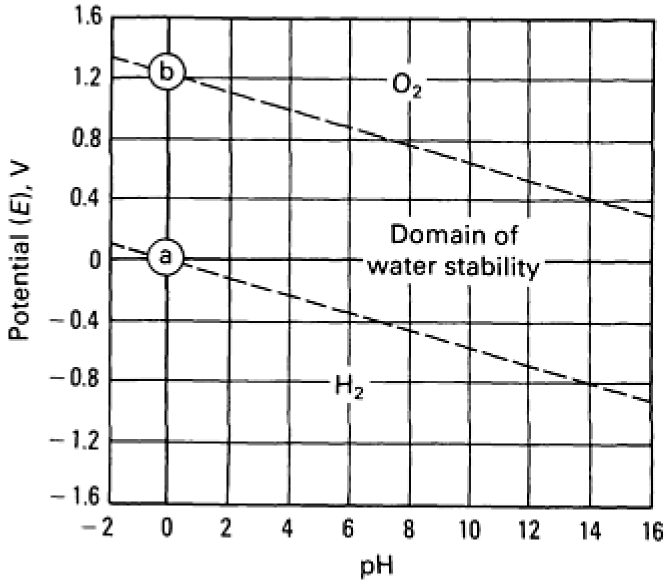

Fig. 18 The water *E*-pH diagram of 1 atm

The equilibrium potential for the oxygen/water reaction is given by the Nernst equation:

$$E^{O_2}_{eq} = E^\circ_{O_2} + \frac{0.059}{2} \log \frac{(p_{O_2})^{1/2} (H^+)^2}{(H_2O)}$$

where pO_2 equals the pressure of O_2 near the electrode. The activity is, as usual , assumed to be 1, and the standard potential for $0_2/H_2O$ is computed to be 1.23 V. The following can then be written:

$$E^{O_2}_{eq} = 1.23 - 0.059 \text{ pH} + \frac{0.059}{4} \log p_{O_2} \quad \textbf{(Eq 23)}$$

Equation 23 is represented under 1 atm pressure by line b in Fig. 18.

It is interesting to note that the pressures of hydrogen and oxygen in the vicinity of the electrode are usually identical and nearly equal to the pressure that exists in the electrochemical cell. To be rigorous, the water vapor pressure should be taken into account, but it is frequently neglected as not being very significant.

When the pressure increases, line b in Fig. 18 is displaced upward in the diagram, and line a is lowered. The result is that the domain of water stability increases with increasing pressure. The water diagram is so important for a good understanding of the corrosion behavior of a metal that it is usually represented by dotted lines in all Pourbaix diagrams (Ref 13).

Practical Use of *E*-pH Diagrams

The *E*-pH diagram is an important tool for understanding electrochemical phenomena. It provides much useful thermodynamics information in a simple figure. A few cases are presented here to illustrate its practical use in corrosion.

Acid Corrosion of Nickel. A rod of nickel is immersed in an aqueous deaerated acid solution with a pH of 1 that contains 10^{-4} g ion/L of Ni^{2+} ions. The system is under 1 atm pressure. These conditions make it possible to simplify the *E*-pH diagram, as shown in Fig. 19.

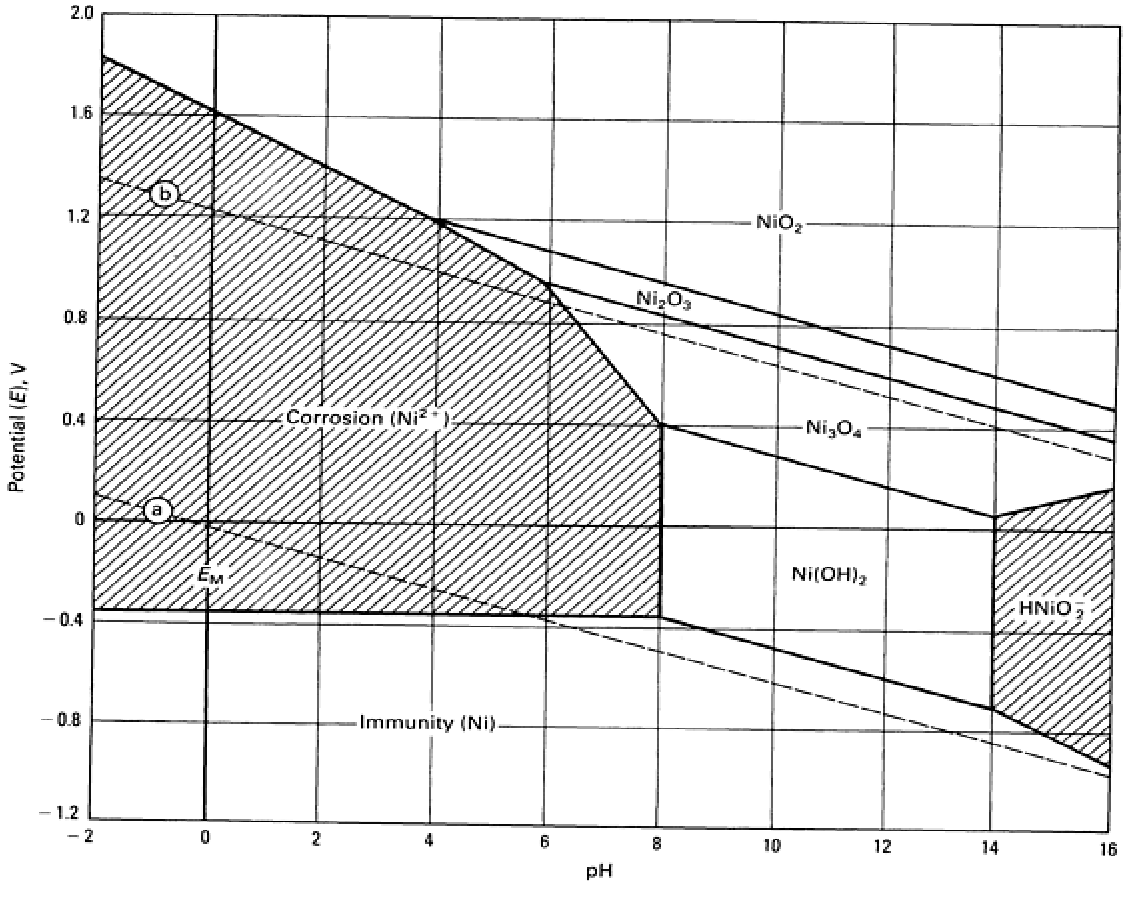

Fig. 19 *E*-pH diagram for nickel

At the metallic nickel/water interface, two electrochemical reactions are possible, and their equilibrium potentials can be computed:

$$Ni \rightarrow Ni^{2+} + 2e^-$$

with E_{Ni} = -0.25 + 0.03 log $a_{Ni^{2+}}$, which for concentration $a = 10^{-4}$ gives E_{Ni} = -0.37 V (see Fig. 13). It follows that:

$$2H^+ + 2e^- \rightarrow H_2$$

with E_H = -0.06 pH. At pH = 1, E_H = -0.06 V.

The nickel equilibrium potential is then more active than that of hydrogen, and electrons tend to flow from the negative nickel to the more positive hydrogen. Because both reactions occur on the same electrode surface, the electrons can go directly from the nickel to the hydrogen. The two reaction then tend to proceed under a common electrode potential of mixed potential, with a value somewhere between the nickel and hydrogen equilibrium potentials.

The mixed potential E_M is then above the Ni^{2+}/Ni equilibrium potential in the region of Ni^{2+} stability (Fig. 19). Nickel is then not stable at low pH in water, and it tends to oxidize or corrode, producing Ni^{2+}, according to the reaction:

$$Ni \rightarrow Ni^{2+} + 2e^-$$

This charge separation could stop the ionization reaction if there were not another chemical reaction--the reduction of H^+. The mixed potential E_M is located below the H^+/H_2 equilibrium potential in a region where H_2 is stable (Fig. 19). As a result, H^+ can accept the electrons and is reduced according to $2H^+ + 2e^- \rightarrow H_2$, producing H_2 gas.

The Pourbaix diagram explains the tendency for nickel to corrode in strong acid solutions. It does not indicate the rate of corrosion, however. This important information has to be obtained from a kinetic experiment, for example, by measuring the corrosion current in a polarization experiment.

The Pourbaix diagram can also show that when the pH increases the difference between the nickel and the hydrogen equilibrium potential decreases in magnitude and that, consequently, the corrosion tendency becomes less important. For pHs between 6 and 8, Fig. 19 shows that hydrogen is more active than nickel. Under this condition, H^+/H^2 can no longer accept the electrons from nickel. Moreover, the potential of the system is in this case below the equilibrium potential of nickel in the region of metal immunity. In pure water at room temperature, nickel does not corrode for pHs between 6 and 8. Moreover, an increase in pressure according to Eq 22 lowers the equilibrium line of H^+/H_2 and does not change the equilibrium line of nickel. As a result, an increase in pressure favors the corrosion resistance of nickel. This behavior of nickel makes the metal slightly noble, and it is expected from the diagram to resist corrosion better than iron or zinc.

The presence of elements, such as chloride, not considered in Fig. 19 may increase the corrosion tendency of nickel. For pHs higher than 8, NiO, $Ni(OH)_2$, or Ni_3O_4 can form, as can be seen in Fig. 19. These oxides may in some cases protect the metal by forming a protective layer that prevents or mitigates further corrosion. This phenomenon is called passivation (passivation is described in detail in the article "Kinetics of Aqueous Corrosion" in this Volume). The presence of chloride is dangerous here, because it may attack the protective layer and then favor corrosion. Figure 19 also illustrates that for very strong alkaline solutions nickel may corrode as $HNiO_2^-$ when the potential is made anodic.

Corrosion of Copper. Observation of the copper *E*-pH diagram in Fig. 20 immediately reveals that the corrosion of copper immersed in deaerated acid water is not likely to occur. The H^+/H_2 equilibrium potential represented by line a is always more active than the Cu^{2+}/Cu equilibrium potential. The H^+ ions are then always in contact with immune copper metal that cannot corrode.

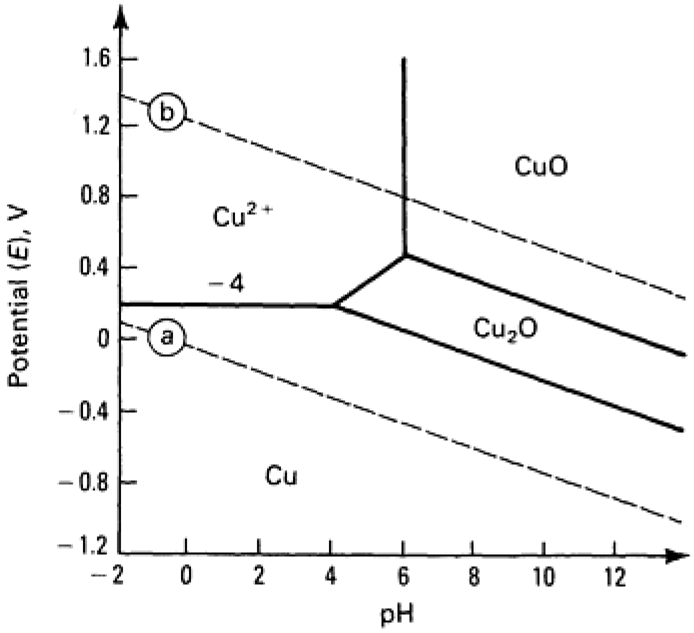

Fig. 20 Partial *E*-pH diagram for copper

The presence of dissolved oxygen in nondeaerated solutions introduces another possible reaction--O_2/H_2O reduction, with an equilibrium potential more noble than that of Cu^{2+}/Cu. The O_2/H_2O system is then a good acceptor for the electrons abandoned by copper oxidation. The two electrochemical reactions:

$$\frac{1}{2}O_2 + 2H^+ + 2e^- \rightarrow H_2O$$

and

$$Cu \rightarrow Cu^{2+} + 2e^-$$

take place at the same metal/solution interface at a common mixed potential.

This discussion assumes that the solution does not contain chloride or other compounds capable of forming soluble complexes with copper. In the presence of such impurities, another diagram must be traced for copper that in some conditions reveals different corrosion behavior. The diagram gives valuable information if all the substances present in the actual system under investigation are taken into account when it is traced.

Kinetics of Aqueous Corrosion

D. W. Shoesmith, Fuel Waste Technology Branch, Atomic Energy of Canada Ltd.

Introduction

THE AQUEOUS CORROSION of metal is an electrochemical reaction. For metal corrosion to occur, an oxidation reaction (generally a metal dissolution or oxide formation) and a cathodic reduction (such as proton or oxygen reduction) must proceed simultaneously. For example, the corrosion of iron in acid solutions is expressed as follows:

Oxidation (anodic) $Fe \rightarrow Fe^{2+} + 2e^-$ **(Eq 1)**

Reduction (cathodic) $2H^+ + 2e \rightarrow H_2$ **(Eq 2)**

Overall reaction
$Fe + 2H^+ \rightarrow Fe^{2+} + H_2$ **(Eq 3)**

As a second example, for the corrosion of iron in a solution containing dissolved oxygen, the following expressions are used:

Oxidation (anodic) $Fe \rightarrow Fe^{2+} + 2e^-$

Reduction (cathodic)
$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O$ **(Eq 4)**

Overall reaction
$2Fe + O_2 + 4H^+ \rightarrow 2Fe^{2+} + 2H_2O$ **(Eq 5)**

The reaction for metal dissolution ($M \rightarrow M^{n+}$) driven by the cathodic reaction $O \rightarrow R$, is:

$$M + O \rightarrow M^{n+} + R \quad \textbf{(Eq 6)}$$

where M is a metal, O is oxygen or another oxidizing reagent, *n*+ is the multiple of the charge, and R is the reduced species or reduction. The corrosion process has been written as two separate reactions occurring at two distinct sites on the same surface (Fig. 1a). These two sites are known as the anode, or metal dissolution site, and the cathode, or the site of the accompanying reduction reaction.

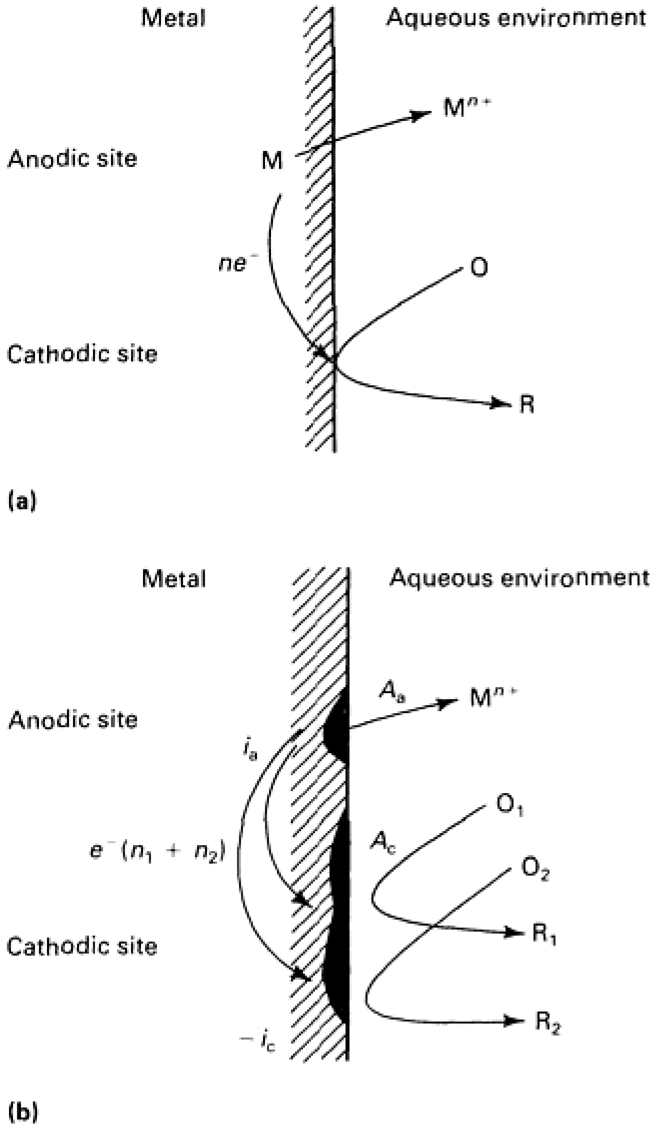

Fig. 1 Schematics of two distinct corrosion processes. (a) The corrosion process M + O $\rightarrow M^{n+}$ + R showing the separation of anodic and cathodic sites. (b) The corrosion process involving two cathodic reactions.

As shown in Fig. 1(a), the corroding metal is equivalent to a short-circuited energy-producing cell in which the energy is dissipated during the consumption of cathodic reagent and the formation of corrosion products. To maintain a mass balance, the amount of cathodic reagent consumed must be equal, in chemical and electrochemical terms, to the amount of corrosion product formed. Because electrons are liberated by the anodic reaction and consumed by the cathodic reaction, corrosion can be expressed in terms of an electrochemical current. Expressing the mass balance requirement in electrochemical terms, it can be stated that the total current flowing into the cathodic reaction must be equal, and opposite in sign to, the current flowing out of the anodic reaction (Fig. 1b).

If measurable, this current can be taken as a gage of the rate of the corrosion process and therefore the rate of metal wastage. The current, known as the corrosion current, i_{corr}, and the amount of metal corroded are related by Faraday's law:

$$i_{corr}t = \frac{nFw}{M} \quad \textbf{(Eq 7)}$$

where i_{corr} is expressed in amps; t is the time (in seconds) for which the current has flowed; nF is the number of coulombs (C) required to convert 1 mol of metal to corrosion product, where n is the number of electrons involved in the metal dissolution reaction (n = 2 for Eq 1), and F is the Faraday constant (96,480 C/mol); M is the molecular weight of the metal (in grams); and w is the mass of corroded metal (in grams).

Two additional observations can be made with regard to Fig. 1(b). First, several cathodic reactions may simultaneously support the metal corrosion; for example, in oxygenated acidic solutions, iron corrosion (Eq 1) could be simultaneously driven by the proton reduction (Eq 2) and the oxygen reduction (Eq 4). When complex alloys are involved, the metal corrosion process may also be the sum of more than one dissolution process. The corrosion current then equals the sum of the component partial currents:

$$i_{corr} = \sum i_a = -\sum i_c \quad \textbf{(Eq 8)}$$

Second, the area of the anodic and cathodic sites (A_a and A_c) may be very different (A_a is shown smaller than A_c in Fig. 1b). Therefore, although the anodic and cathodic currents must be equal, the respective current densities need not be:

$$i_a = -i_c \; ; A_a \neq A_c$$

therefore:

$$\frac{i_a}{A_a} \neq \frac{i_c}{A_c} \quad \textbf{(Eq 9)}$$

The term i/A is a current density and will be designated I.

This inequality can have serious implications. For a smooth, single-component metal surface the anodic and cathodic sites will be separated, at any one instant, by only a few nanometers. The areas will shift with time so that the surface reacts evenly, thus undergoing general corrosion. However, such a situation often does not apply, and the presence of surface irregularities, alloy phases, grain boundaries, impurity inclusions, residual stresses, and high-resistance oxide films can often lead to the stabilization of discrete anodic and cathodic sites. Under these circumstances, metal dissolution can be confined to specific sites, and corrosion is no longer general but localized. The specific combination of a small anode and large cathode confines metal dissolution to a small number of localized areas, each dissolving with a large current density. Such a situation exists during such processes as pitting or cracking.

Aqueous corrosion is a complicated process that can occur in various forms and is affected by many chemical, electrochemical, and metallurgical variables, including:

- The composition and metallurgical properties of the metal or alloy
- The chemical (composition) and physical (temperature and conductivity) properties of the environment.
- The presence or absence of surface films
- The properties of the surface films, such as resistivity, thickness, nature of defects, and coherence.

The thermodynamic feasibility of a particular corrosion reaction is determined by the relative values of the equilibrium potentials, E_e, of the reactions involved. These potentials can be determined from the Nernst equation. The thermodynamics of a particular metal/aqueous system can be summarized in a potential-pH, or Pourbaix, diagram, as discussed in the section "Potential Versus pH (Pourbaix) Diagrams" of the article "Thermodynamics of Aqueous Corrosion" in this Volume. However, for this discussion, it is sufficient to state that if the corrosion reaction is to proceed such that metal M corrodes as M^{n+}, then:

$$(E_e)_{M/M^{n+}} < (E_e)_{O/R} \quad \textbf{(Eq 10)}$$

However, the most important questions for the corrosion engineer are, How fast does the corrosion reaction occur? Is it localized? Can it be prevented or at least slowed to an acceptable rate? To answer these questions and to determine a course of action, it is essential to have some knowledge of the steps involved in the overall corrosion process.

The overall process could be controlled by any one of several reactions, as shown in Fig. 2. Either the anodic (reaction area 1, Fig. 2) or cathodic (area 2) electron transfer reactions could be rate controlling. Alternatively, if these reactions are fast and the concentration of the cathodic reagent is low, then the rate of transport of the reagent O to the cathodic site (area 3) could be rate limiting. This situation is quite common for corrosion driven by dissolved oxygen that has limited solubility. If the metal dissolution reaction is reversible--that is, the reverse metal deposition reaction $M^{n+} + ne^- \rightarrow M$ can also occur--then the rate of transport of M^{n+} away from the anode (area 4) could also be the slow step.

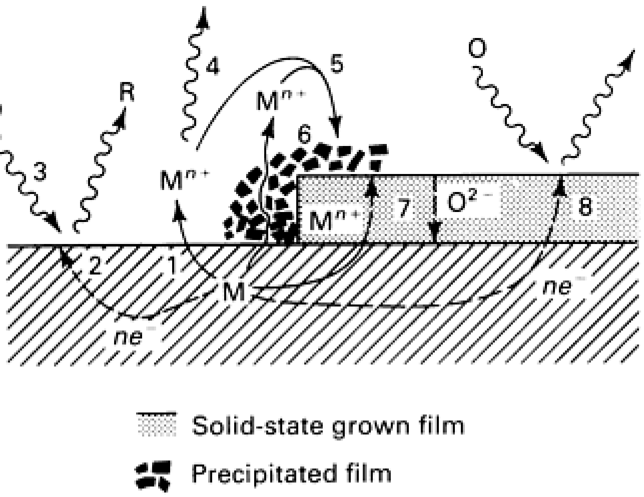

Fig. 2 Schematic of corrosion process showing various charge-transfer, film formation, and transport processes. See text for explanation of numbered reaction areas.

The presence of corrosion films adds other complications. If the concentration of dissolved metal cations close to the electrode achieves a value at which oxides, hydroxides, or metal salts precipitate (area 5), then corrosion could become controlled by transport of M^{n+} (or O) through these porous precipitates (area 6). Alternatively, when coherent surface films form spontaneously on the metal surface by solid-state, as opposed to precipitation, reactions, then ionic transport of M^{n+}, or O^{2-}, to the film growth sites at the two interfaces (oxide/metal or oxide/solution) (area 7) will ensure very low corrosion rates. The presence of film defects in the form of pores and grain boundaries will affect the rates of these processes. Finally, it is possible, under certain circumstances, for the corrosion process to be controlled by the electronic conductivity of surface films (area 8) when the cathodic process occurs on the surface of the film. In light of these numerous possibilities for control of the corrosion process, the remainder of this article will discuss these individual processes and the laws that govern them.

Activation Control

Activation control is the term used to describe control of the corrosion process shown in Fig. 2 by the electrochemical reactions given in Eq 1 and 2. The overall anodic reaction is the transfer of a metal atom from a site in the metal lattice to the aqueous solution as the cation M^{n+} or as some hydrolyzed or complexed metal cation species:

$$M_{\text{lattice}} \rightarrow M^{+}_{\text{surface}} \rightarrow M^{n+}_{\text{surface}} \rightarrow M^{n+}_{\text{solution}} \quad \textbf{(Eq 11)}$$

These steps are not necessarily separable experimentally. Similarly, cathodic reaction--for example, oxygen reduction--consists of a number of steps:

$$O_2 + 2H^+ + 2e^- \rightarrow H_2O_2 \quad \textbf{(Eq 12)}$$

$$H_2O_2 + 2H^+ + 2e^- \rightarrow 2H_2O \quad \textbf{(Eq 13)}$$

The overall reactions are known as charge transfers. Either the anodic or cathodic charge-transfer reaction can control the overall corrosion rate. Both the anodic and cathodic reactions can be individually studied by using electrochemical methods in which the electrical potential applied to the electrode (or the current flowing through it) is controlled and the resulting current (or electrode potential) measured. Thus, the current-potential, or polarization, curves for both anodic and cathodic reactions can be determined. An example of an anodic polarization curve is shown in Fig. 3. This curve, for the anodic reaction, follows the Butler-Volmer equation:

$$i = i_o \left\{ \exp\left(\beta \frac{nF}{RT} \eta\right) - \exp\left(-(1-\beta)\frac{nF}{RT}\eta\right) \right\} \quad \textbf{(Eq 14)}$$

where R is the gas constant, T is the absolute temperature, and β the symmetry coefficient taken to be close to 0.5. The term η the overpotential, defined by:

$$\eta\ E - E_e \quad \textbf{(Eq 15)}$$

and is a measure of how far the reaction is from equilibrium. At equilibrium ($E = E_e$, $\eta = 0$), no measurable current flows. However, the equilibrium is dynamic, with the rate of metal dissolution, i_a, equal to the rate of metal cation deposition, $-i_c$:

$$i_a = -i_c = i_o \quad \textbf{(Eq 16)}$$

where i_o is the exchange current.

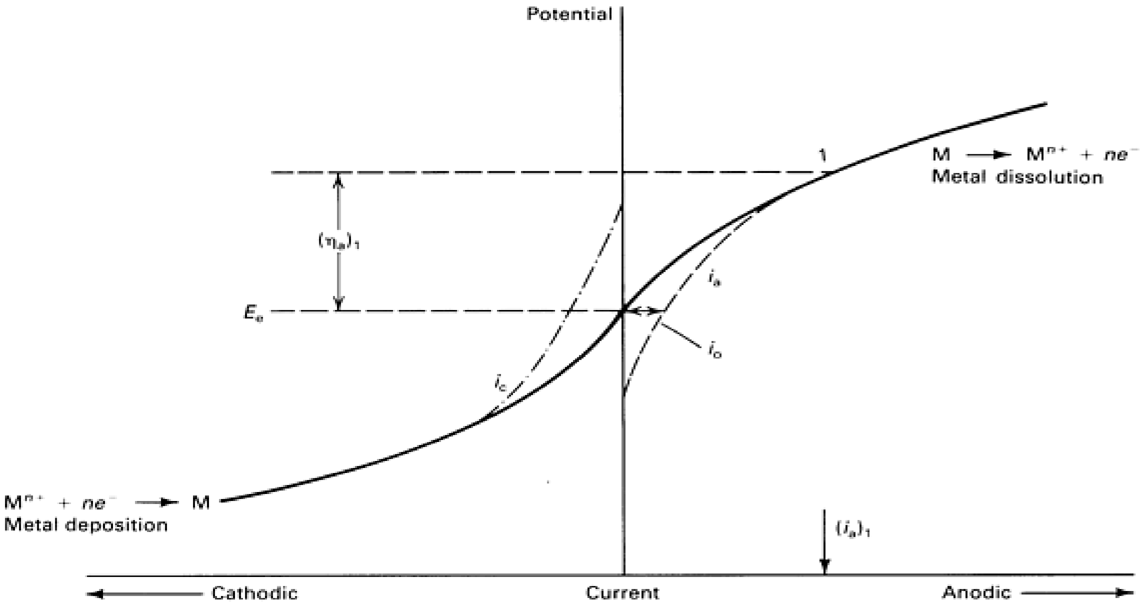

Fig. 3 Current-potential relationship for a metal dissolution (M $\rightarrow$ M^{n+})/deposition (M^{n+} $\rightarrow$ M) process

If the potential is made more positive (anodic) than the equilibrium potential, then $i_a > |i_c|$ and metal dissolution proceeds. Similarly, for cathodic potentials, $i_a < |i_c|$ and metal cation deposition proceeds (Fig. 3). Over a short potential range, the two reactions oppose each other, but for sufficiently large overpotentials (η_a, anodic, and η_c, cathodic), one reaction occurs at a negligible rate, and the overpotential is then in the Tafel region, as indicated by point 1 in Fig. 3. The last term in Eq 14 can then be dropped, and the metal dissolution current density is given by:

$$i_a = i_o \exp\left(\beta \frac{nF}{RT} \eta\right) \quad \textbf{(Eq 17)}$$

Taking logarithms and rearranging yields:

$$\eta_a = b_a \log \left(\frac{i_a}{i_o}\right) \quad \textbf{(Eq 18)}$$

where b_a is the Tafel coefficient given by:

$$b_a = \frac{2.303RT}{\beta nF} \quad \textbf{(Eq 19)}$$

and is obtained from the slope of a plot of η_a against log i_a. The intercept of this plot yields a value for i_o. Similarly, at cathodic overpotentials, a Tafel coefficient can be obtained for the metal cation deposition:

$$b_c = \frac{-2.303RT}{(1-\beta)nF} \quad \textbf{(Eq 20)}$$

A similar analysis can be performed for the cathodic process (O + $ne \rightarrow$R), and Fig. 4 shows the two current-potential (polarization) curves.

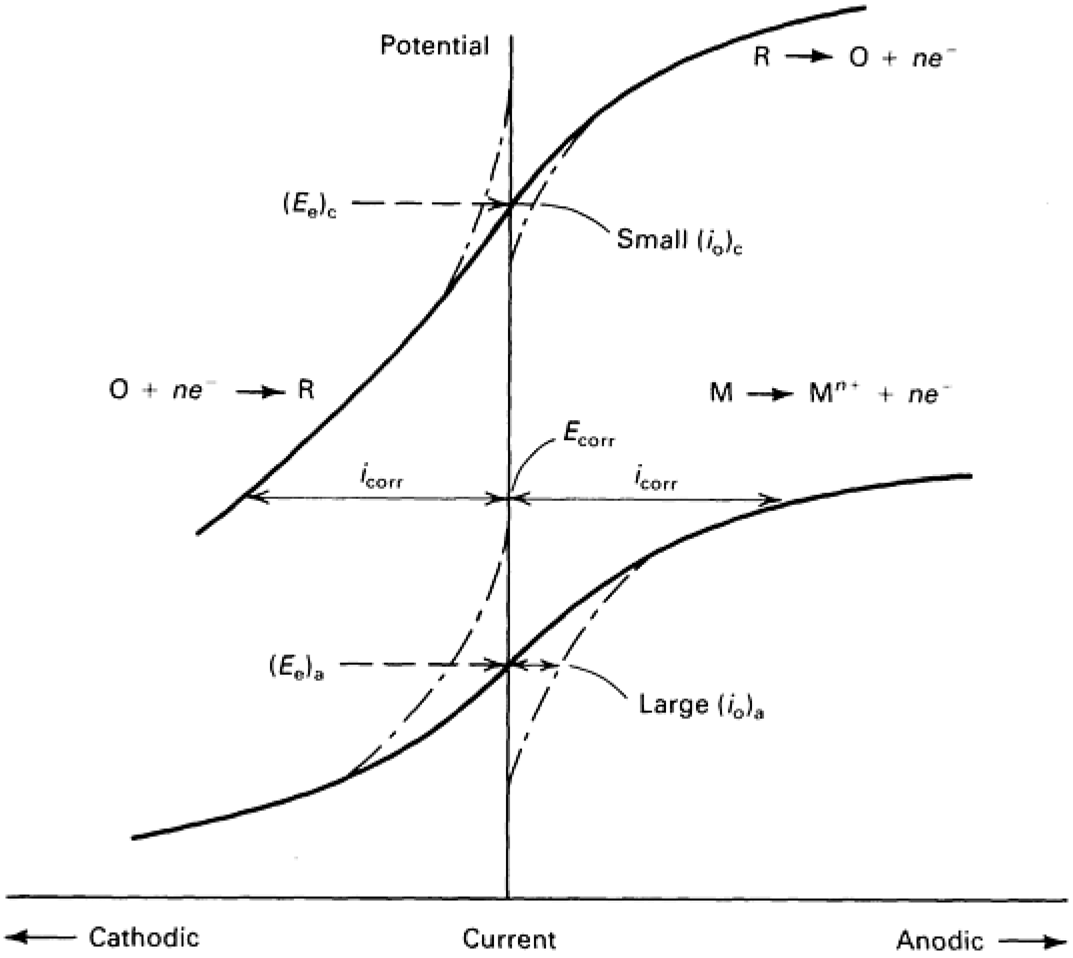

Fig. 4 Current-potential relationships for a metal dissolution/deposition and an accompanying redox reaction showing how the two reactions couple together at the corrosion potential, E_{corr}

If the two reactions are to couple together as a corrosion process, then the anodic current flowing because of metal dissolution must be counter-balanced by an equal cathodic current due to the reduction of O to R:

$$i_a = -i_c = i_{corr} \quad \textbf{(Eq 21)}$$

where i_{corr} is the corrosion current. This condition can be achieved only at a single potential, the corrosion potential, E_{corr}, which must lie between the two equilibrium potentials, thus satisfying Eq 10:

$$(E_e)_a < E_{corr} < (E_e)_c \quad \textbf{(Eq 22)}$$

such that the metal dissolution reaction is driven by an anodic activation overpotential:

$$\eta_a^A = E_{corr} - (E_e)_a \quad \textbf{(Eq 23)}$$

and the cathodic reaction is driven by a cathodic activation overpotential:

$$\eta_c^A = E_{corr} - (E_c)_c \quad \textbf{(Eq 24)}$$

The activation overpotential is a measure of how hard the anodic and cathodic reactions must be driven to achieve the corrosion current.

Two additional observations can be made with regard to Fig. 4. First the thermodynamic driving force for corrosion is equal to the difference in equilibrium potentials:

$$\Delta E_{\text{therm}} = (E_e)_c - (E_e)_a \qquad \textbf{(Eq 25)}$$

Generally, ΔE_{therm} is large, and the reverse reactions ($M^{n+} \rightarrow M$, $R \rightarrow O$) can be neglected. Consequently, E_{corr} is in the Tafel regions for both reactions (assuming no complications due to the presence of films).

Second, the two polarization curves are not necessarily symmetrical and are seldom identical (Fig. 4). The shape of a curve is determined by the exchange current and the Tafel coefficient. The latter is determined by *n* and β in Eq 19 and 20. As shown in Fig. 4, the metal dissolution/deposition reaction has a large i_o, and the anodic and cathodic branches are close to symmetrical, as expected for β close to 0.5. The consequence of a large i_o is that the current-potential curve is steep, and only small overpotentials are required to achieve large currents. By contrast, the current-potential relationship for the cathodic reaction is shallow due to a small i_o, and the anodic and cathodic branches are not symmetrical. Rather than attempt to interpret this lack of symmetry in terms of an ill-defined symmetry coefficient, it is sufficient for this discussion to know that it is taken care of in the values of the Tafel coefficients.

Because both reactions are occurring on different sites on the same surface (Fig. 1a), the corrosion current cannot be measured by coupling the material to a current-measuring device. The corrosion potential can be measured against a suitable reference electrode by using a voltmeter with an input impedance high enough to draw no current in the measuring circuit.

The actual value of E_{corr} cannot be predicted from the equilibrium potentials and therefore has no basic thermodynamic meaning. Figure 4 shows that its value is determined by the shape of the current-potential relationship for the two reactions and therefore by the kinetic parameters (i_o, β, *n*) for the two reactions. Because its value is determined by the properties of more than one reaction, the corrosion potential is often termed a mixed potential.

In the literature, diagrams such as Fig. 4 are often plotted in the form log *i* versus *E*. The algebraic sign of the cathodic current is neglected so that the anodic and cathodic currents can both be plotted in the same quadrant (Fig. 5). Such diagrams are generally called Evans diagrams. The two linear portions in the log $|i|$ versus *E* curves are the Tafel regions with slopes given by Eq 19 and 20. The exchange currents for the two reactions can be obtained by extrapolating the Tafel lines back to the respective equilibrium potentials (Fig. 5). Whether such diagrams are plotted linearly (*i* versus *E*) or in the logarithmic form is simply a matter of convenience. Sometimes, in the logarithmic plots, the nonlinearity close to the equilibrium potentials is ignored, and the curves are plotted as totally linear.

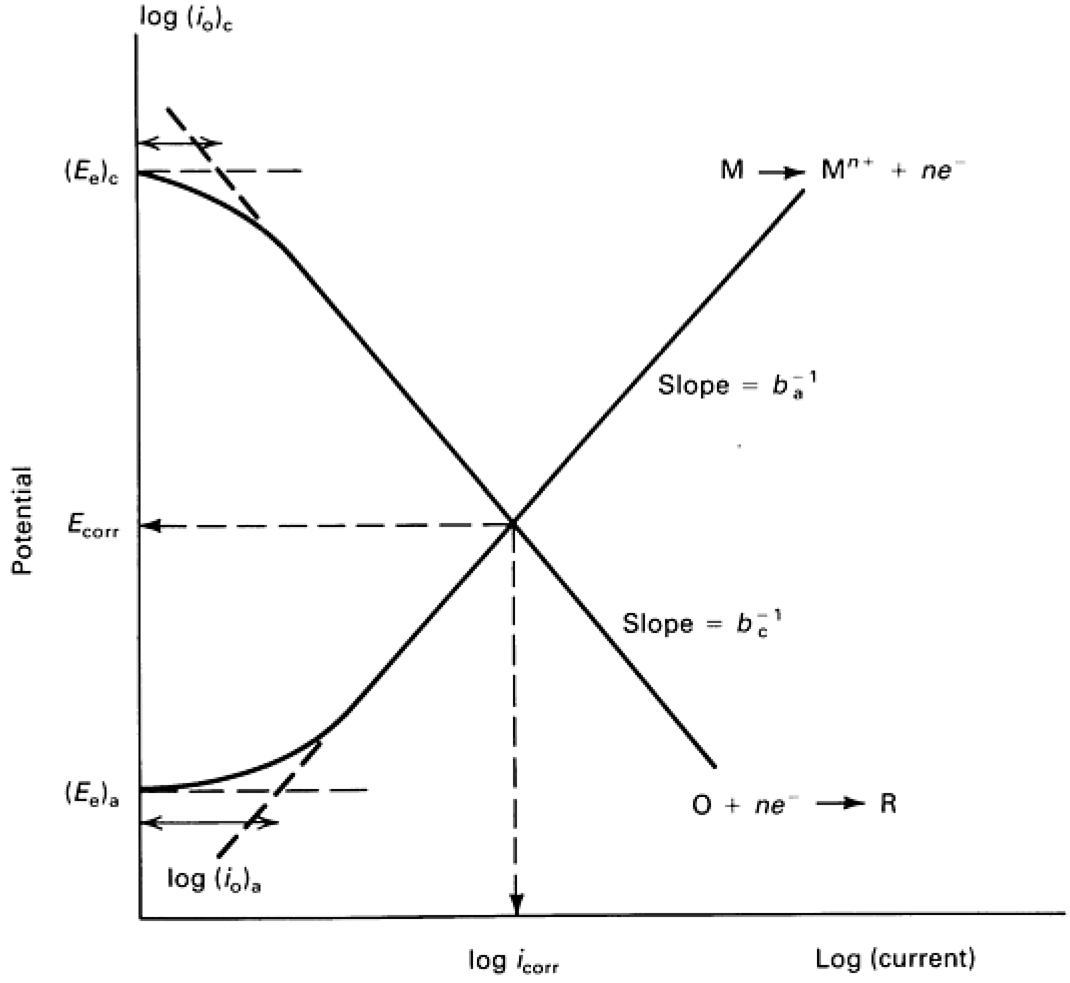

Fig. 5 Evans diagram for the corrosion process M + O →M^{n+} + R

The intersection of the two polarization curves in the Evans diagrams gives a value for the corrosion current. This is true whatever the shape of the curves and irrespective of the rate-determining process. Such diagrams can be used to illustrate the impact of a variety of parameters on the corrosion process.

Thermodynamic Driving Force. Figure 6(a) shows the same dissolution process driven by two different cathodic reactions. Recalling the definition of ΔE_{therm} from Eq 25, the following can be written:

$$\Delta E'_{therm} < \Delta E''_{therm} \quad \textbf{(Eq 26)}$$

giving:

$$i'_{corr} < i''_{corr} \quad \textbf{(Eq 27)}$$

That is, the bigger the difference in equilibrium potentials, the larger the corrosion current. The anodic activation overpotential for the first reaction $[E'_{corr} - (E_e)_a]$, is less than that for the second reaction $[E''_{corr} - (E_e)_a]$, and therefore the corrosion current for the second reaction is larger than for the first reaction, as shown in Eq 27.

$$(\eta_a^A)'' > (\eta_a^A)' \quad \textbf{(Eq 28)}$$

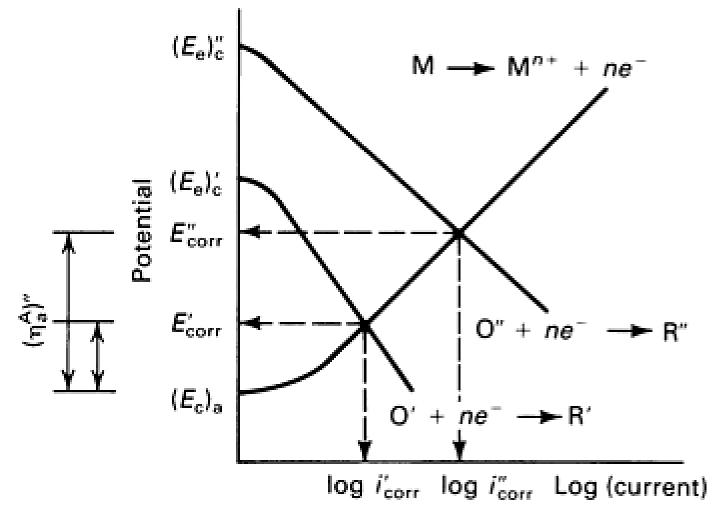

Fig. 6(a) Evans diagram for a metal dissolution coupled separately to two cathodic reactions with distinctly different equilibrium potentials, $(E_e)''_c$ and $(E_e)'_c$

Kinetics of the Charge Transfer Reactions. The value of ΔE_{therm} is not the only parameter controlling the corrosion rate. Figure 6(b) shows the same situation as in Fig. 6(a) except the two cathodic reactions possess very different polarization characteristics. Despite the fact that $(E_e)''_c > (E_e)'_c$, the activation overpotential, $(\eta_a^A)''$ is less than $(\eta_a^A)'$; therefore, the corrosion couple with the largest thermodynamic driving force produces the lowest corrosion current. Figure 6(b) shows that this can be attributed to the differences in exchange current, i_o, and Tafel coefficient, b_c, for the two cathodic reactions. This situation often occurs for the corrosion of a metal in acid compared to its corrosion in dissolved oxygen. Even though the thermodynamic driving force is greater for corrosion in dissolved oxygen, corrosion often proceeds more quickly in acid. This is due to the slowness of the kinetics of oxygen reduction and can be appreciated by comparing the kinetic characteristics for the two processes on iron. Thus, $(I_o)_{H^+/H_2}$ = 10^{-3} to 10^{-2} A/m^2 and $(b_c)_{H^+/H^2}$ ~120 mV/decade compared to $(I_o)_{O_2/H_2O}$ ~10^{-10} A/m^2 and $(b_c)_{O_2/H_2O}$ > 120 mV/decade.

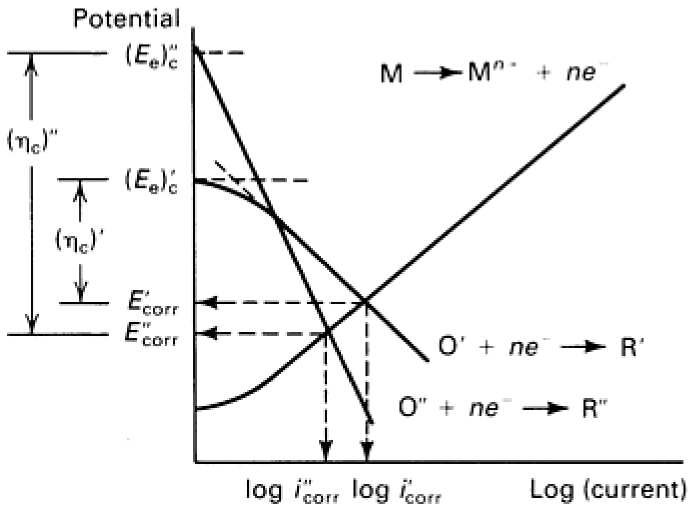

Fig. 6(b) Evans diagram for a metal dissolution coupled separately to two cathodic reactions, in which the impact of relative kinetics is greater than the thermodynamic driving force, ΔE_{therm}

Rate Control by the Anodic or Cathodic Reaction. The overall rate of corrosion will be controlled by the kinetically slowest reaction, that is, the one with the smallest exchange current, i_o, and/or largest Tafel coefficient. The significance of this point and its importance in determining which reaction is rate controlling can be appreciated from Fig. 6(c), in which $(i_o)_a > (i_o)_c$ and $b_a < b_c$. This leads to a large difference in activation overpotentials with $\eta_a^A \ll \eta_a^A$. This means the cathodic reaction is strongly polarized and must be driven hard to achieve the corrosion current. However, the anodic reaction remains close to equilibrium, requiring only a small overpotential to achieve the corrosion current. Under these conditions, the corrosion potential lies close to the equilibrium potential for the kinetically fastest reaction. If the cathodic reaction was the faster, then $E_{corr} \rightarrow (E_e)_c$, and metal dissolution would be rate controlling. If the kinetics of the two reactions are close, the corrosion potential will be approximately equidistant between the two equilibrium potentials, and the corrosion reaction will be under mixed anodic/cathodic control, as shown in Fig. 5.

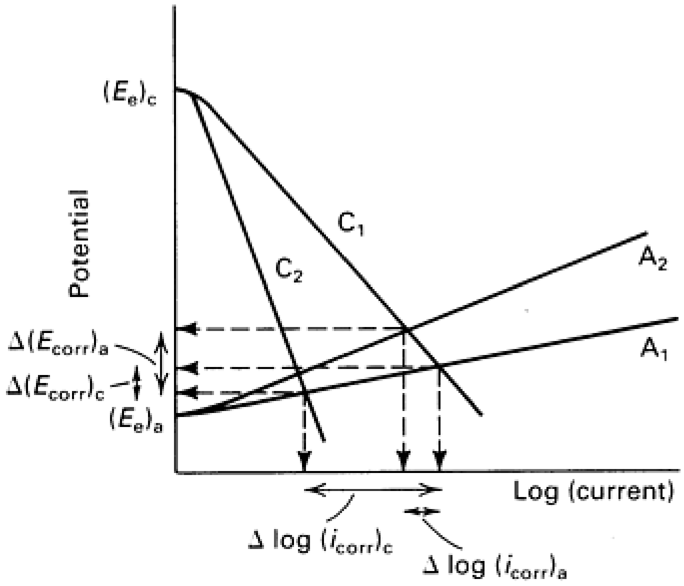

Fig. 6(c) Evans diagram showing the impact on the corrosion current, i_{corr}, and potential, E_{corr}, of varying the kinetics of a fast metal dissolution (A_1, A_2 or a slow cathodic process (C_1, C_2)

The corrosion of iron in dissolved oxygen can be used to illustrate this point. For the metal dissolution reaction, $(I_o)_{Fe/Fe^{2+}}$ ~10^{-5} to 10^{-4} A/m^2 and $(b_a)_{Fe/Fe^{2+}}$ ~50 to 80 mV/decade, whereas for oxygen reduction, $(I_o)_{O_2/H_2O}$ ~10^{-10} A/m^2 and $(b_c)_{O_2/H_2O}$ > 120 mV/decade. Consequently, oxygen reduction should be rate controlling, and the corrosion potential would be expected to be close to the metal dissolution equilibrium potential.

Figure 6(c) shows the effects of changing the kinetics of the two reactions. Changes in the kinetics of the fast anodic reaction are reflected in variations in the value of E_{corr} but have little effect on i_{corr}; however, changes in the kinetics of the slow cathodic reaction have a large impact on the corrosion current but have little effect on the corrosion potential. Such effects can sometimes be used as diagnostic tests for ascertaining the rate-determining step. The maximum benefit in attempting to slow corrosion can be gained by attending to the rate-determining reaction. However, such measurements may not be unequivocal in the presence of corrosion films.

Measurement of Corrosion Rates

A common method of measuring corrosion rates is simply to expose a carefully weighed piece of the material to the corrosion environment for a known length of time, remove and reweigh it, and calculate the mass lost. This is not always convenient in industrial applications because of the difficulty in placing, removing, and replacing metal coupons. However, it is possible to make use of the fact that corrosion is electrochemical in nature and to employ electrochemical methods to measure the corrosion rate.

When attempting an electrochemical measurement of the corrosion rate, one of the problems encountered is the desire to measure the current flowing at the corrosion potential. At this potential, no current will flow through an external measuring device (as discussed above). Consequently, any electrochemical attempt to measure i_{corr} will rely on current measurements at potentials other than the corrosion potential. An approximation or extrapolation is then made to estimate the current flowing internally at the corrosion potential.

The Tafel Method. As mentioned in the discussion of Fig. 4, the corrosion potential is generally in the Tafel region, in which the anodic and cathodic reactions are both proceeding under conditions appropriate for a Tafel analysis. Consequently, the polarization curves for both processes are determined by applying potentials well away from the corrosion potential, plotting the logarithm of the current against overpotential as for the Tafel analysis (Eq 18), and then extrapolating the currents in the two Tafel regions to the corrosion potential to obtain the corrosion current. The method is illustrated in Fig. 7, in which, as with the Evans diagram, both currents are plotted in the same quadrant. The polarization curve shown in Fig. 7 is in the form obtained experimentally; as a result, the current at E_{corr} passes through 0. In the Evans diagrams shown in Fig. 5 and 6(a), 6(b), and 6(c), i_a and i_c are shown independently, although it is generally not possible to measure them experimentally. The current measured in the external circuit and plotted in Fig. 7 is always the sum $i_a + i_c$ (= 0 at E_{corr}).

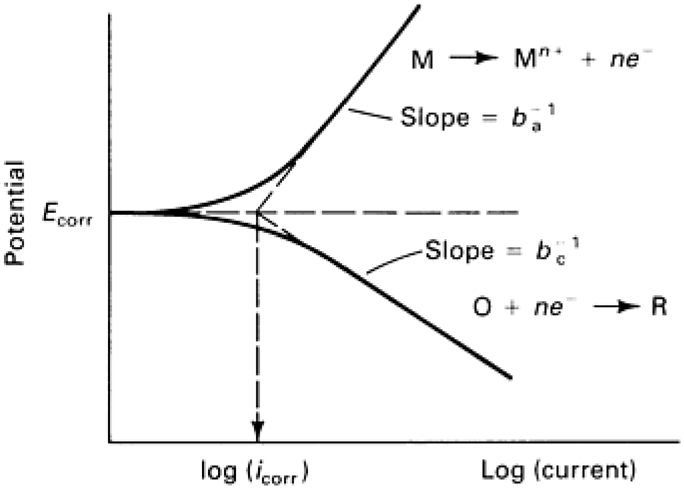

Fig. 7 Plot of the total current ($i_T = i_a + i_c$) versus potential showing the extrapolation of the Tafel regions to the corrosion potential, E_{corr}, to yield the corrosion current, i_{corr}

A simplified application of this method can be used to estimate the corrosion current from a simple measurement of the corrosion potential, because the latter may be the only measurable parameter in an industrial system. In this case, values of the exchange current (i_o), Tafel coefficients (b_a, b_c), and equilibrium potential (E_e) for the metal dissolution reaction must be known from a previous experiment. Combining Eq 18 and 23 yields:

$$E_{corr} = (E_e)_a + b_a \log \left(\frac{i_{corr}}{i_o}\right) \quad \textbf{(Eq 29)}$$

or

$$i_{corr} = i_o \exp \left\{2.303 \frac{E_{corr} - (E_e)_a}{b_a}\right\} \quad \textbf{(Eq 30)}$$

Complications arise when corrosion films are present or when corrosion is not uniform.

The linear polarization method is applicable when corrosion occurs under activation control. As opposed to the Tafel method, in which a large potential perturbation is applied to the system and seriously disturbs it, the linear polarization method uses only a small potential perturbation, $\pm \Delta E$ ($\lesssim$10 mV), for the freely corroding situation that occurs at E_{corr}. This small perturbation makes the method appropriate for ***in situ*** measurements. The current measured in the external circuit then equals the change in corrosion current, $\pm\Delta i$, caused by the small perturbation. Because both reactions proceed in their respective Tafel regions and in the vicinity of the corrosion potential, the currents are exponentially dependent on potential. For a small enough potential range ($\lesssim$20 mV), these exponentials can be linearized, giving an approximately linear current-potential relationship. The relationship between Δi and ΔE can then be obtained geometrically, as indicated in Fig. 8, which shows an expansion of the current-potential relationships around the corrosion potential. The terms s_a and s_c are the respective slopes of the anodic and cathodic curves at $E = E_{corr}$. Thus, the following can be written:

$$\Delta i = wy = wx + xy = \frac{s_a - |s_c|}{s_a|s_c|} \cdot \Delta E \qquad \textbf{(Eq 31)}$$

Rearranging and differentiating Eq 30 yields:

$$\frac{di_{corr}}{dE} = \frac{2.303}{b_a} i_{corr} = \frac{1}{s_a} \qquad \textbf{(Eq 32)}$$

for the anodic reaction. A similar process for the cathodic reaction gives:

$$\frac{2.303}{b_c} i_{corr} = \frac{1}{|s_c|} \qquad \textbf{(Eq 33)}$$

Substituting for s_a and s_c in Eq 31 yields:

$$i_{corr} = \frac{1}{2.303} \frac{b_a|b_c|}{b_a + |b_c|} \cdot \frac{\Delta i}{\Delta E} \qquad \textbf{(Eq 34)}$$

The quantity $\Delta E/\Delta i$ is termed the polarization resistance. Again, a knowledge of the Tafel coefficients is required before the method can be applied.

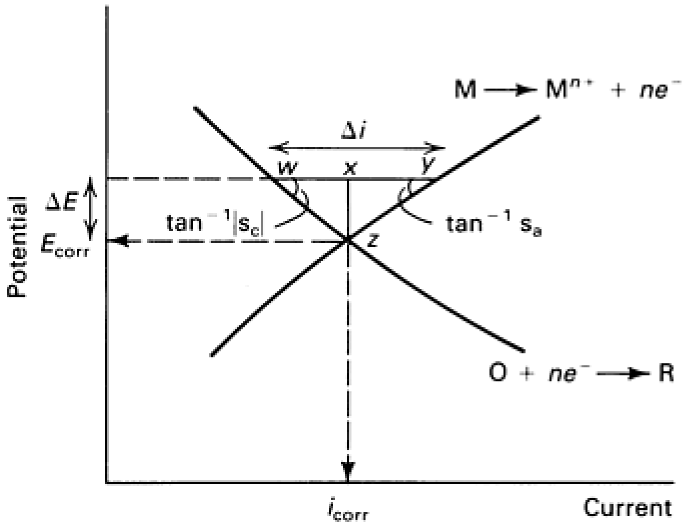

Fig. 8 Plot of the current-potential relationships, expanded around the corrosion potential, showing their linearization (for small values of Δ*E*) to obtain i_{corr} by using the linear polarization technique

The corrosion current can be converted into a mass flux by the application of Faraday's law (Eq 7). If the density of the material is known, a penetration rate (distance/time) can be obtained. Corrosion rates are generally expressed in millimeters per year or mils per year.

Mass Transport Control

It has been assumed in this article that the corrosion rate is controlled by either the anodic or cathodic charge-transfer process (reaction area 1 or 2, Fig. 2). However, if the cathodic reagent at the corrosion site is in short supply, then mass transport of this reagent could become rate controlling (reaction area 3, Fig. 2). Under these conditions, the cathodic charge-transfer process is fast enough to reduce the concentration of the cathodic reagent at the corrosion site to a value less than that in the bulk solution. Because the rate of the cathodic reaction is proportional to the surface concentration of reagent, the reaction rate will be limited (polarized) by this drop in concentration. For a sufficiently fast charge transfer, the surface concentration will fall to zero, and the corrosion process will be totally controlled by mass transport.

Because the corrosion rate is now determined at least in part by the rate of transport (the flux) of reagent to the corrosion site, this flux needs to be calculated. This can be accomplished by using the Nernst diffusion layer treatment, a simplification of the Fick's diffusion law treatment. The model is illustrated in Fig. 9. Because the concentration of reagent O is lower at the surface than in the bulk of solution, O will be transported down the chemical gradient at a rate (the flux *J*) proportional to the gradient of the concentration-distance profile. This is a statement of Fick's first law, which applies under steady-state conditions, that is, surface concentration and concentration gradient constant with time:

$$J = -D\left(\frac{\partial C_O}{\partial x}\right) \quad \textbf{(Eq 35)}$$

where *D* is the proportionality constant known as the diffusion coefficient (the negative sign accounts for the fact that the flux is down the gradient), and C_o is the reagent concentration at a point *x*. The solid line in Fig. 9 represents the concentration profile calculated from Fick's treatment.

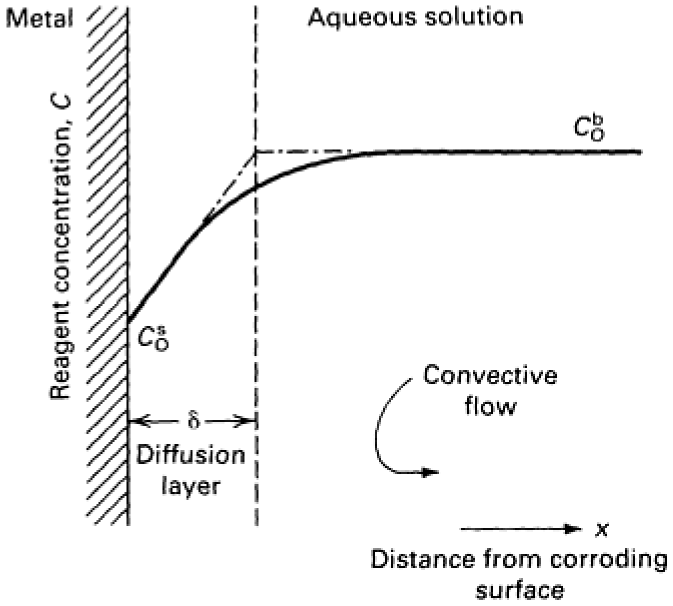

Fig. 9 Concentration-distance profile for the cathodic reagent O, depleted at the metal surface. The solid line shows Fick's treatment, and the dashed-dotted line indicates the approximation known as the Nernst diffusion layer treatment.

A simpler analysis can be achieved by linearizing the profile according to the Nernst diffusion layer treatment, as represented by the dashed-dotted line in Fig. 9. The resistance to mass transport lies within this diffusion layer, and the linearization yields a demarcation line at a distance δfrom the surface such that, for $x > \delta$, the bulk concentration is maintained by convective processes. By contrast, for $x \leq \delta$, reagent O is transported to the surface by diffusion only. This solution layer is called the diffusion layer, and its thickness is determined by the solution velocity.

Using this simplified treatment, Eq 35 can be written as:

(Eq 36)

where C_O^s is the reagent concentration at the corroding surface ($x = 0$), and C_O^b is the concentration for $x \geq$. For the steady state to be maintained, all the reagent transported down the gradient must react electrochemically, giving a current:

$$\frac{i_c}{nF} = \frac{-D_O(C_O^s - C_O^b)}{\delta} \quad \textbf{(Eq 37)}$$

where the term *nF* takes care of the chemical to electrochemical conversion (see Eq 7, Faraday's law). Under the limiting conditions $C_O^s \rightarrow O$, a limiting or maximum current is obtained:

$$(i_c)_{lim} = \frac{nFD_OC_O^b}{\delta} \quad \textbf{(Eq 38)}$$

Because this is the maximum cathodic current that can flow, it represents the maximum achievable corrosion rate:

$$(i_{corr})_{max} = (i_c)_{lim} = \frac{nFD_O C_O^b}{\delta} \quad \textbf{(Eq 39)}$$

When corrosion occurs at this limit, the corrosion rate can be increased or decreased only by varying the bulk concentration of reagent, C_O^b, or the diffusion layer thickness, . For nonlimiting conditions, the corrosion current will be given by: Eq 37.

The effect of the concentration polarization can be seen by considering Fig. 10. For small shifts from the equilibrium potential (point 1), = , there is no limitation on the reagant supply. Charge transfer is completely rate controlling, and the overpotential is purely an activation overpotential:

$$\eta_T = \eta^A \quad \textbf{(Eq 40)}$$

For larger shifts from the equilibrium potential, < (point 2), and the current is correspondingly less than expected on the basis of activation control; that is, the current follows the solid line as opposed to the dashed-dotted line. The current is both activation and concentration polarized, and the overpotential is the sum of an activation and a concentration overpotential:

$$_T = {}^A + {}^C \quad \textbf{(Eq 41)}$$

For a sufficiently large shift from equilibrium, the current becomes independent of potential, and the concentration overpotential becomes infinite (point 3). The corrosion rate is now at a maximum given by Eq 39.

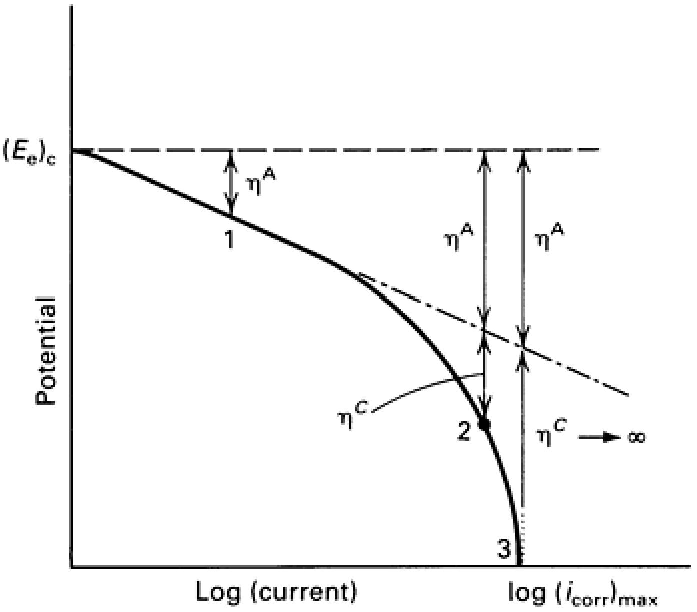

Fig. 10 Polarization curve for the cathodic process showing activation polarization (point 1), joint activation-concentration polarization (point 2), and transport-limited corrosion control (point 3)

The impact of various parameters on a corrosion process proceeding under mass transport or mixed activation-transport control can be assessed by the use of an Evans diagram, as shown in Fig. 11. Three situations are considered. For cathodic curve 1, corrosion occurs with the cathodic reaction totally mass transport controlled; that is, = 0. If the solution is now stirred or made to flow, the thickness of the diffusion layer (Fig. 9) will decrease, and the corrosion current, given

by Eq 39, will increase as shown (curve 2). The corrosion potential will shift to more positive values. This shift in E_{corr} is a consequence of the decrease in overpotential for the cathodic reaction due to the decrease in concentration overpotential:

$$ _{T} = E_{corr} - (E_e)_c = \ ^{A} + \ ^{C} $$ **(Eq 42)**

because:

$$ (\ ^{C})_2 < (\ ^{C})_1 $$
$$ (\ _{T})_2 < (\ _{T})_1 $$ **(Eq 43)**

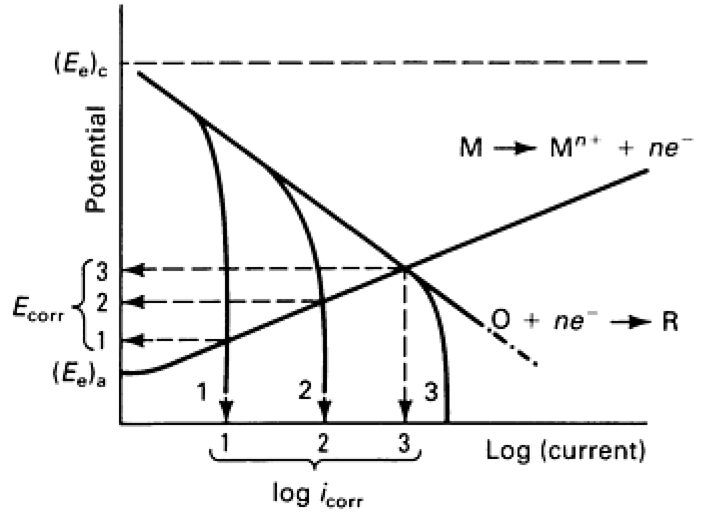

Fig. 11 Evans diagram for a corrosion process initially controlled by the transport of cathodic reagent to the corroding surface (line 1). Lines 2 and 3 show the effect of increasing the transport rate of reagent.

For more vigorous stirring, the concentration overpotential becomes zero because the flux of reagent O to the corroding surface is now fast enough to maintain the surface concentration equal to the bulk concentration. The reaction becomes activation controlled again (curve 3). Fluid velocity no longer affects corrosion rate.

Such changes in E_{corr} and i_{corr} with stirring or solution velocity can be used to indicate whether mass transport control is operative. If the anodic, as opposed to the cathodic, reaction was mass transport controlled, E_{corr} would shift to more cathodic (negative) values with increased stirring or flow rate.

Equation 38 indicates for mass transport control by the cathodic reaction the rate is directly proportional to the concentration of cathodic reagent and is inversely proportional to the thickness of the diffusion layer, which is determined by the fluid velocity (assuming the solution properties do not change). Corrosion in dissolved oxygen often proceeds in this manner, because the concentration of oxygen in solution is limited. Using this situation to demonstrate how velocity affects corrosion in flowing environments, Eq 37 can be written as:

$$ \frac{i_{corr}}{nF} = m_c \left(C_O^b - C_O^s \right) $$ **(Eq 44)**

where m_c is a mass transport coefficient and would be given by $D_O/$ if the Nernst diffusion layer treatment had been employed. As discussed above, to maintain the steady state, all the oxygen reaching the corroding surface is consumed, and the corrosion rate is given by:

$$\frac{i_{corr}}{nF} = k_c C_O^b$$ **(Eq 45)**

where k_c is the potential-dependent rate constant for the electron transfer reaction. The relationship between k_c and i_o, and b_a can be appreciated by comparing Eq 45 and 30. Eliminating between Eq 44 and 45 yields:

$$i_{corr} = nF\, C_O^b \left\{\frac{m_c k_c}{(m_c + k_c)}\right\}$$ **(Eq 46)**

where the constant k_c can be considered the activation control parameter, and m_c can be considered the mass transport control parameter. Whether or not activation kinetics or mass transport is rate determining is determined by the relative values of m_c and k_c. If $m_c \gg k_c$, the bracketed term in Eq 46 reduces to k_c, and the corrosion current is activation controlled. For $k_c \gg m_c$, the term reduces to m_c, and the corrosion current becomes mass transport controlled. For $m_c \sim k_c$, Eq 46 cannot be simplified, and corrosion would be under joint control.

If mass transport is a contributor to corrosion control, then a knowledge of the dependence of m_c on flow rate is required. This dependence is found experimentally, and its form varies, depending on the geometry of the system. In general, this dependence takes the form:

$$i_{corr} \propto f^n$$ **(Eq 47)**

where f is the flow rate, and n is a constant that depends primarily on the geometry of the system. Confining attention to flow over a flat plate, n is 0.33 for laminar (smooth, Re < 2200) flow and ~0.7 for turbulent (Re > 2200) flow, where Re is the Reynold's number (Eq 48).

The variation of the diffusion layer thickness, with flow conditions depends on flow rate as well as on solution properties, such as the kinematic viscosity (v), the diffusion coefficient of the reagent (D), and the geometry of the system (L). These effects can be accounted for by introducing two dimensionless parameters, the Reynolds number, Re, and the Schmidt number, Sc, given by:

$$\mathrm{Re} = \frac{fL}{v}$$ **(Eq 48)**

$$\mathrm{Sc} = \frac{v}{D}$$ **(Eq 49)**

It can be shown that for flow over a smooth, flat, corroding surface:

$$(i_{corr})_{max} = 0.62\, nFD_O \quad (\mathrm{Re})^{0.5}(\mathrm{Sc})^{0.33}$$ **(Eq 50)**

showing that the corrosion rate is proportional to $f^{0.5}$. Laminar flow can be maintained only up to a certain Reynolds number (or flow rate if L and v are constant), beyond which the flow becomes turbulent and the dependence on flow rate increases.

For still higher flow rates, the condition m_c k_c can be achieved, and the corrosion rate will become activation controlled and therefore independent of flow rate. This is equivalent to the situations discussed in Fig. 11, in which the corrosion rate (current) reached a constant value as the effect of concentration overpotential was removed.

These three regions are shown schematically in Fig. 12. The solid line shows the effect of flow rate when the anodic corrosion reaction is fast (k_c large) and a large flow rate is required to achieve activation control (m_c k_c). The dotted

line shows the behavior expected for a slow anodic reaction (k_c small) when only a low flow rate is required to achieve activation control.

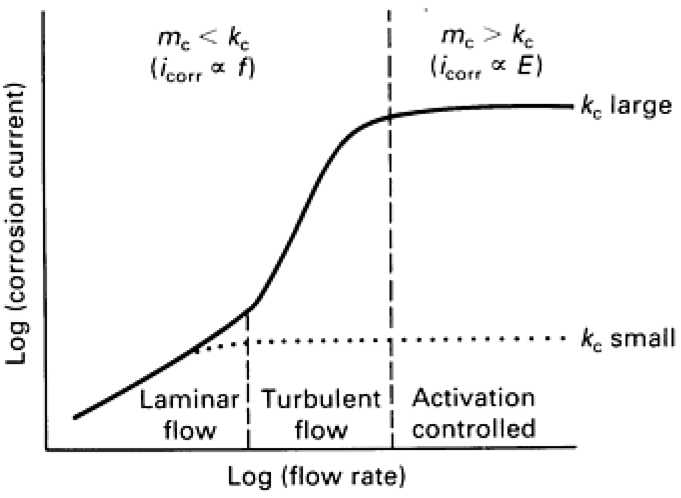

Fig. 12 Impact of flow rate on corrosion current showing the regions of laminar and turbulent flow and the switch from transport to activation control at high flow rates

Passivation

Thus far in the discussion on transport effects, only the transport of the cathodic reagent (area 3, Fig. 2) has been considered. The transport of metal dissolution product (area 4, Fig. 2) also affects the corrosion rate but in a different way. If the corrosion product is allowed to build up at the surface, supersaturation with regard to solid oxides and hydroxides can occur, leading to film formation reactions (area 5, Fig. 2).

The effects of film formation have been referred to above. With regard to the Evans diagrams shown in Fig. 5, 6(a), 6(b), 6(c), and 11, it can be seen that very substantial corrosion rates would be achieved if the kinetics of both the anodic and cathodic reactions were fast. Fortunately, in many cases, the metal dissolution rate decreases to low values once the potential is raised above a critical value. The metal is said to be passivated.

Passivation can occur when the corrosion potential exceeds (becomes more positive than) the potential corresponding to equilibrium between the metal and one of its oxides/hydroxides:

$$E_{corr} > (E_e)_{M/MO} \qquad \textbf{(Eq 51)}$$

Inspection of the Pourbaix diagram for the particular metal/metal oxide/aqueous solution system shows that this condition moves the potential into the oxide stability region (Fig. 13). For point 1, $E_{corr} < (E_e)_{M/MO}$ and corrosion of bare metal is expected, but for point 2, $E_{corr} > (E)_{M/MO}$, the metal should be oxide covered and passive. Under passive conditions, the corrosion rate will be dependent on the oxide film properties.

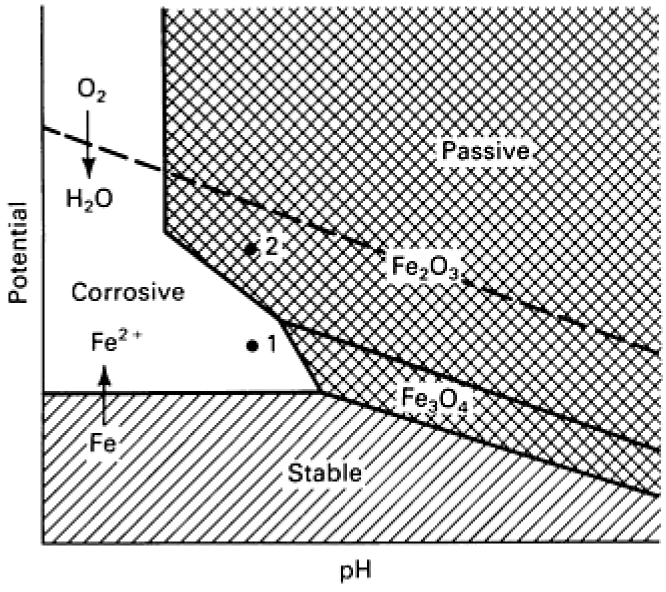

Fig. 13 Pourbaix diagram for the iron/water/dissolved oxygen system showing the effect of potential in moving the system from a corrosive (active) region (point 1) to a passive region (point 2)

The current-potential, or polarization, curve for the anodic process is shown in Fig. 14 and can be divided into a number of regions. In region AB, the active region, metal dissolution occurs unimpeded by the presence of surface films. The current, i_a, should conform to the Tafel relationship (Eq 17), and its extrapolation back to $(E_e)_a$ would yield a value of $(i_o)_a$. At a potential B, shown in Fig. 14 to coincide with $(E_e)_{M/MO}$, there is a departure from the Tafel relationship that becomes more pronounced as the potential increases, leading eventually to a decrease in current to a low value. The electrode is said to have undergone an active-passive transition and, by point C, has become passive. The potential at point B may or may not correspond to the potential $(E_e)_{M/MO}$. Thermodynamics demands only that the condition given in Eq 51 be satisfied for passivation to occur. The maximum current achieved immediately before the transition is termed the critical passivating current density. This can be considered as the current density required to generate a sufficiently high surface concentration of metal cations such that the nucleation and growth of the surface film can proceed.

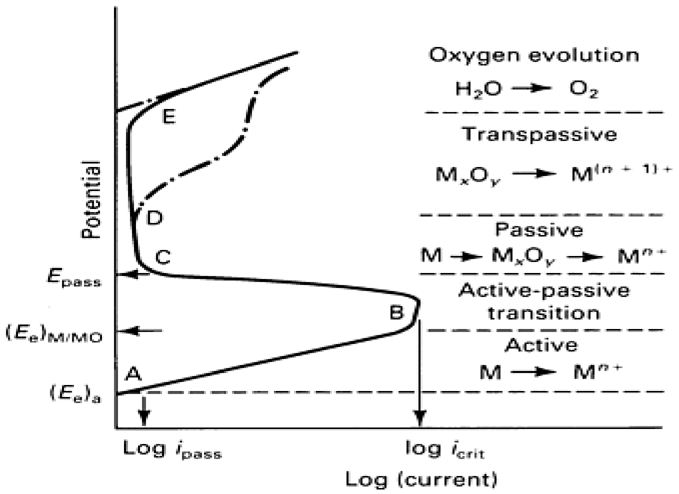

Fig. 14 Polarization curve for a metal/metal ion system that undergoes an active to passive transition. See text for details.

The potential at which the current falls to the passive value is called the passivation potential. It corresponds to the onset of full passivity and is sometimes called the Flade potential. In most cases, it has no thermodynamic significance. For gold, platinum, and silver, it is close to $(E_e)_{M/MO}$, but for most other metals, the passivation potential is much more positive than this equilibrium value.

For $E > E_{pass}$, the metal is said to be in the passive region. In this region, the current is independent of potential, and metal dissolution occurs at a constant rate. Two possible explanations can be offered for this constancy. First, dissolution in the passive region occurs by the transport of ionic species through the film (reaction area 5, Fig. 2) under the influence of the electric field across the film. The increase in potential through the passive region is accompanied by a progressive thickening of the film such that the electric field within the oxide, and therefore the dissolution current, remain constant. Second, the current is controlled by the rate of dissolution of the film (a chemical, as opposed to an electrochemical, process) and is potential independent. The current is just sufficient to replace the dissolving film.

For potentials greater than point E, oxygen evolution can occur on the outside of the oxide film by the reaction:

$$4OH^- \rightarrow O_2 + 2H_2O + 4e^- \quad \textbf{(Eq 52)}$$

For this last reaction to occur the film must be electronically conducting. This is possible because the passive films formed are commonly thin (nanometers) and possess semiconducting or even metallic properties.

The dashed-dotted line in Fig. 14, in the potential region D to E, corresponds to the phenomenon of transpassivity. In this region, the oxide film starts to dissolve oxidatively, generally as a hydrolyzed cation in a higher oxidation state. An example would be the further dissolution of the passive film on chromium. Cr_2O_3 with chromium in the +3 oxidation state, to chromate. CrO_4^{2-} with chromium in the +6 state.

The current in the passive region, then, is very dependent on the physical (conductivity, defect structure) and chemical (oxidation state) properties of the oxide. If the oxide were not present, then the current at potentials in the region C to E would be given by values obtained from the extrapolation of the active dissolution region, that is, line AB. These values would be extremely large. Any disruption of the passive film is a dangerous situation, and film breakdown at localized points leads to the initiation of such localized corrosion processes as pitting and cracking. These processes are characterized by very high local rates of metal dissolution and can lead to very rapid penetration of metal structures. Such processes will be discussed in the Section "Forms of Corrosion" in this Volume.

The following discussion will describe the properties of the cathodic reaction required to force the corrosion potential into the passive region, thus causing passivation and maintaining the corrosion current equal to the passive dissolution current. For passivation to occur, two conditions must be met:

- The equilibrium potential for the cathodic reaction must be greater than E_{pass}, the passivation potential
- The cathodic reaction must be capable of driving the anodic reaction to a current in excess of the critical passivation current, i_{crit}

Three possible situations are shown in Fig. 15. The dashed-dotted line shows the anodic polarization curve for the metal dissolution ($M \rightarrow M^{n+} + ne^-$), and lines 1, 2, and 3 show the cathodic polarization curves for three different cathodic processes ($O_n + ne^- \rightarrow R_n$).

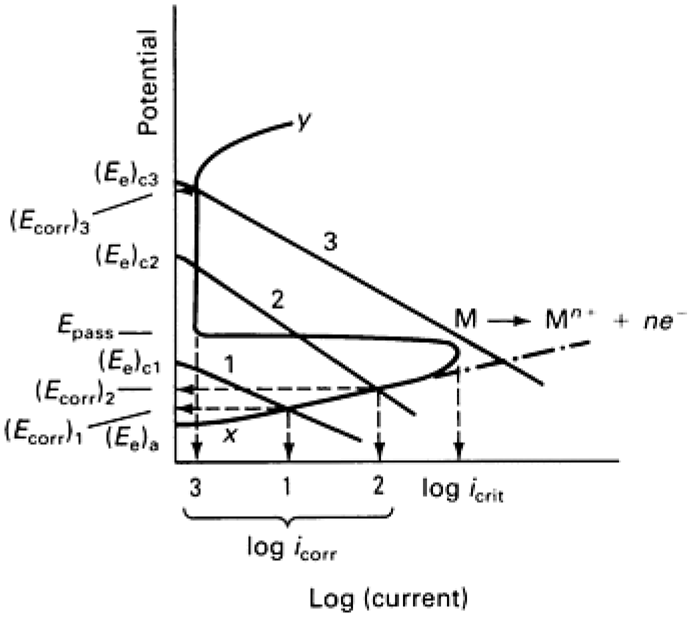

Fig. 15 Impact of various cathodic reactions on the corrosion current and potential for a metal capable of undergoing an active-passive transition.

Consider cathodic reaction 1 (Fig. 15), in which $(E_e)_{c1} < E_{pass}$. Because the corrosion potential must lie between $(E_e)_a$ and $(E_e)_{c1}$ for the two reactions to form a corrosion couple (Eq 22), the required condition for passivation, $E_{corr} > E_{pass}$, cannot be achieved. Therefore, the corrosion potential stays in the active region, and the metal will actively corrode.

For cathodic reaction 2 (Fig. 15), the condition $(E_e)_{c2} > E_{pass}$ is met, but the two polarization curves intersect at an anodic current less than i_{crit} (i_{crit} is the minimum current density required to supply a sufficient concentration of M^{n+} at the surface to initiate film growth by supersaturation with respect to the passivating oxide). Again, $E_{corr} < E_{pass}$, and the metal corrodes in the active region at a higher corrosion current than before.

For cathodic reaction 3 (Fig. 15), the conditions $(E_e)_{c3} > E_{pass}$ and $i > i_{crit}$ are both met. Therefore, $E_{corr} > E_{pass}$ and the metal passivates, with the corrosion current decreasing to a low value equal to the passive dissolution current.

Mild oxidizing agents ($\Delta E_{therm} = (E_e)_c - (E_e)_a$, small) will allow active corrosion, and strong oxidizing agents (ΔE_{therm} large) are required to force the metal or alloy into the passive region. As an example, steel corrosion in strong acid may proceed in the active region at a high rate, but in dissolved oxygen, the steel will passivate and corrode passively at an insignificant rate.

Effects of Environmental Variables on Aqueous Corrosion

D.C. Silverman and R.B. Puyear, Monsanto Company

Introduction

CORROSION involves the interaction (reaction) between a metal or alloy and its environment. Corrosion is affected by the properties of both the metal or alloy and the environment. In this discussion, only the environment variables will be addressed, the more important of which include:

- pH (acidity)
- Oxidizing power (potential)
- Temperature (heat transfer)
- Velocity (fluid flow)
- Concentration (solution constituents)

The influence of biological organisms on these environmental variables is also an important consideration, as explained in the Appendix "Biological Effects" in this article. Additional information is available in the references cited in this article and in the Section "Specific Alloy Systems" in this Volume.

Before discussing the relationships, the expanded portion of the potential-pH diagram of iron at 25 °C (77 °F) shown in Fig. 1 should be considered. As discussed in the article "Thermodynamics of Aqueous Corrosion" (see the section "Potential Versus pH (Pourbaix) Diagrams") in this Volume, these diagrams are thermodynamic and show the most stable state of the metal in an aqueous solution. The dependence of iron corrosion on oxidizing power (emf), acidity (pH), temperature, and species concentration is illustrated in Fig. 1. For example, suppose the corrosion potential lies at -0.5 V (standard hydrogen electrode, SHE) at a pH of 8. The most stable state of iron is Fe^{2+}, indicating that iron dissolution is possible. If the pH is increased to 10 (the acidity is decreased,) the most stable state becomes magnetite (Fe_3O_4), and most likely, iron corrosion would greatly decrease. If the pH is then decreased to about 8.5, the most stable state (Fe^{2+} or Fe_3O_4) becomes dependent on the concentration of the dissolved iron species. Thus, the corrosion rate may become dependent on the dissolved species. A change in temperature would change the entire diagram.

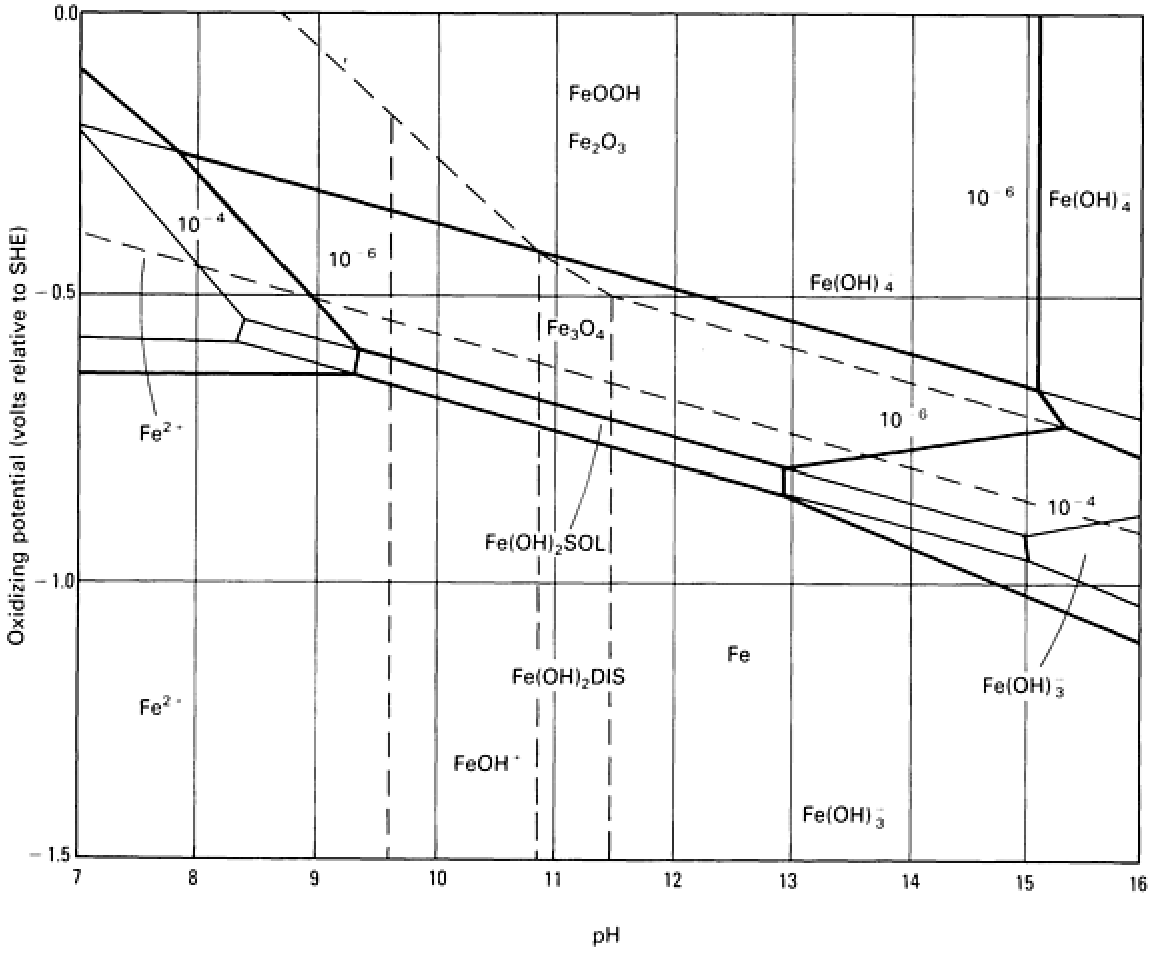

Fig. 1 Potential-pH (Pourbaix) diagram for iron at 25 °C (77 °F) in water. Ionic species are at activities of 10^{-6} and 10^{-4}. Source: Ref 1

This simple example shows the dominating role that the environmental variables play in corrosion. Complex interrelationships can exist. The combined values of the variables pH, potential, concentration, and temperature not only affect corrosion but also affect the action of each variable. For example, with respect to Fig. 1, the effect of a pH change is dependent on the concentration of the dissolved species, and vice versa. Therefore, although the variables are discussed individually, the important point is to realize that the effect of one variable can be dependent on the magnitude of another. This point will be further discussed in this article.

Effect of pH (Acidity)

The concept of pH is complex. It is related to, but not synonymous with, hydrogen concentration or amount of acid. Before discussing how the magnitude of pH affects corrosion, some fundamentals are required. The pH is defined as the negative of the base ten logarithm of the hydrogen ion activity (Ref 2). This latter quantity is related to the concentration or molality through an activity coefficient. The term is expressed as

$$\text{pH} = -\log a_{\text{H}^+} = -\log \gamma_{\text{H}^+} m_{\text{H}^+} \quad \textbf{(Eq 1)}$$

where a_{H^+} is the hydrogen ion activity, γ_{H^+} is the hydrogen ion activity coefficient, and m_{H^+} is the molality (mol/1000 cm^3 of water). The value of the activity coefficient is a function of everything in the solution (ions, nonionized species, and so on).

The pH is usually measured with a pH meter, which is actually an electrometer. The voltage of a hydrogen ion specific electrode is measured relative to a reference electrode. This voltage is compared to the internally stored calibration obtained from a defined standard to yield the unknown pH. The actual hydrogen ion concentration (acidity level) can be calculated from this measured pH if the activity coefficient is known. Because the test solution usually has constituents that are far different from those of the buffer, the calculated hydrogen ion concentration is at best an estimate (Ref 3). Thus, the pH measured by a pH meter and the actual amount of acid as defined by the hydrogen ion concentration are related but not necessarily equal.

The importance of the hydrogen ion lies in its ability to interact with an alloy surface. Many alloys of commercial interest form an oxidized surface region, the outer most atomic layer of which often contains hydroxide-like species when water is present. Such a structure would tend to have a dependence on hydrogen ion concentration, possibly through a reaction that can be one step in corrosion (Ref 4):

$$H_2O \leftrightarrows OH_{adsorbed} + H^+ + e^- \quad \textbf{(Eq 2)}$$

Thus, under a number of conditions, the hydrogen ion concentration can influence corrosion through the equilibrium that exists among it, water, and the hydroxide ion formed on the alloy surface.

This interaction often results in a corrosion rate dependence on hydrogen ion concentration in the form of:

$$r = k\, C^{n}_{H^+} \quad \textbf{(Eq 3)}$$

where r is the corrosion rate, k is the rate constant, C_{H^+} is the hydrogen ion concentration, and n is an exponent. The value of n can be dependent on the hydrogen ion concentration. This type of dependence of the reaction rate on the hydrogen ion concentration is found in a number of systems, which are discussed below. This discussion is not meant to be all-encompassing, but is meant to provide a flavor for how this dependence is observed in practice.

Strongly Acid Conditions (pH < 5). Iron or carbon steel shows a complex dependence of the corrosion rate on pH. At low pH, the corrosion mechanism is dependent not only on the hydrogen ion concentration but also on the counter-ions present. Thus, all discussion must include the total constituency of the fluid. For example, the corrosion rate of iron in sulfuric acid (H_2SO_4) between a pH of less than 0 and about 4 tends to be limited by the diffusion of and saturation concentration of iron sulfate ($FeSO_4$) (Ref 5, 6). The metal dissolution rate is so high that the corrosion rate is equal to the mass transfer rate of iron from the saturated film of $FeSO_4$ at the metal surface. Because mass transfer rates are sensitive to fluid velocity, the corrosion rate is sensitive to fluid flow. This effect is well documented for concentrated H_2SO_4.

Corrosion of iron in hydrochloric acid (HCl) follows a different mechanism, and pH has a different effect on corrosion. The rate of corrosion is rapid at all acidic concentrations of pH < 3. Unlike the sulfate ion in H_2SO_4, the chloride ion seems to participate in and accelerate the corrosion rate (Ref 7). The corrosion rate increases with hydrogen ion concentration (decreasing pH). These effects are reflected in Eq 3. This behavior indicates that in HCl hydrogen ion directly influences the reaction kinetics. The ion does not influence corrosion through mass transfer.

Corrosion of iron in phosphoric acid (H_3PO_4) solution follows a similar mechanism but with a subtle twist. Again, no passive film exists on the surface; however, the corrosion rate, at least between a pH of 0.75 and 4, seems to be independent of phosphate ion concentration at constant pH (Ref 8).

The important point is that the pH effect on corrosion of carbon steel at low pH is not simple. Knowledge of how pH affects corrosion in one acid does not necessarily translate to knowledge in another acid. Very little information is available on the effect of acid mixtures on corrosion.

Ferritic iron-chromium alloys have been found to exhibit behavior in concentrated H_2SO_4 reminiscent of the behavior of carbon steel. A strong fluid velocity sensitivity has been noted in 1 *M* H_2SO_4 (5 to 10 wt%) (Ref 9) for those alloys with less than 12 wt% Cr and in the 68 to 93 wt% range (Ref 10) for E-Brite 26-1 (26 wt% Cr). The corrosion rate tends to be related to the rate of mass transfer of $FeSO_4$ from a saturated film on the surface. The one difference is that the presence of oxygen may impart a pseudopassivity that can be unstable. The major point is that the presence of chromium may provide little benefit in this environment. Both chromium content and H_2SO_4 concentration must be considered simultaneously, especially because an 18 wt% Cr ferritic alloy tends to be under activation control in 1 *M* H_2SO_4 (Ref 9).

The addition of nickel to create austenitic alloys alters this behavior in H_2SO_4 and eliminates, or at least diminishes, this velocity sensitivity, especially in the pH range of -0.5 to 3. At lower pH, the higher acid concentrations may produce a velocity sensitivity (Ref 11). Unfortunately, data are sparse on the effect of pH on the low corrosion rates expected for many of these alloys in this low pH range of -0.5 to 3. At still lower pH, the behavior is complex, and the particular literature on the alloy should be consulted. Impurities in the H_2SO_4 can significantly alter the corrosion resistance.

The behavior of austenitic alloys in HCl is far different from that in H_2SO_4, even at the same pH or hydrogen ion concentration. The change from sulfate to chloride anion tends to be detrimental. The presence of the chloride ion raises the possibility of localized attack, for example, crevice corrosion, pitting, and stress-corrosion cracking (SCC) (Ref 12). Once again, behavior with respect to pH is complex. The literature on the particular alloy should be consulted to determine the actual behavior as a function of pH in acidic solutions.

Non Group VIII base alloys show different types of pH dependencies at low pH. For example, in HCl, titanium is passive to a pH of about 0 or slightly lower. Then, a fairly abrupt change in mechanism occurs at still lower pH. There, titanium begins to corrode rather rapidly (Ref 13). The hypothesis is that the titanium valence changes from +4 to +3 and that Ti^{3+} is soluble (Ref 13, 14). The behavior in H_2SO_4 is somewhat different.

Other metals and alloys are affected by acidic pH in different ways. Unfortunately, mechanistic data are less plentiful than for iron-base alloys. A number of metals show a very strong dependence of corrosion on pH. With aluminum, the rate increases exponentially as pH decreases in the acidic region (Ref 15). Indeed, the corrosion rate tends to have a very sharp minimum at a pH of 7 to 9, with sharp corrosion rate increases with both increasing and decreasing pH (Ref 15, 16).

A similar effect of a sharp decrease in corrosion rate with increasing pH for pH < 4 has been noted for both zinc in HCl and lead in nitric acid (HNO_3) (Ref 17). Indeed, this type of behavior would be expected for any metal or alloy whose oxide is soluble in acids, such as zinc, aluminum, lead, tin, and copper.

Near-Neutral Conditions (5 < pH < 9). Corrosion behavior and alloy-environment interactions in the near-neutral pH region differ significantly from those under acidic conditions. In most cases, pH no longer plays a direct role in corrosion.

Iron (as carbon steel) has been one of the most extensively studied metals in this environment. Under acidic conditions, the oxide or hydroxide layers tend to dissolve. However, in the higher pH range, especially above a pH of about 5, these layers tend to remain on the surface. These layers have significant structure, which tends to be determined by the anions present in the solution (Ref 18). In addition, the corrosion kinetics become independent of pH, and hydrogen ion reduction is no longer an important reaction (Ref 19). The major reaction governing corrosion in most practical applications is the reduction of oxygen present in solution. Magnetite (Fe_3O_4) can be formed, which will tend to passivate iron (Ref 18). Thus, pH in this range no longer plays a major direct role in corrosion of iron, although the pH can still affect the solubility and equilibrium of other ions, such as sequestering agents. These other components can play a major role in corrosion in cooling water.

This characteristic of pH in the range of 5 < pH < 9 no longer playing a dominant role is found with other metals, such as zinc and lead (Ref 17). Aluminum shows a very sharp minimum in corrosion rate at about a pH of 7 to 9, with the minimum being somewhat dependent on the counter-ion in solution (Ref 15).

Alloys such as the austenitic iron-base and nickel-base alloys, ferritic alloys, and duplex alloys also tend to have general corrosion rates that are independent of pH in this range. Indeed, in pure water, these alloys would be passive. The presence of other constituents, such as chloride ions and oxygen, plays a much more dominant role, possibly changing the mechanism from uniform corrosion to localized attack.

Strongly Basic Conditions (pH > 9). Basic conditions offer yet another set of corrosion characteristics. In a number of cases, corrosion rate increases with pH (decreasing hydrogen ion concentration) or at least remains finite. In other cases, the increase in pH causes corrosion to occur when none was present at lower pH. These two types of behavior seem to encompass most metals and alloys, and representative examples will be described to demonstrate this behavior.

Iron corrosion persists even at high pH. This persistence is caused by soluble species ($Fe(OH)_3^-$ or, at elevated potentials, $Fe(OH)_4^-$) being the most thermodynamically stable corrosion products (Ref 1, 16). Even though a number

of iron hydroxide species can be found that can create a porous barrier (Ref 20), corrosion still persists, although usually at a fairly low rate, until very high pH is reached (Ref 17).

At very high pH and especially at somewhat elevated temperatures, carbon steel can undergo SCC (Ref 21). Some environments that can cause SCC at high pH are sodium hydroxide (NaOH) at very high pH, carbonates and bicarbonates at moderately basic pH values, and possibly amines, although this point is controversial. Steel can also suffer SCC at lower pH, but this behavior is less prevalent. Examples of these environments are hydrogen fluoride (HF) vapors and hydrogen sulfide (H_2S). The mechanism in these cases may be one of hydrogen embrittlement (Ref 22).

A number of metals exhibit a sharp increase in corrosion rate with increasing pH. Among these are aluminum, zinc, and lead (Ref 15, 17). Aluminum corrosion increases very dramatically, changing by almost two orders of magnitude between a pH of 8 and 10. This increase is virtually independent of counter-ion and can be attributed to the formation of soluble aluminum hydroxide products (Ref 16).

Tantalum, which suffers virtually no corrosion under most acidic and neutral pH conditions, shows a significant increase in corrosion rate at high pH (Ref 23). The cause of this corrosion is believed to be a slow dissolution or flaking off of surface layers (Ref 23.) This dissolution is probably caused by the formation of soluble tantalum hydroxide corrosion products (Ref 13).

Some metals, such as nickel and zirconium, are very resistant to corrosion at high pH. Possibly nickel and especially zirconium rely on the formation of insoluble oxides for their corrosion protection (Ref 24).

The austenitic and ferritic alloys tend to be immune to corrosion until very high pH is reached. One reason is that chromium, which is included in many of these alloys and which tends to accumulate on the surface, forms a passive oxide. This oxide, for example, chromium oxide (Cr_2O_3), is insoluble under these conditions. However, changes in temperature can affect corrosion at high pH.

Oxidizing Power (Potential)

Oxidizing power, or potential, relates to the ability to remove or add electrons from the metal so as to oxidize or reduce the surface. This variable is separated from the discussions on solution chemistry because such a potential can be applied by an external voltage source, by galvanic coupling of different metals, or by solution constituents. Practical applications include increasing passivity by altering the surface oxide (anodic protection) or preventing corrosion by supplying electrons to the metal that would normally be yielded by metal corrosion (cathodic protection). The anodic reaction rate is shifted or changed in the protected metal.

The alteration of the surface state to impart passivity is normally accomplished by anodic polarization of the metal or alloy surface to a potential noble to the corrosion potential. If an external voltage source is used to change the voltage, the technique is known as anodic protection (see the article "Anodic Protection" in this Volume). Among the practical examples of using externally applied anodic potentials to mitigate corrosion are mild steel and type 304 stainless steel in concentrated H_2SO_4, and NaOH (Ref 22).

The addition of constituents to the environment may alter the surface potential to create a passive film. In this case, the constituent reacts with the metal to form a tenacious metal-oxide compound that passivates the surface. There are several well-known examples of anodic polarization of the surface by changing the environment. For example, the addition of small amounts of ozone to water decreases the corrosion of carbon steel in water (Ref 25). The hypothesis is that the corrosion potential moves in a noble direction and the ozone reacts with the iron to create a more tenacious oxide. In another example, the addition of HNO_3 to H_2SO_4 has been shown to retard the corrosion of stainless steels. The hypothesis is that the potential is forced in the noble direction and the surface oxide layer becomes more protective.

Polarization of the surface potential in the active or cathodic direction can also be used to decrease corrosion. When the potential is lowered by means of an external voltage source, the technique is known as cathodic protection (Ref 22). Many practical examples exist, such as the protection of steel at coating defects in underground carbon steel pipelines (Ref 25) or the protection of ships hulls in seawater (see the articles "Cathodic Protection," "Marine Corrosion," and "Corrosion of Pipelines" in this Volume). The electrons are supplied from either an inert or active counterelectrode.

Direct electrical coupling of a metal to a more active metal is another example of using cathodic potentials to affect corrosion. Coupling zinc to steel to protect the steel is a major example. In this case, zinc corrosion liberates electrons to the steel, and the steel potential moves in an active direction (Ref 26).

Such cathodic polarization can be produced by constituents in the solution. Oxygen tends to polarize carbon steel in a noble direction and increase its corrosion. The addition of such species as sulfite (SO_3^{2-}) or hydrazine tends to cause a reaction with the oxygen and thus remove it (Ref 26). The effect of (SO_3^{2-}) tends to be to move the surface potential in the active direction. Such movement of potential may decrease the corrosion of iron (Ref 17). However, any change in potential may be dependent on other constituents, especially if they can interact with the inhibitor and the metal surface. Also, if the alloy is passive and this passivity is maintained by the oxygen, this addition could increase corrosion by moving the alloy into an active corrosion region (Ref 17).

Temperature and Heat Transfer

Temperature is a complex external variable. Temperature is analogous to potential. A potential difference creates a current flow, the objective of which is to eliminate the potential difference. In a similar manner, a temperature difference creates a heat flow, the objective of which is to eliminate the temperature difference. Both potential and temperature are measures of energy.

Temperature can affect corrosion in a number of ways. If the corrosion rate is governed completely by the elementary process of metal oxidation, the corrosion rate increases exponentially with an increase in temperature. This relationship is reflected in the Arrhenius expression:

$$r = A \exp\left(\frac{-E}{RT}\right) \quad \textbf{(Eq 4)}$$

where r is the corrosion rate, A is a preexponential factor, E is an activation energy, R is the gas constant, and T is the absolute temperature.

The effect of temperature on corrosion rate is shown by solving Eq 4 at two temperatures and taking the ratio of the rates:

$$\ln\left(\frac{r_2}{r_1}\right) = \frac{-E}{R}\frac{\Delta T}{(T_2)(T_1)} \quad \textbf{(Eq 5)}$$

where the subscripts 1 and 2 refer to the two temperatures and ΔT is the difference in temperature (T_2 - T_1). Equation 5 can be used to evaluate the effect of a temperature change on corrosion rate for this simple rate process. Examples of corrosion that follow this simple rate law are iron in HCl (Ref 27) and iron in sodium sulfate (Na_2SO_4) at a pH of about 2 (Ref 28). This situation is most common for corrosion under acidic conditions.

The temperature of the metal and the temperature of the solution often cannot be discussed separately from other variables. If a constituent in the solution that is important in corrosion has limited solubility, a temperature change can alter the concentration of that constituent. This alteration can have a profound effect on corrosion.

One classical example is the corrosion of iron in the presence of oxygen in systems both closed from the atmosphere and open to the atmosphere. The corrosion rate of iron in a system closed to the atmosphere has been shown to increase almost linearly with temperature from about 40 to 160 °C (105 to 320 °F). However, in the open system, the corrosion rate increases up to about 80 °C (175 °F) and then decreases (Ref 17). Oxygen mass transfer, which is proportional to the oxygen concentration in the liquid, controls the corrosion rate of steel in water. As temperature increases, oxygen solubility decreases so that the oxygen will tend to leave the liquid. In the closed system, the oxygen cannot escape from the vapor space above the liquid. As temperature increases, the water vapor pressure increases, which tends to maintain the oxygen concentration in the liquid. The corrosion rate (mass transfer rate) continues to increase with temperature because of temperature effects on viscosity, diffusivity, and so on. In the open systems, oxygen can escape from the

immediate vicinity of the liquid. The vapor pressure remains constant. Above a certain temperature, the liquid-phase oxygen concentration in equilibrium with oxygen in the atmosphere has decreased to the extent that the corrosion (mass transfer) rate decreases.

Another point often overlooked is that the ionization constant of water increases with temperature. Pure water with pH of 7 at one temperature will have a lower pH at a higher temperature. Thus, an increase in temperature could affect corrosion by moving the pH from a neutral to an acidic value.

Fluid temperature changes can affect the polarity in galvanic corrosion. The corrosion potential of the anode might be more sensitive to temperature than that of the cathode. The anode potential can actually become noble with respect to that of the cathode (Ref 17). An example is the iron-zinc couple, the polarity of which can reverse as temperature increases. Iron will actually protect the zinc. The temperature of this reversal is as low as 60 °C (140 °F), but there is some dependence of temperature on constituents (Ref 26).

Solution temperature can also affect the onset of localized attack of passive alloys such as type 304 and 316 stainless steels. The solution usually contains a species, such as chloride ion, that aids in the initiation process (Ref 29). The time to initiation of crevice corrosion has been shown to be a function of temperature. There are indications that such initiation times do not always decrease with increasing temperature (Ref 29). In addition, a critical crevice temperature can be defined for many of these alloys (Ref 30). This critical temperature determines the temperature boundary at which crevice corrosion can initiate. Indeed, the critical crevice temperature has been shown to be a function of the chromium and molybdenum content of austenitic and ferritic alloys.

In practice, elevated or depressed temperatures are often created by heat transfer through a metal wall. Thus, the metal wall can be at a temperature different from that of the bulk fluid. There is a controversy over whether corrosion in the absence of heat transfer is identical to corrosion in the presence of heat transfer even if the metal temperatures are identical in the two situations (Ref 28).

The effect of a difference between wall and fluid temperatures on corrosion depends on the corrosion mechanism. If the corrosion rate is under activation control and follows Eq 4, the corrosion rate in the presence of heat transfer might be similar to that expected for corrosion at the same wall temperature in the absence of heat transfer. If the corrosion rate is controlled by the diffusion of a species, such as oxygen, to the surface then heat transfer may greatly change the corrosion rate. This effect has several possible causes (Ref 31, 32). First, a temperature difference between the wall and bulk solution can affect the solubility and diffusion coefficient of the diffusing species. Second, boiling near or on the wall can increase turbulence and possibly cause cavitation or increased diffusion (mass transfer). Third, heat transfer in the absence of fluid flow, as in stagnant tanks, can cause natural convection currents that can enhance mass transfer. Thus, if heat transfer is present, it must be considered an environmental variable.

Velocity / Fluid Flow Rate

Fluid flow rate, or fluid velocity, is also a complex variable (Ref 33). Its influence on corrosion is dependent on the alloy, fluid constituents, fluid physical properties, geometry, and corrosion mechanism. These relationships are best discussed in terms of specific examples. In a number of instances, the corrosion rate is determined by the rate of transfer of a species between the surface and the fluid. This situation arises when the corrosion reaction itself is very rapid and one of the corrosion reactants or products has low solubility in the bulk fluid. The corrosion rate becomes a function of the concentration gradient and is expressed by:

$$r = k\,(C_W - C_B) \qquad \textbf{(Eq 6)}$$

where r is the corrosion rate, k is a mass transfer coefficient, C_W is the concentration of the rate-limiting species at the metal wall, and C_B is the concentration of the rate-limiting species in the bulk fluid. The value of k can often be correlated with the dimensionless quantities Reynolds number (Re) and Schmidt number (Sc). The mass transfer coefficient is expressed in terms of the Sherwood number (Sh). These numbers are related to physical properties of the fluid and geometry by:

$$\mathrm{Re} = \frac{vd}{\nu} \qquad \textbf{(Eq 7a)}$$

$$\mathrm{Sc} = \frac{\nu}{D} \qquad \textbf{(Eq 7b)}$$

$$\mathrm{Sh} = \frac{kd}{D} \qquad \textbf{(Eq 7c)}$$

where *v* is the fluid velocity, *d* is a characteristic length (for example, pipe diameter), *v* is the kinematic viscosity (absolute viscosity divided by density), and *D* is the diffusion coefficient.

For many geometries, these quantities can be related by:

$$\mathrm{Sh} = a\,\mathrm{Re}^b\,\mathrm{Sc}^c \qquad \textbf{(Eq 8)}$$

where *a, b,* and *c* are constants. Equations 6, 7a, 7b, 7c, and 8 indicate that the corrosion rate can be calculated if it depends on the mass transfer rate of a species from or to the bulk fluid. The only information required is the geometry, fluid velocity, and physical properties. There are a number of examples of corrosion that follow this behavior. The corrosion of carbon steel and E-Brite 26-1 in concentrated H_2SO_4 is governed by the rate of mass transfer of $FeSO_4$ from a saturated layer on the surface (Ref 5, 6, 10). Carbon steel corrosion in water in the near-neutral pH range is governed by the rate of mass transfer of dissolved oxygen from the bulk fluid to the surface (Ref 34). If a porous surface hydroxide layer forms, the mass transfer rate might become limited by diffusion through the porous film.

This effect of velocity has ramifications for localized attack, especially pitting and crevice corrosion. The presence of fluid flow can sometimes be beneficial in preventing or decreasing localized attack. For example, type 316 stainless steel has been shown to pit in quiescent seawater but not in moving seawater (Ref 35). When the seawater is moving, the mass transfer rate of oxygen is high enough to maintain a completely passive surface, but in the absence of flow, the mass transfer of oxygen is too slow and the surface cannot remain passive (Ref 36). This observation indicates that sometimes fluid velocity can be beneficial even if the corrosion rate involves the mass transfer of a reactant or product. The propensity for localized attack to occur can sometimes be decreased by maintaining sufficient fluid motion.

Under other circumstances, fluid flow can cause a type of erosion of a surface through the mechanical force of the fluid itself. This common process is called impingement. The process involves the removal of metal or alloy by the high wall shear stress created by the flowing fluid. Examples of such erosion occur either where fluid is forced to turn direction, for example, at pipe bends (Ref 22), or where high surface shear stresses can exist, for example, on ship hulls (Ref 35). Evidence exists that a critical wall shear stress can be defined for an alloy above which impingement causes erosion and below which such erosion is absent (Ref 37, 38). Thus, shear stress can be translated to a maximum velocity. This phenomenon has been demonstrated for copper-nickel alloys and aluminum alloys in salt water (Ref 39).

When solids are present in the liquid, they can cause wear or solid erosion corrosion (Ref 40). The wear is caused by the relative movement of the solids with respect to the surface. Again, such wear is more prevalent where fluid is forced to change direction or where high shear stresses occur. The particles must penetrate the laminar sublayer with enough force to remove the passive film on the alloy. Therefore, high shear stresses are often required for this type of erosion to occur. This problem can be significant in such systems as salt water carrying solids (for example, sand or coal) and carbon steel carrying air plus particulates.

Concentration

The concentration of constituents within the fluid often influences how the other variables manifest themselves. This discussion will focus on how the concentration of constituents works with other variables to influence corrosion behavior.

During the previous discussion, the point was made that pH plays a major role in corrosion. For iron, the corrosion rate is large at very low pH, is independent of pH in the neutral pH range, decreases with increasing pH, and finally increases again at very high pH. Additions of small amounts of other components can change this behavior.

For example, additions of chloride to H_2SO_4 increase the corrosion rate of iron. This increase is reported to be proportional to the chloride ion concentration raised to about the 0.5 power (Ref 41). A similar effect is reported for

chloride ion in HCl (Ref 7). Thus, chloride ion accelerates the corrosion of ion in acidic solutions. However, bromide and iodide ions may inhibit corrosion (Ref 41), although this finding is controversial (Ref 17).

The dependence of the corrosion rate of iron on chloride ion concentration significantly decreases in neutral solutions when oxygen is present (Ref 17, 42). Oxygen accelerates the cathodic reaction far more than chloride can accelerate the anodic reaction. As salt concentration increases, the oxygen solubility decreases, masking the effect of chloride ion. The chloride ion effect is dependent on the cation, with the rate increasing in the order lithium chloride (LiCl), sodium chloride (NaCl), and potassium chloride (KCl) partially because of differences in oxygen solubility in the presence of these salts (Ref 17). These results illustrate that the effect of the concentration of one component on corrosion is often dependent on other environmental variables.

Small additions of certain inhibitors or passivators have a marked effect on corrosion. For example, as little as 0.0023 mol/L of sodium nitrite ($NaNO_2$) or sodium sulfite (Na_2SO_3) can decease the pit initiation rate of aluminum. Little improvement is found at higher concentration for this system (Ref 43). This behavior is often found with many types of inhibitors. For example, small concentrations (10 ppm) of $NaNO_2$ (a passivator) can drastically inhibit the corrosion of iron, with little further decrease in corrosion found at higher concentrations (Ref 44). However, the critical concentration can depend on pH and on the presence of other constituents. Much higher concentrations may be required, depending on the other constituents. The actual concentration needed for a given system must be determined experimentally. Similarly, many organic inhibitors cause a drastic decrease in corrosion rate at very low concentrations, especially for iron in acidic solutions, with no benefit observed upon increasing the inhibitor concentration (Ref 45). All of these inhibitors tend to interact with the surface in one of three ways: a gettering of a finite amount of impurity in the solution (hydrazine), oxidation (passivation) of the surface (nitrite or chromate), or adsorption on the finite surface area to block corrosion (many organic inhibitors in acid).

However, although this type of behavior is common even for iron in neutral, aqueous environments, exceptions do exist. Sometimes, corrosion can increase with inhibitor concentration until a maximum is reached, followed by a rapid decrease with still further increases in concentration (Ref 44). An example is chromate ion. Chromate ion is normally considered to be an inhibitor. However, at very low concentrations and in the presence of strong activating ions such as chlorides in acidic media, chromate ion can actually accelerate corrosion until enough chromate is present. Also, synergistic action may be observed in which the efficacy of one inhibitor is dependent on the presence of another species, for example, oxygen or other oxidizing agents.

A question often asked is, What is the amount of chloride that is allowable before localized corrosion (crevice corrosion, pitting, or SCC) can occur in austenitic alloys? The answer is not straightforward. Work with boiling, saturated magnesium chloride suggests that 42 wt% Ni in the alloy prevents SCC (Ref 22). However, this rule of thumb does not answer the question. The maximum chloride concentration is dependent on the pH, other constituents, temperature, and other variables. Guidelines are available (Ref 29), and the articles in this Volume on the resistance of individual alloys to localized attack should be consulted.

Appendix: Biological Effects

Stephen C. Dexter, College of Marine Studies, University of Delaware

Biological organisms are present in virtually all natural aqueous environments. In seawater environments, such as tidal bays, estuaries, harbors, and coastal and open ocean seawaters, a great variety of organisms are present. Some of these are large enough to observe with the naked eye, while others are microscopic. In freshwater environments, both natural and industrial, the large organisms are missing, but there is still a great variety of microorganisms, such as bacteria and algae.

In all of these environments, the tendency is for organisms in the water to attach to and grow on the surface of structural materials, resulting in the formation of a biological film, or biofilm. The film itself can range from a microbiological

slime film on freshwater heat transfer surfaces to a heavy encrustation of hard-shelled fouling organisms on structures in coastal seawater. There is a voluminous amount of literature on the formation of such films and their many adverse effects (Ref 46, 47, and 48).

The biofilms that form on the surface of virtually all structural metals and alloys immersed in aqueous environments have the capability to influence the corrosion of those metals and alloys. This influence derives from the ability of the organisms to change the environmental variables discussed earlier in this article (pH, oxidizing power, temperature, velocity, and concentration). Thus, the value of a given parameter at the metal/water interface under the biofilm may be quite different from that in the bulk electrolyte away from the interface. The result can be the initiation of corrosion under conditions in which there would be none in the absence of the film, a change in the mode of corrosion (that is, from uniform to localized), or an increase or decrease in the corrosion rate. It is important to note, however, that the presence of a biofilm does not necessarily mean that there will always be a significant effect on corrosion. The purpose of this Appendix is to consider in general the characteristics of organisms that allow them to interact with corrosion processes and the general mechanisms by which organisms can influence the occurrence or rate of corrosion.

General Characteristics of Organisms

The organisms that are known to have an important impact on corrosion are mostly microorganisms such as bacteria, algae, and fungi (yeasts and molds). In this section, the general characteristics of the microorganisms that facilitate their influence on the electrochemistry of corrosion will be discussed (Ref 49, 50, and 51). Information on the individual organisms can be found in the discussions of biological corrosion in the article "General Corrosion" and "Localized Corrosion" in this Volume.

Physical Characteristics. Microorganisms range in length from 0.1 to over 5 μm (some filamentous forms can be several hundred micrometers long) and up to about 3 μm in width. Many of them are motile; that is, they can "swim" to a favorable, or away from an unfavorable, environment. Because of their small size, they can reproduce themselves in a short time. Under favorable conditions, it is common for bacterial numbers to double every 20 min or less. Thus, a single bacterium can produce a mass of over one million organisms in less than 7 h.

In addition to rapid reproduction, the bacteria as a group can survive wide ranges of temperature (-10 to > 100 °C, or 15 to 212 °F), pH (~0 to 10.5), dissolved oxygen concentration (0 to saturation), pressure (vacuum to > 31 MPa, or 4500 psi), and salinity (tolerances vary from the parts per billion range to about 30% salt). Despite these wide ranges of tolerance for the microorganisms as a whole, most individual species have much narrower ranges. Most bacteria that have been implicated in corrosion grow best at temperatures of 15 to 45 °C (60 to 115 °F) and a pH of 6 to 8. Oxygen requirements vary widely with species. Microbes may be obligate aerobes (require oxygen for growth), microaerophilic (require minute levels of oxygen for growth), facultative anaerobes (grow with or without oxygen), or obligate anaerobes (grow only in the complete absence of oxygen).

Some microbes can produce spores that are resistant to a variety of environmental extremes, such as drying, freezing, and boiling. Spores have been known to survive for hundreds of years under arctic conditions and then to germinate and grow 0when conditions become favorable. Many microbes can quickly adapt to a wide variety of compounds as food sources. This gives them high survivability under changing environmental conditions.

Metabolic Characteristics. Many of the microorganisms implicated in corrosion are able to have an influence on the electrochemical reactions involved by virtue of the products produced by their metabolism. A large percentage of them can form extracellular polymeric materials termed simply polymer, or slime. The slime helps glue the organisms to the surface, helps trap and concentrate nutrients for the microbes to use as food, and often shields the organisms from the toxic effect of biocides. The slime film can influence corrosion by trapping or complexing heavy-metal ions near the surface. It can also act as a diffusion barrier for chemical species migrating to or from a metal surface, thus changing the concentrations and pH at the interface where the corrosion takes place.

Some species of microbes can produce organic acids, such as formic and succinic, or mineral acids, such as H_2SO_4. These chemicals are corrosive to many metals. One series of bacteria is involved in metabolizing nitrogen compounds. As a group, they can reduce nitrates (NO_3^-) (often used as a corrosion inhibitor) to nitrogen (N_2) gas. Others can convert NO_3^- to nitrogen dioxide (NO_2), or vice versa, or they can break it down to form ammonia (NH_3). Still other series of

bacteria are involved in the transformation of sulfur compounds (Fig. 2). They can oxidize sulfur or sulfides to sulfates (SO_4^{2-}) (or H_2SO_4), or they can reduce SO_4^{2-} to sulfides, often producing corrosive H_2S as an end product.

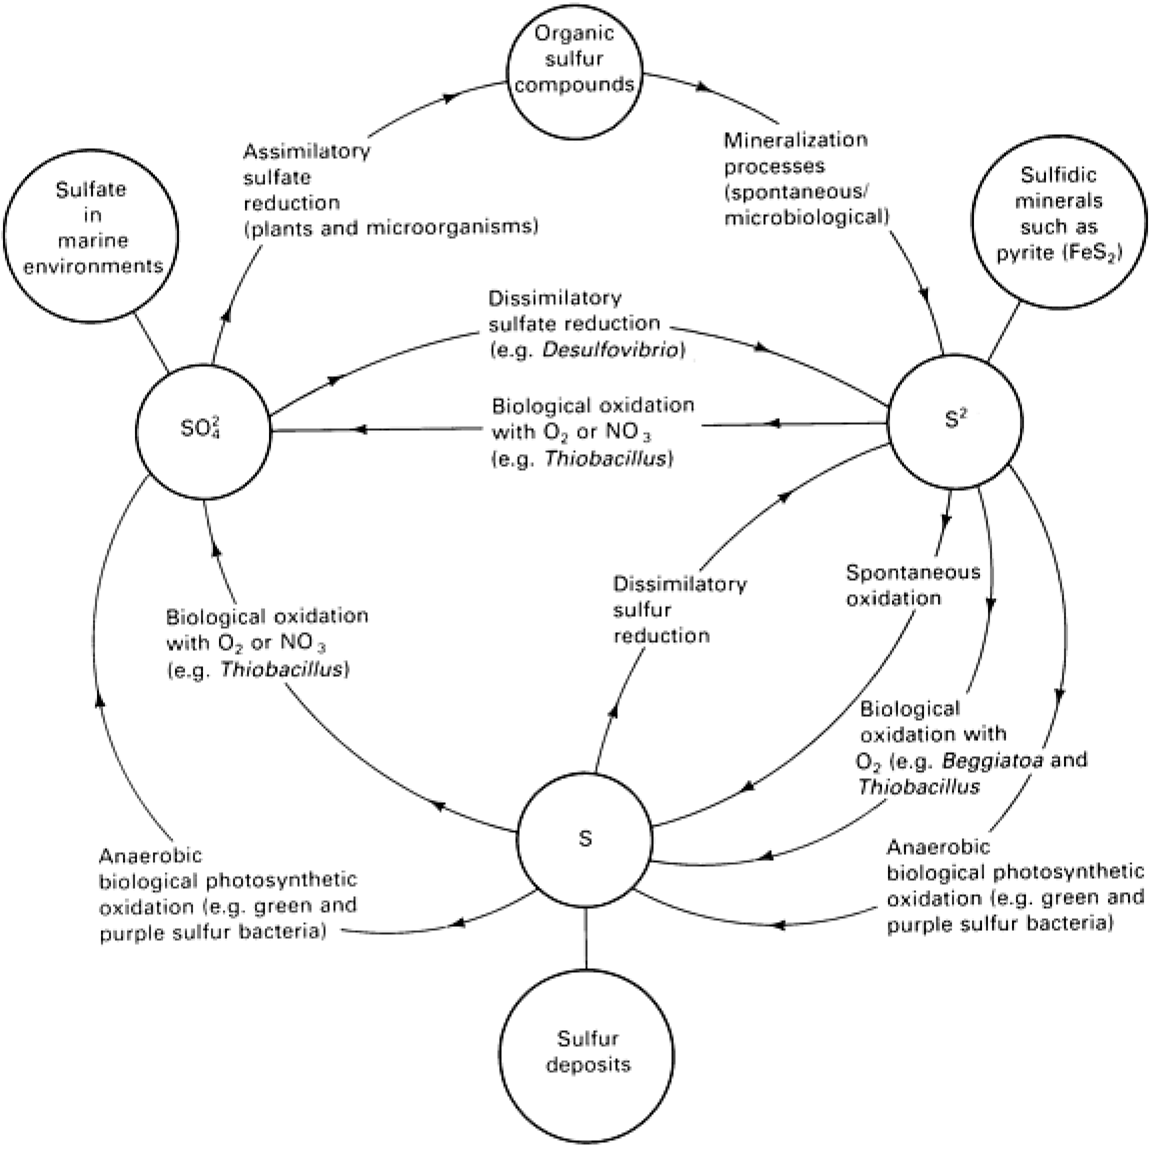

Fig. 2 The sulfur cycle showing the role of bacteria in oxidizing elemental sulfur to sulfate (SO_4^{2-}) and in reducing sulfate to sulfide (S^{2-}). Source: Ref 52

Organisms that have a fermentative type of metabolism produce carbon dioxide (CO_2) and hydrogen (H_2); others can utilize CO_2 and H_2 as sources of carbon and energy, respectively. Numerous species of bacteria and algae either produce or utilize oxygen. It is rare that a corrosion process would not depend on the concentration of at least one of these three dissolved gasses.

Finally, some bacteria are capable of being directly involved in the oxidation or reduction of metal ions, particularly iron and manganese. Such bacteria can shift the chemical equilibrium between Fe, Fe^{2+}, and Fe^{3+}, which will often influence the corrosion rate.

Community Structure. The ability of an organism to survive on a surface and to influence corrosion is often related to associations between that organism and those of other species. The bacteria implicated in corrosion may begin their lives on a metal surface as a scatter of individual cells, as shown in Fig. 3(a). As the biofilm matures, however, the organisms

will usually be found in thick, semicontinuous films (Fig. 3b) or in colonies (Fig. 3c). It is in these latter two forms that there is the most potential for survival and growth of the organisms capable of influencing corrosion.

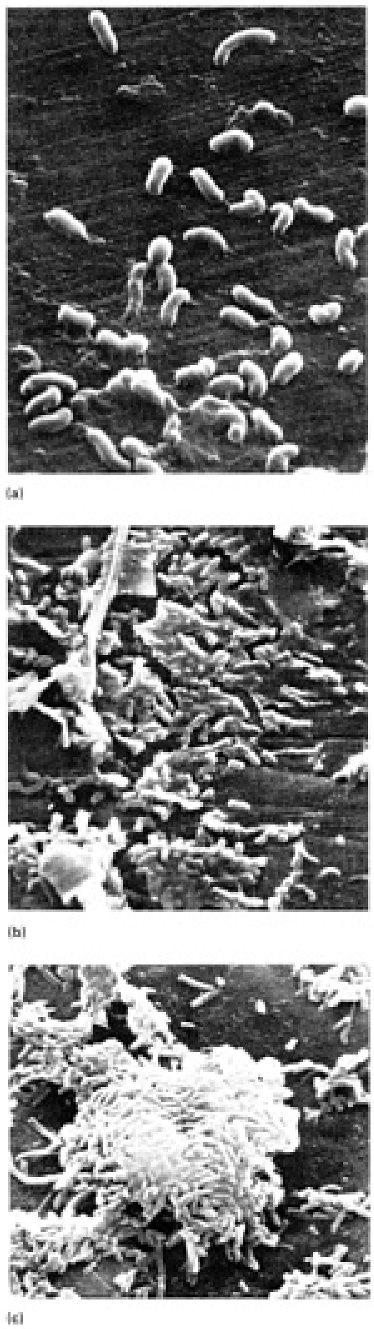

Fig. 3 Various forms of bacterial film that can influence corrosion. (a) Scatter of individual cells. 6050×. (b) Semicontinuous film of bacteria in slime. 3150×. (c) Bacterial cells in a colony. 2700×

For example, the sulfate-reducing bacteria (SRB) are implicated in the corrosion of iron-base alloys in a variety of environments (Ref 52, 53). Most sulfate-reducing bacteria are obligate anaerobes, yet they are known to accelerate corrosion in aerated environments. This becomes possible when aerobic organisms form a film or colony and then, through their metabolism, create an anaerobic microenvironment with the organic acids and nutrients necessary for growth of the sulfate-reducing bacteria (Fig. 4). Thus, the organisms influencing corrosion can often flourish at the corrosion site by associating with other organisms in a microbial colony or consortium, even when the bulk environment is not conducive to their growth.

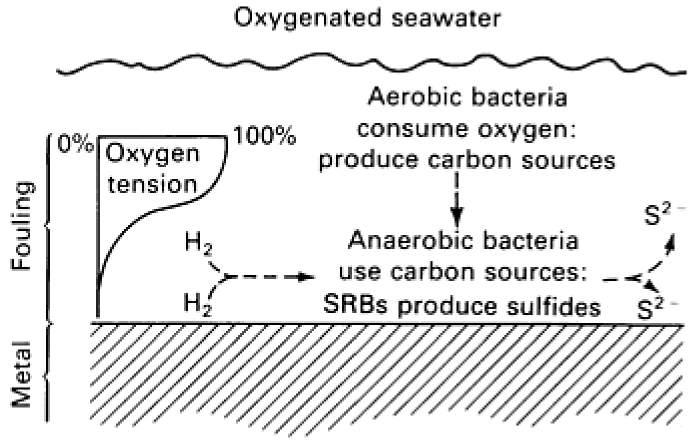

Fig. 4 Variations through the thickness of a bacterial film. Aerobic organisms near the outer surface of the film consume oxygen and create a suitable habitat for the sulfate-reducing bacteria at the metal surface. Source: Ref 52.

It should be noted that the dynamics of fluid flow past the metal surface can alter the form of the biofilm or can even prevent its formation. This can result in acceleration or deceleration of corrosion, depending on the role of the biofilm.

General Mechanisms of Influence

The presence of a biological film on a corroding metal surface does not introduce some new type of corrosion, but it influences the occurrence and/or the rate of known types of corrosion. These biological influences can be divided into three general categories:

- Production of differential aeration or chemical concentration cells
- Production of organic and inorganic acids as metabolic by-products
- Production of sulfides under oxygen-free (anaerobic) conditions

Oxygen/Chemical Concentration Cells. Any biofilm that does not provide for complete, uniform coverage of the entire immersed surface of a metal or alloy has the potential to form concentration cells. In aerated environments, uncovered areas of the metal surface, in contact with oxygenated electrolyte, will be cathodic relative to those areas under the biofilm. Beneath the film or colony, oxygen is depleted as it is used by the organisms in their metabolism. Oxygen from the bulk electrolyte is unable to replenish those areas because of a combination of effects. First, oxygen migration through the film is slowed by the diffusion barrier effect, and second, oxygen that does penetrate the film is immediately utilized by the microbial metabolism. Formation of such a corrosion cell, as shown in Fig. 5, causes a pit to form at the anodic area under the bacterial colony.

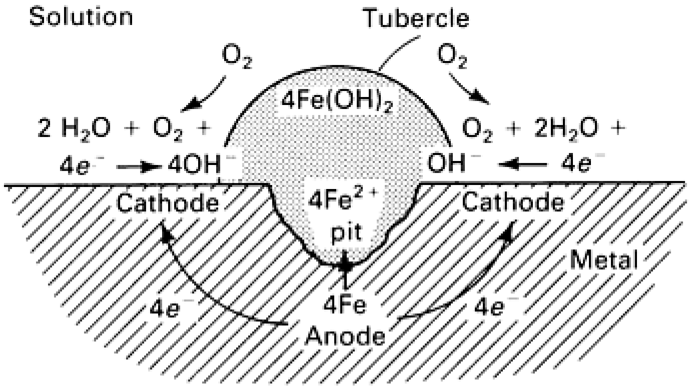

Fig. 5 Schematic of pit initiation and tubercule formation due to an oxygen concentration cell under a biological deposit. Source: Ref 53

As the pit grows, iron dissolves according to the anodic reaction:

$$Fe \rightarrow Fe^{2+} + 2e^-$$

The cathodic reaction is reduction of dissolved oxygen outside the pit to form OH^- according to:

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^-$$

The insoluble ferrous hydroxide corrosion product forms by the reaction:

$$3Fe^{2+} + 6OH^- \rightarrow 3Fe(OH)_2$$

Corrosion products mingle with bacterial film to form a corrosion tubercule, which itself may cause a problem with obstruction of fluid flow in piping systems.

In addition, if the above process takes place in the presence of bacteria capable of oxidizing ferrous ions to ferric ions, the corrosion rate will be accelerated because the ferrous ions are removed from solution as soon as they are produced. This depolarizes the anode and accelerates corrosion of iron under the deposit. The ferric ions form ferric hydroxide ($Fe(OH)_3$), which contributes to the rapid growth of the tubercule. This process has been responsible for corrosion and plugging of iron water pipes.

If chlorides are present in the system, the pH of the electrolyte trapped inside the tubercule may become very acid by an autocatalytic process similar to that described in the article "Localized Corrosion" in this Volume for crevice corrosion and pitting. Chloride ions from the environment combine with ferric ions produced by corrosion in the presence of the bacteria to form a highly corrosive, acidic ferric chloride solution inside the tubercule. This has been responsible for severe pitting of stainless steel piping systems, as described in the section "Localized Biological Corrosion" in the article "Localized Corrosion" in this Volume.

Acid Production. The sulfur oxidizing bacteria can produce up to about 10% H_2SO_4. This mineral acid, with its accompanying low pH, is highly corrosive to many metals, ceramics, and concrete. Other species of bacteria produce organic acids that are similarly corrosive.

The acids produced by these organisms can also contribute to corrosion by aiding the breakdown of coatings systems. Alternatively, other organisms that have no direct influence on corrosion may be involved in the breakdown of coatings. The breakdown products are then sometimes usable as food by the acid-producing bacteria, ultimately leading to accelerated corrosion of the underlying metal.

Anaerobic Sulfide Production. The most thoroughly documented case in which microbes are known to cause corrosion is that of iron and steel under anaerobic conditions in the presence of sulfate-reducing bacteria. Based on electro-chemistry, deaerated soils of near-neutral pH are not expected to be corrosive to iron and steel. However, if the soil contains sulfate-reducing bacteria and a source of sulfates, rapid corrosion has been found to occur.

The classical mechanism originally proposed for this corrosion involved the removal of atomic hydrogen from the metal surface by the bacteria using the enzyme hydrogenase (Ref 54). The removed hydrogen was then supposedly utilized by the bacteria in the reduction of sulfates to sulfides. The following set of equations was proposed to explain this mechanism:

$$4Fe \rightarrow 4Fe^{2+} + 8e^{-} \quad \text{(Eq 9)}$$
Anodic reaction

$$8H_2O \rightarrow 8H^{+} + 8OH^{-} \quad \text{(Eq 10)}$$
Dissociation of water

$$8H^{+} + 8e^{-} \rightarrow 8H \quad \text{(Eq 11)}$$
Cathodic reaction

$$SO_4^{2-} + 8H \xrightarrow{SRB} S^{2-} + 4H_2O \quad \text{(Eq 12)}$$
Cathodic depolarization

$$Fe^{2+} + S^{2-} \rightarrow FeS \quad \text{(Eq 13)}$$
Corrosion product

$$3Fe^{2+} + 6OH^{-} \rightarrow 3Fe(OH)_2 \quad \text{(Eq 14)}$$
Corrosion product

Without sulfate-reducing bacteria, the mechanism would stop after Eq 11, when the surface became covered by a monolayer of hydrogen. According to the theory, this hydrogen is stripped off by the bacteria, a process known as cathodic depolarization; this allows corrosion to continue.

It is now recognized that this original mechanism, although it undoubtedly plays an important role, does not represent the entire process (Fig. 6). It has been shown that the iron sulfide (FeS) film produced is protective if continuous but that it causes galvanic corrosion of the bare iron underneath if defective. Other corrosive substances, such as H_2S, can also be produced. The sulfate-reducing bacteria have been identified as contributors to the corrosion of stainless, copper, and aluminum alloys, but the details of the mechanism are still being debated (Ref 52, 53).

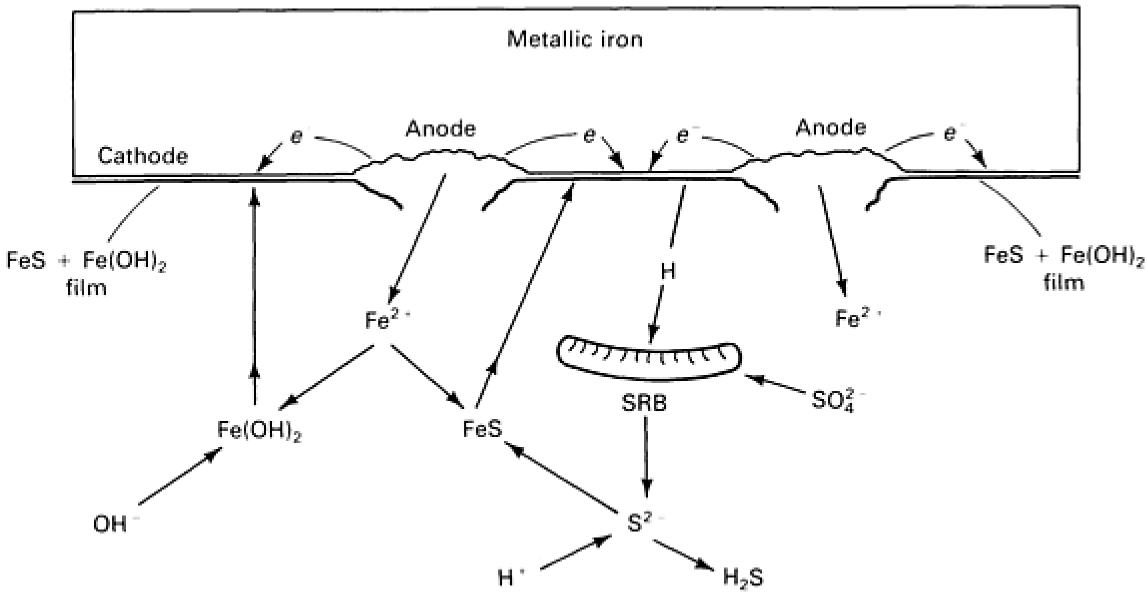

Fig. 6 Schematic of the anaerobic corrosion of iron and steel showing the action of sulfate-reducing bacteria in removing hydrogen from the surface to form FeS and H_2S

Additional information on the organisms involved in corrosion and the industries, environments, and alloy-electrolyte systems in which they have been active can be found in the articles "General Corrosion" and "Localized Corrosion" in this Volume. Information on detecting and characterizing biological corrosion in the laboratory and in the field can be found in the article "Evaluation of Microbiological Corrosion." Information on controlling biological corrosion can be found in the article "Control of Environmental Variables in Water Recirculating Systems."

Effects of Metallurgical Variables on Aqueous Corrosion

D.W. Shoesmith, Fuel Waste Technology Branch, Atomic Energy of Canada Ltd.

Introduction

THE STRUCTURE AND COMPOSITION of both metals and alloys are important in deciding their corrosion characteristics. Indeed, structure and composition are critical in many forms of localized corrosion. For a metal or alloy to corrode evenly, the anodic and cathodic sites must be interchangeable. This implies that every site on the surface is energetically equivalent and therefore equally susceptible to dissolution, but this is never the case.

This article will provide an introduction to the effects of crystal structure, alloying, heat treatments, and the resulting microstructures on corrosion properties. Detailed information on these metallurgical variables for a wide variety of ferrous and nonferrous metals and alloys can be found in the Section "Specific Alloy Systems" in this Volume. Reference should also be made to Volumes 9 and 10 of *ASM Handbook,* formerly 9th Edition of *Metals Handbook* for supplementary data on crystallographic/microstructural analysis and interpretation.

Metals and Metal Surfaces

Metals form as a series of irregular crystals. If these crystals or grains were perfect, the metal atoms would lie in regular close-packed planes. If this were true, the rate of metal dissolution would depend on which crystallographic planes were exposed to the corrosive environment. In addition to these perfect features, there are many sources of atomic disarray within the crystals that can lead to defects where they emerge at the surface. Some of the more significant crystal defects are described below. Additional information on defects can be found in the article "Crystal Structure of Metals" in *Metallography and Microstructures,* Volume 9 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Stacking Faults. The atoms in metals form close-packed layers that stack in various sequences. The most common crystal structures found in metals are the body-centered cubic (bcc), the face-centered cubic (fcc), and the hexagonal close-packed (hcp). The unit cells for these structures are shown schematically in Fig. 1 (a unit cell is a parallelepiped whose edges form the axes of a crystal; it is the smallest pattern of atomic arrangement). If the crystal structures are mixed, resulting in an error in the normal sequence of stacking of atomic layers, stacking faults are produced. These faults can extend for substantial distances through, and across, the crystal.

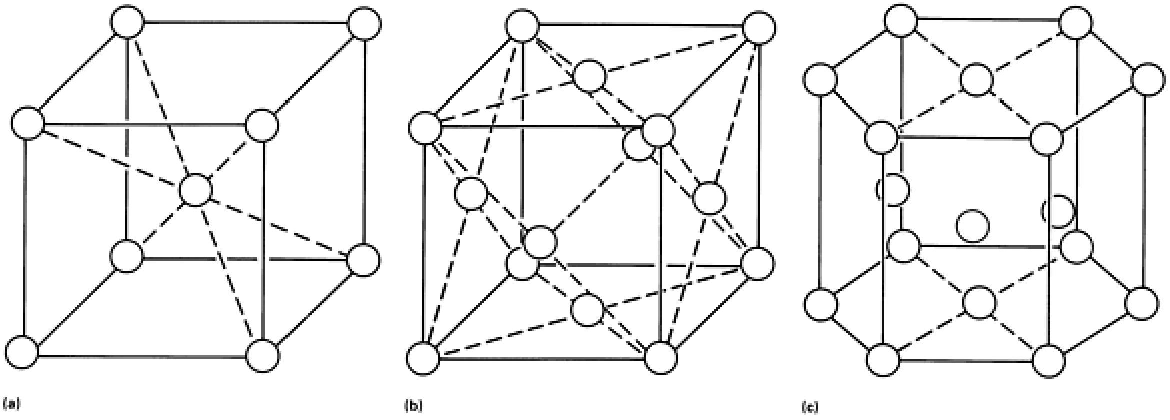

Fig. 1 Schematic of the unit cells for the most common crystal structures found in metals and alloys. (a) bcc. (b) fcc. (c) hcp

A slip plane is the lattice plane separating two regions of a crystal that have slipped relative to each other. Such permanent displacements occur under the influence of plastic deformation, as described in the article "Plastic Deformation Structures" in *Metallography and Microstructure,* Volume 9 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Dislocations. Slip regions can be caused by the movement of various small lattice dislocations, such as an additional layer of atoms or a stacking fault on one side of the defect. Dislocations are defects that exist in nearly all real crystals. An edge dislocation, which is the edge of an incomplete plane of atoms within a crystal, is shown in cross section in Fig. 2. In this illustration, the incomplete plane extends partway through the crystal from the top down, and the edge dislocation (indicated by the standard symbol ⊥) is its lower edge.

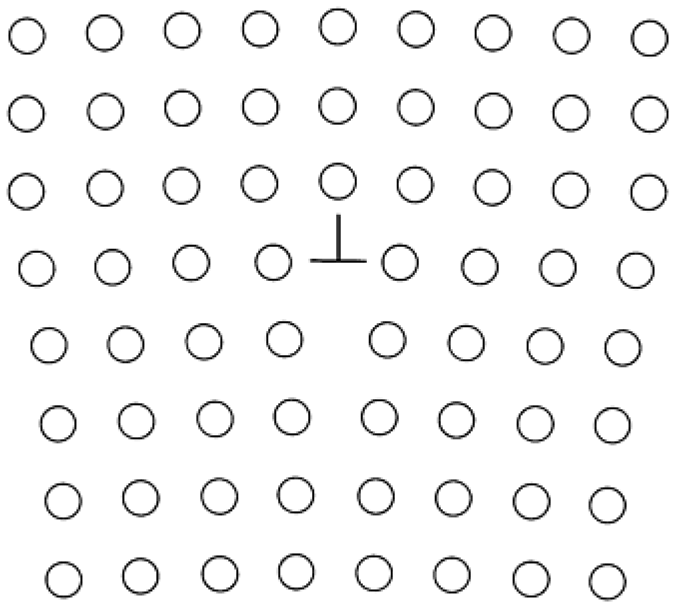

Fig. 2 Schematic of a section through on edge dislocation, which is perpendicular to the plane of the illustration and is indicated by the symbol ⊥

If forces are applied (arrows, Fig. 3) to a crystal, such as the perfect crystal shown in Fig. 3(a), one part of the crystal will slip. The edge of the slipped region, shown as a dashed line in Fig. 3(b), is a dislocation. The portion of this line at the left near the front of the crystal and perpendicular to the arrows (Fig. 3b) is an edge dislocation, because the displacement involved is perpendicular to the dislocation.

The slip deformation in Fig. 3(b) has also formed another type of dislocation. The part of the slipped region near the right side, where the displacement is parallel to the dislocation, is termed a screw dislocation. In this part, the crystal no longer consists of parallel planes of atoms, but of a single plane in the form of a helical ramp (screw).

As the slipped region spread across the slip plane, the edge-type portion of the dislocation moved out of the crystal, leaving the screw-type portion still embedded (Fig. 3c). When all of the dislocation finally emerged from the crystal, the crystal was again perfect but with the upper part displaced one unit from the lower part (Fig. 3d). Therefore, Fig. 3 illustrate the mechanism of plastic flow by the slip process, which is actually produced by dislocation movement.

Point defects may be vacancies caused by the absence of one or more atoms in the crystal, impurity atoms of different sizes, and interstitial atoms (small atoms in spaces between the lattice atoms). Points defects can affect significant volumes of the crystal.

Grain Boundaries. The interface between grains is termed the grain boundary, and it is a region of major atomic disarray at which many faults and dislocations congregate. This disarray makes it energetically easier for impurities to concentrate at grain boundaries as opposed to the grain interior, where the atomic arrangement is more regular.

The areas at which these defects emerge on the surface constitute sites of high energy. These energetic sites possess increased chemical activity because each contains atoms with an incomplete number of nearest neighbors (Fig. 4). Atom A, lying within a relatively perfectly closed-packed plane, is strongly coordinated on all but one side. Therefore, it has a lower chemical free energy compared to atom B in a step. When compared to atom C at a kink site, atom A has an even lower chemical free energy. Dissolution of kink sites, concentrated at dislocations or grain boundaries, will obviously be accompanied by a greater release of energy than dissolution of atoms from the planes.

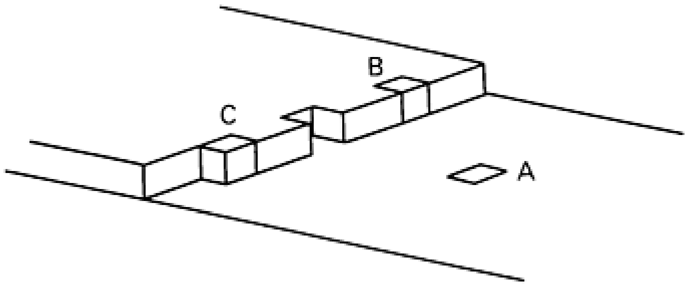

Fig. 4 Schematic of a dislocation emerging at a surface. A, plane atom; B, step atom; C, kink atom

Anodic metal dissolution sites are more likely to be found at dislocations, and grain boundaries. In electrochemical terms:

$$(E_e)_{kink} < (E_e)_{step} < (E_e)_{plane} \quad \textbf{(Eq 1)}$$

and because these dislocations tend to concentrate at grain boundaries:

$$(E_e)_{grain\ boun} < (E_e)_{grain} \quad \textbf{(Eq 2)}$$

where E_e is the equilibrium corrosion potential, as described in the article "Kinetics of Aqueous Corrosion" in this Volume. Therefore, the thermodynamic driving force. ΔE_{therm}, for dissolution (the difference in cathodic and anodic equilibrium potentials):

$$\Delta E_{therm} = (E_e)_c -- (E_e)_a \quad \textbf{(Eq 3)}$$

will be greater for grain-boundary sites than for the grains themselves. This does not mean that grain boundaries will always corrode preferentially, because the initial etching of the grain boundary will produce an increased surface area in this region. The corresponding additional interfacial energy will decrease the total free energy of the site. The chemical or mechanical activation of the grain boundaries determines whether they will be more active than the grains.

Alloys and Their Surfaces

Pure metals have a low mechanical strength and are rarely used in engineering applications. Stronger metallic materials, which are combinations of several elemental metals known as alloys, are most often used. Commonly used alloys have a good combination of mechanical, physical, fabrication, and corrosion qualities. The specific applications determines which of these qualities is deemed most important for alloy selection.

Alloys can be single phase or polyphase, depending on the elements present and their mutual solubilities. For example, the addition of nickel to copper does not alter the fcc structure. The nickel occupies a lattice position within the copper host lattice, and the two metals are said to form a substitutional solid solution. By contrast, the alloying element can occupy an interstitial site in the host lattice and is said to form an interstitial solid solution. An example of such an alloy would be carbon steel, in which the small carbon atom is interstitially accommodated in the iron lattice.

It is often impossible to dissolve a large amount of one element in another. When this is attempted, two or more phases may form. The predominant phase is known as the primary phase, or matrix. The other, smaller phase is known as the secondary phase, or precipitate. Precipitates often contain the nonmetallic elements present in the alloy. If they are insoluble in the matrix, they concentrate, like impurities, as dislocations. This means they are often found at grain boundaries.

Phase Diagrams

Graphs of phase stability as a function of temperature and composition are called phase diagrams. They are based on the equilibrium conditions in the alloy. The stable phases at each temperature and composition are shown on the diagram. If two metallic components are involved, the graph is termed a binary phase diagram. Ternary and quaternary diagrams are necessary for more complex, systems.

Figure 5 shows a portion of the binary phase diagram for the Fe-C system. Even for this system, the diagram is complex. As discussed below, this complexity is the key to the wide range of steel properties available.

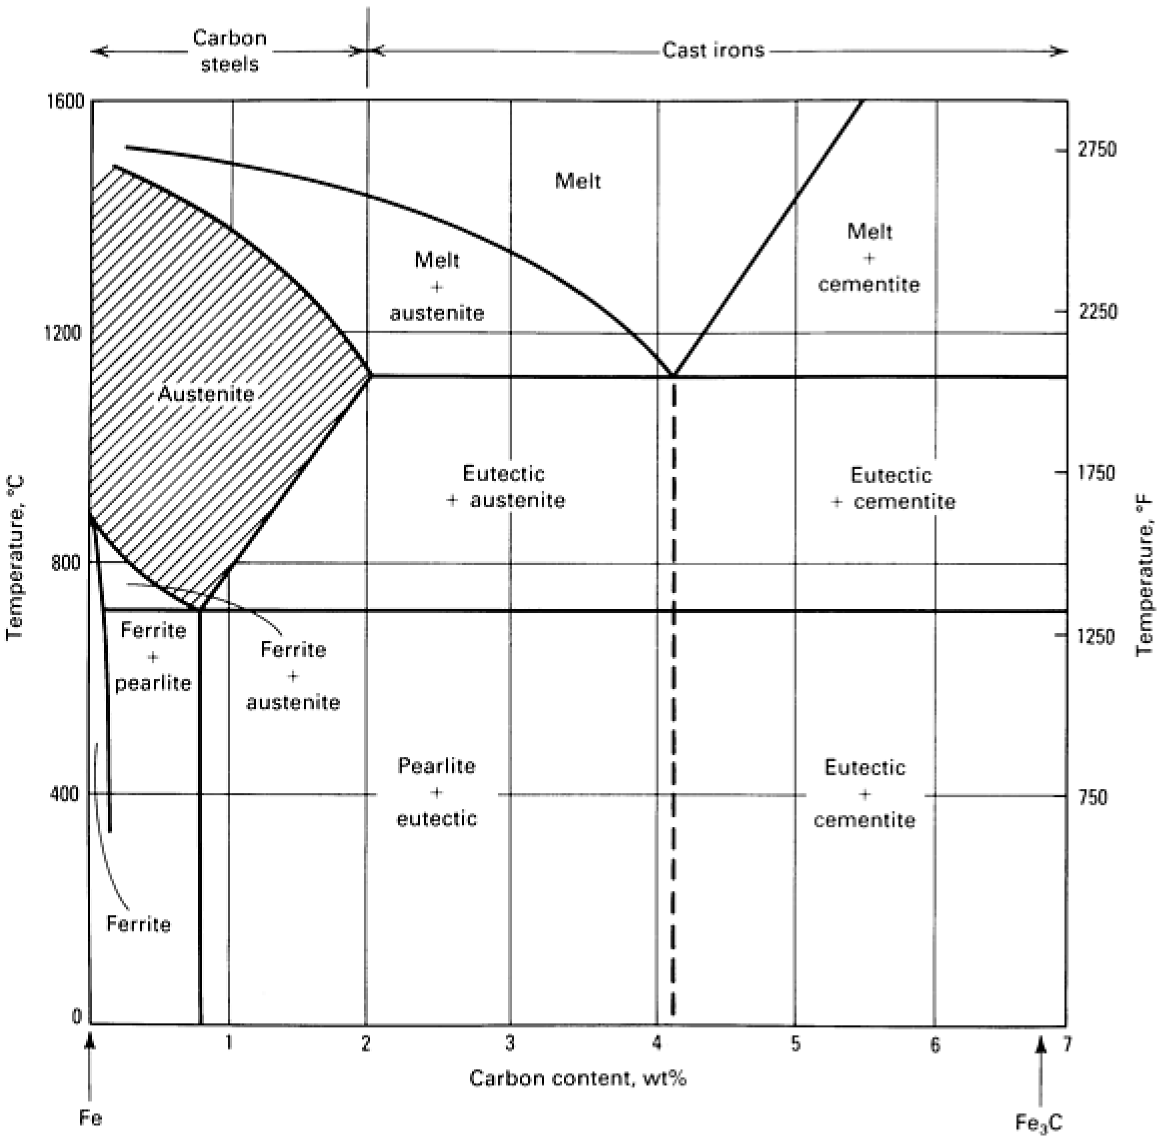

Fig. 5 Portion of the binary phase diagram for the Fe-C system

Iron and Steels

As an example of the diversity of structures possible for a given material and its alloys, the structures and phases possible for iron, carbon steels, and stainless steels will be discussed. The primary purpose in this discussion will be to emphasize the principles, because these systems are covered in detail in the Section "Specific Alloy Systems" in this volume (especially the articles "Corrosion of Cast Irons," "Corrosion of Carbon Steels," "Corrosion of Alloy Steels," and "Corrosion of Stainless Steels").

Iron. Depending on the temperature of formation, iron can exist in three different phase modifications, or allotropes: ferrite (α-iron), which is bcc; austenite (γ-iron), which is fcc; and δ-ferrite, which is bcc but of slightly different cell dimensions than normal ferrite. These allotropes are shown in Fig. 6.

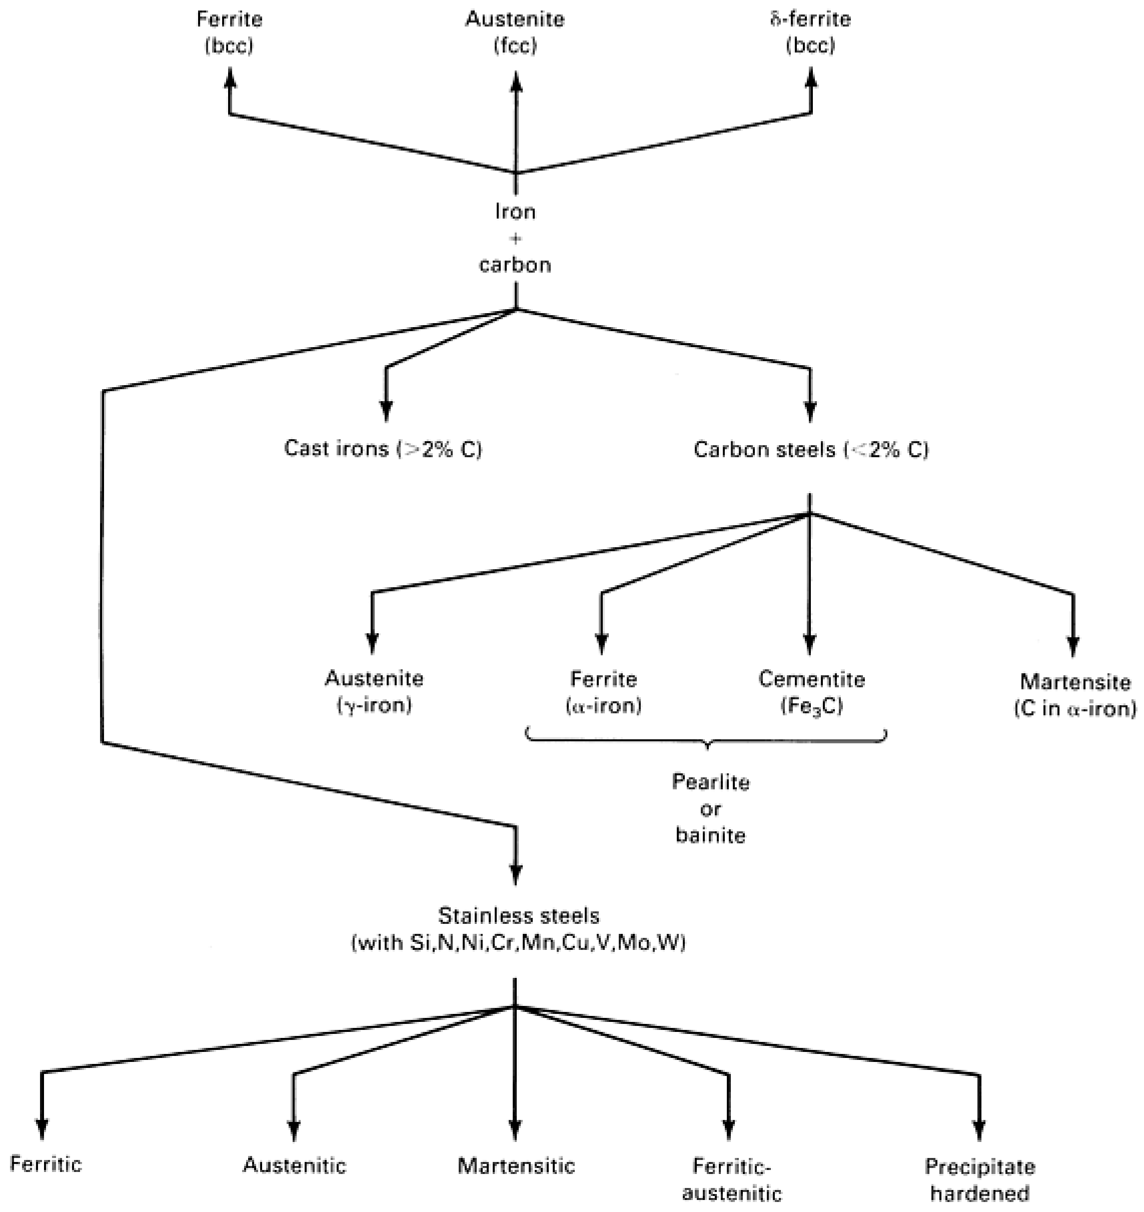

Fig. 6 Phases of iron, carbon steel, and stainless steel

Cast Irons and Carbon Steels. The most important alloying element of steel is carbon, whose solubility is different in the various phase modifications of iron. The small carbon atoms occupy interstitial positions between the iron atoms. Consequently, the less densely packed fcc lattice of austenite (γ-iron) can accommodate the carbon atom more readily

than the bcc ferrite γ-iron). Therefore, austenite formation is promoted by alloying with carbon. Carbon is said to be an austenite-stabilizing element.

Carbon steels contain less than 2% C; cast irons contain more than 2% C. For steels, any composition can be heated until a homogeneous solid solution of austenite is obtained. This is apparent from the phase diagram shown in Fig. 5. Upon cooling, the four phases (ferrite, austenite, cementite, and martensite) can be formed. The relative proportions of these phases are determined by the carbon content, the rate of cooling, and any subsequent heat treatment.

Cementite is an iron carbide containing 6.67% C (by weight) with the composition Fe_3C. It forms as a mixture with ferrite when cooling slowly from the austenite region of the phase diagram (Fig. 5). The mixture, know as pearlite, forms separate grains, along with ferrite grains, in plain carbon steels. It possesses a lamellar structure with alternate bands of ferrite and cementite. Bainite, an austenite transformation product, is a lathlike aggregate of ferrite and cementite that forms under conditions intermediate to those that result in the formation of pearlite and martensite.

The way austenite is cooled determines the rate of segregation and the grain size of the ferrite and cementite phases. This provides the opportunity to produce a range of carbon steels, each having different mechanical properties. Very rapid cooling, or quenching, produces martensite. Under these conditions, the normal phase separation to produce ferrite and pearlite does not occur. A metastable forced solution of carbon in ferrite is obtained. The forcing of a martensite structure is known as hardening. Additional information on the microstructural constituents of carbon steels can be found in the article "Carbon and Alloy Steels" in *Metallography and Microstructures,* Volume 9 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

For a carbon content greater than 2%, the phase diagram in Fig. 5 shows that heating will not bring the mixture into the single-phase austenite region. In other words, a homogeneous solid solution cannot be achieved. Cast irons in this composition region are formed by casting from the molten state. They are used where hardness and corrosion resistance are required and where brittleness due to the cementite content poses no problem.

Stainless Steels. The three major phases in carbon steels--ferrite, austenite and martensite--are also formed in stainless steels. In addition, two other stainless steel categories, ferritic-austenitic (duplex) and precipitate-hardened, can be produced by specific heat treatments (Fig. 6). The microstructural characteristics of iron-chromium and iron-chromium-nickel alloys are discussed in the articles "Wrought Stainless Steels" and "Stainless Steel Casting Alloys" in *Metallography and Microstructures,* Volume 9 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

The stability and the mechanical and physical properties of the various phases depend on the combination of alloying elements present. Alloying elements can be divided into two categories:

- *Austenite stabilizers:* carbon, nitrogen, nickel, and manganese
- *Ferrite stabilizers:* silicon, chromium, molybdenum, niobium, and titanium

The selection of a stainless steel for a particular engineering application depends on which mechanical or physical property is considered to be most important.

Effect of Alloying on Corrosion Resistance

One of the primary reasons for producing alloyed, or stainless, steels is to improve corrosion resistance. Alloying can affect corrosion resistance in many different ways.

Increased Nobility. Alloying can have a genuinely thermodynamic effect on corrosion resistance by increasing the nobility of the material. This is achieved by a decrease in ΔE_{therm}, which is expressed by Eq 3 and illustrated in the Evans diagram shown in Fig. 7. Thus:

$$[(E_e)_c - \{(E_e)_a\}_M] > [(E_e)_c - \{(E_e)_a\}_A] \quad \textbf{(Eq 4)}$$

or:

$$(\Delta E_{therm})_M > (\Delta E_{therm})_A \quad \textbf{(Eq 5)}$$

and:

$$(i_{corr})_M > (i_{corr})_A \quad \textbf{(Eq 6)}$$

where i_{corr} is the corrosion current, and the subscripts M and A indicate metal and alloy, respectively. The decrease in corrosion current is caused by an increase in the equilibrium potential for the anodic reaction. The equilibrium potential for the cathodic reaction may also change from metal to alloy, but this change is insignificant compared to the effect on the anodic reaction.

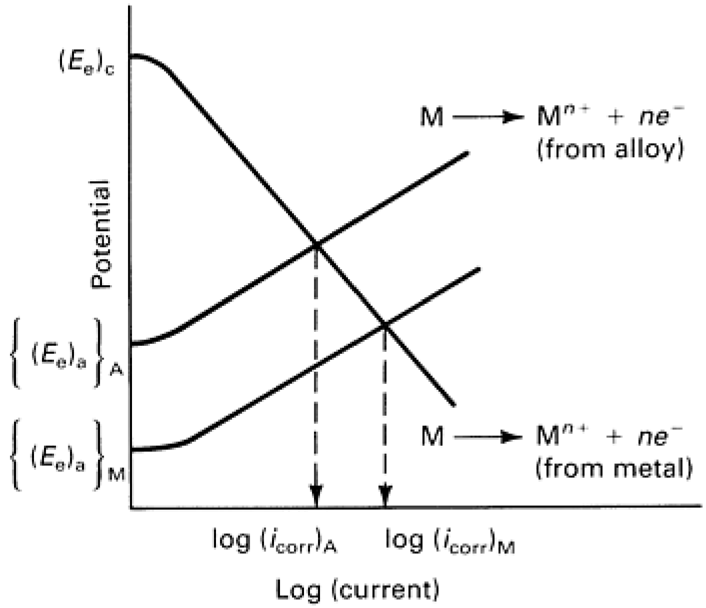

Fig. 7 Evans diagram for metal M in the pure form and incorporated into a more noble alloy

Noble systems of this intermetallic type are rare and generally produced only when the alloying element is a noble metal, such as gold, platinum, or palladium. For such alloys, the less noble constituent metal, for example, titanium in a Ti-2Pd alloy, often dissolves preferentially, leaving a protective film of noble metal on the alloying surface. Disruption of this surface film, which is often thin, will reinitiate corrosion.

Formation of a Protective Film. The addition of controlled amounts of selected alloying elements can often improve the stability and protectiveness of surface oxide films formed on the material surface. Thus, the addition of chromium to iron has a major effect on the corrosion resistance in acid. This can be appreciated by studying the anodic polarization curves for iron-chromium alloys shown in Fig. 8. The curves exhibit an active-passive transition, as discussed in the article "Kinetics of Aqueous Corrosion" in this Volume. The addition of chromium leads to decreases in the critical current for passivation (i_{crit}), the passivation potential (E_{pass}), and the passive current (i_{pass}), as indicated by the arrows in Fig. 8. Therefore, for the cathodic reaction shown, passivation is achievable only in case 3 for a steel containing more than approximately 12% Cr. The improved resistance to corrosion is due to an increase in chromium content of the iron-chromium oxide layer formed on the alloy surface.

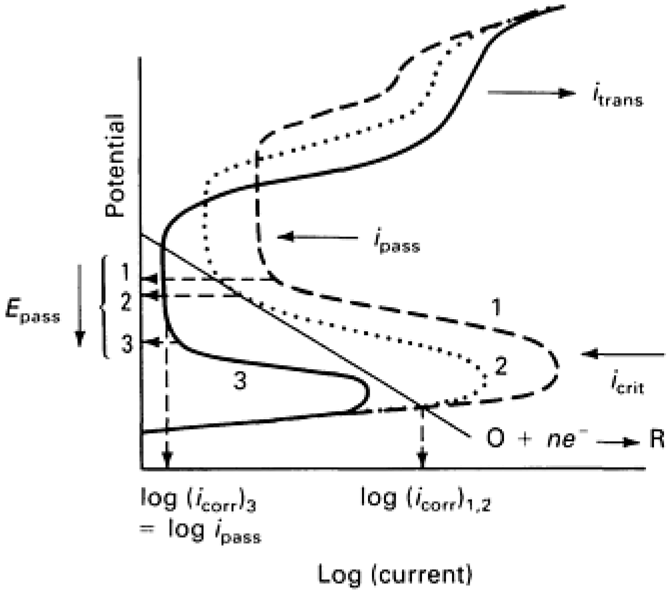

Fig. 8 Schematic anodic polarization diagrams for stainless steels containing various amounts of chromium. (1) 3% Cr; (2) 10% Cr; (3) 14% Cr. The polarization curve for the cathodic reaction O + ne^- →R is also shown. Arrows indicate the effect of chromium addition on i_{crit}, E_{pass}, i_{pass}, and i_{trans}.

The parameters i_{crit}, i_{pass}, and E_{pass} can be decreased even further by the addition of up to 8% Ni. This is the reason for the extensive use of 18-8 stainless steel (Fe-18Cr-8Ni).

Problems of Alloying. Alloying is not without its problems, one of which is illustrated in Fig. 8. As the chromium content is increased, the current due to transpassive dissolution, i_{trans}, at positive potentials also increases. Thus, under very aggressive oxidizing conditions, steels with high chromium contents become less resistant to corrosion because of oxidative dissolution of chromium (as Cr^{6+}, that is, $HCrO_4^-$) from the oxide (containing Cr^{3+}).

Other problems can also be introduced if the alloy is carelessly heat treated in the range 420 to 700 °C (790 to 1290 °F). A high carbon content in chromium steels can lead to the formation of chromium carbide. The carbides separate to the grain boundaries, leaving the steel deficient in chromium close to the grain boundary. This region is consequently less noble and is preferentially attacked. The steel is said to be sensitized to intergranular (intercrystalline) attack. One method of counteracting this process is to make further alloying additions of niobium or titanium, either of which will stabilize the carbon and prevent chromium carbide separation.

Impurities remaining after the fabrication process can also have a major effect on corrosion resistance. For example, sulfide inclusions in the form of conductive metal sulfides can act as local cathodes in steel and can promote corrosion. Sulfides catalyze the cathodic reactions, as shown by the Evans diagram in Fig. 9. The rate of the proton reduction reaction (determined by the exchange current, i_o, and the Tafel coefficient, b_c, as described in the article "Kinetics of Aqueous Corrosion" in this Volume) is increased at the sulfide inclusions, leading to a higher corrosion potential and increased corrosion current. The corrosion tends to occur locally, and pitting is observed near the inclusion.

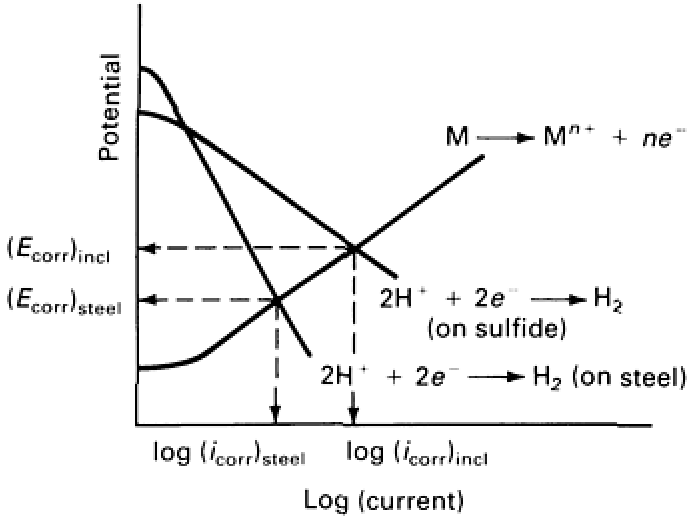

Fig. 9 Evans diagram for steel corrosion showing the increased corrosion rate when the cathodic reaction is catalyzed by a sulfide inclusion

The presence of precipitates with minor alloying elements and impurities can lead to problems, because phases with widely different electrochemical properties are then present. This can result in local variations in corrosion resistance. Also, the addition of alloying elements to improve the resistance to general, or uniform, corrosion may cause increased susceptibility to localized corrosion processes, such as pitting or intergranular corrosion.

Effect of Heat Treatment

Many of the mechanical properties of materials are improved by various heat treatments. Unfortunately, such properties as hardness and strength are often achieved at the expense of corrosion resistance. For example, the hardness and strength of martensitic steels are counterbalanced by a lower corrosion resistance than for the ferritic and austenitic steels. The very high strengths achieved for precipitation-hardened steels are due to the secondary precipitates formed during the solution heat treating and aging process. As discussed above, precipitates with electrochemical properties distinctly different from those of the matrix have a deleterious effect on corrosion.

Processes such as cold working, in which the material is plastically deformed into some desired shape, lead to the formation of elongated and highly deformed grains and a decrease in corrosion resistance. Cold working can also introduce residual stresses that make the material susceptible to stress-corrosion cracking. An improvement in corrosion resistance can be achieved by subsequently annealing at a temperature at which grain recrystallization can occur. A partial anneal leads to stress relief without a major effect on the overall strength of the material.

From the corrosion viewpoint, welding is a particularly troublesome treatment. Because welding involves the local heating of a material, it can lead to phase transformations and the formation of secondary precipitates. It can also induce stress in and around the weld. Such changes can lead to significant local differences in electrochemical properties as well as the onset of such processes as intergranular corrosion. Therefore, the weld filler metal should be as close in electrochemical properties to the base metal as technically feasible, and the weld should be subsequently stress relieved. Detailed information on the corrosion problems associated with welded joints can be found in the article "Corrosion of Weldments" in this Volume.

Fundamentals of High-Temperature Corrosion in Molten Salts

John W. Koger, Martin Marietta Energy Systems, Inc.

Introduction

MOLTEN SALTS, often called fused salts, can cause corrosion by the solution of constituents of the container material, selective attack, pitting, through electrochemical reactions, by mass transport due to thermal gradients, by reaction of constituents of the molten salt with the container material, by reaction of impurities in the molten salt with the container material, and by reaction of impurities in the molten salt with the alloy. Many hundreds of molten salt-metal corrosion studies have been documented, and predictions of corrosion are difficult if not impossible in engineering systems.

The most prevalent molten salts in use are nitrates and halides. Other molten salts that have been extensively studied but are not widely used include carbonates, sulfates, hydroxides, and oxides.

A somewhat general discussion of molten salt corrosion will be presented in this article, with emphasis on nitrates/nitrites and fluorides. Specific examples of results from experiments will be presented for some actual systems; these examples will indicate the scope of a program needed for a particular application.

Thermodynamics and Kinetics of Molten Salt Corrosion

The chemistry of molten salts can be as complicated as one wishes to make it, based on the definition of a molten salt and whether or not the media may be wholly ionic. For simplicity, most of the processes considered in this article involve electrode processes.

According to Inman and Lovering (Ref 1), except in rare cases in which hydrogen is a part of the molten salt or the melts are exposed to hydrogen atmosphere, the hydrogen ion plays a very small role. The oxygen ions are generally quite important in matters of corrosion. The function pO^{2-} (equivalent to pH in aqueous environments) defines the oxide ion activity. The higher the value of pO^{2-}, the more corrosion of metal will occur. Also, the concentration of oxide ions can influence the corrosive effects of certain nonoxygen-containing melts that have been subject to hydrolysis through contact with atmospheric moisture. In molten salt systems, corrosion is rarely inhibited because of the reactivity of the molten salts and the high temperatures. Molten salts often act as fluxes, thus removing oxide layers on container materials that generally might prove to be protective. Molten salts are generally good solvents for precipitates; therefore, passivation, because of deposits, generally does not occur.

One of the most familiar mechanisms of corrosion arises from ions of metals more noble than the container material, that is, the metal being corroded. In some cases, the more noble metal can be a constituent part of the molten salt, and in others, it can occur as an impurity in the system.

Another mechanism is best described by the example of silver in molten sodium chloride (NaCl). Thermodynamics would not predict a corrosion problem. However, the reaction occurs because sodium, as a result of the formation of silver chloride (AgCl), can dissolve in molten NaCl and distill out of the system. Thus, the reaction proceeds.

If a molten salt contains oxyanion constituents that can be reduced, oxide ions are released. Corrosion will occur on a metal in contact with the salt.

Lastly, oxygen itself can be reduced to oxide ions. However, uncombined oxygen is rarely found in molten salts because of limited solubility.

The potential, *E,* versus pO^{2-} diagram is often used as the equivalent of the *E* versus pH (Pourbaix) diagrams for aqueous corrosion (Ref 2). Both of these diagrams are used to establish the stability characteristics of a metal in the respective media. A typical *E* versus pO^{2-} diagram for iron in a molten salt at an elevated temperature is shown in Fig. 1. Areas of corrosion, immunity, passivation, and passivity breakdown are evident. Additional information on Pourbaix diagrams used in aqueous corrosion studies is available in the article "Thermodynamics of Aqueous Corrosion" in this Volume.

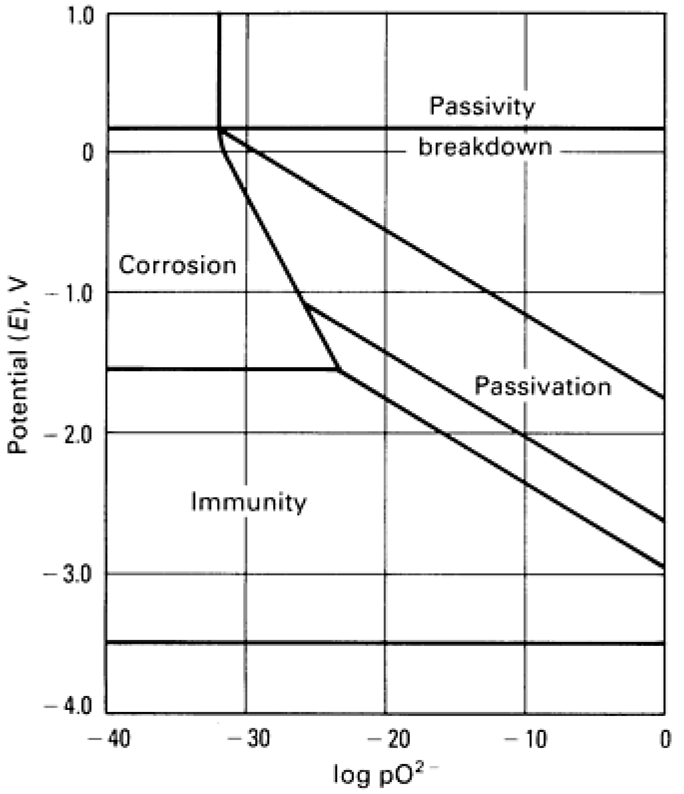

Fig. 1 Typical *E* versus pO^{2-} diagram for iron in a molten salt at an elevated temperature

Actually, the *E* versus pO^{2-} diagram is probably more useful than the Pourbaix diagram because of the absence of kinetic limitations at elevated temperatures. The following problems, however, do exist:

- Molten salt electrode reactions and the concomitant thermodynamic data are not readily available
- Products from the reactions are often lost by vaporization
- Diagrams based on pure component thermodynamic data are unrealistic because of departure from ideality
- Lack of passivity even where predictions would show passive behavior
- The stable existence of oxides other than the O^{2-} species

Test Methods

A number of kinetic and thermodynamic studies have been carried out in capsule-type containers. These studies can determine the nature of the corroding species and the corrosion products under static isothermal conditions and do provide some much-needed information. However, to provide the information needed for an actual flowing system, corrosion

studies must be conducted in thermal convection loops or forced convection loops, which will include the effects of thermal gradients, flow, chemistry changes, and surface area effects. These loops can also include electrochemical probes and gas monitors. An example of the types of information gained from thermal convection loops during an intensive study of the corrosion of various alloys by molten salts will be given below. A thermal convection loop is shown in Fig. 2.

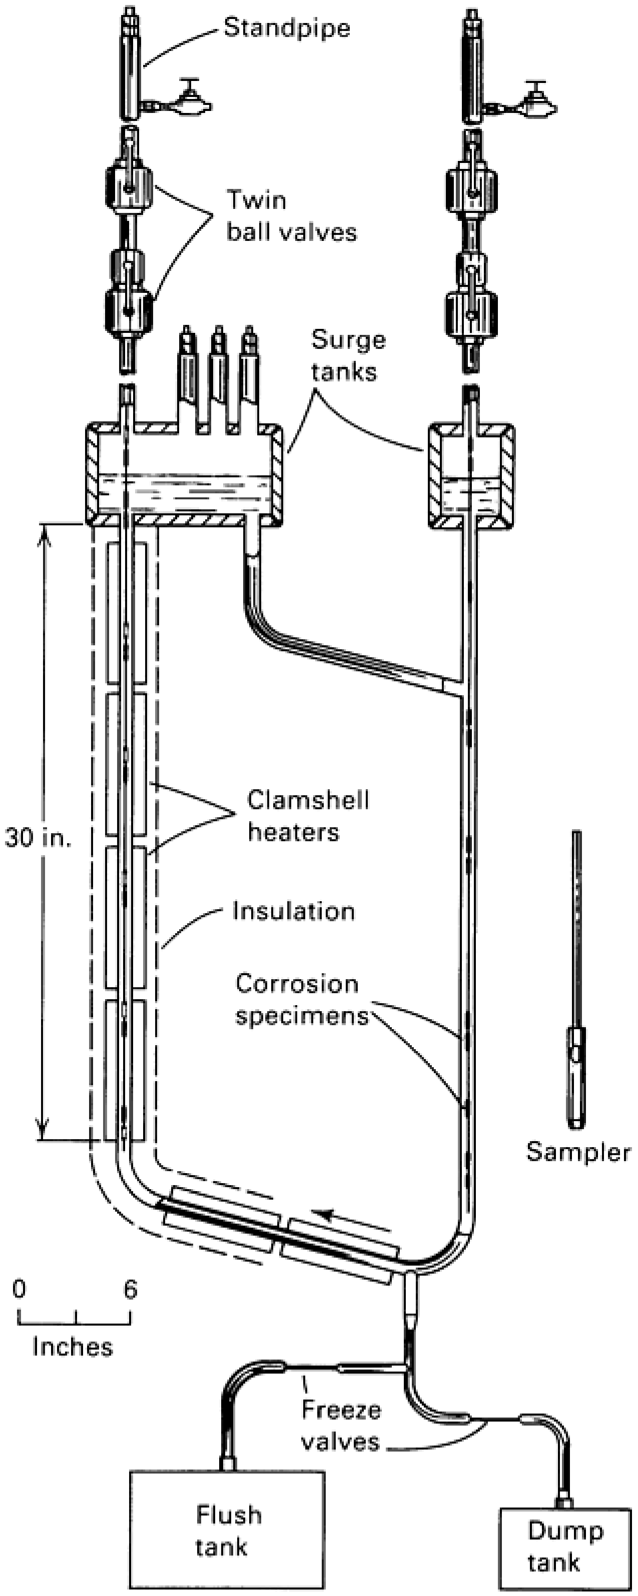

Fig. 2 Natural circulation loop and salt sampler

Purification

Molten salts, whether used for experimental purposes or in actual systems, must be kept free of contaminants. This task, which includes initial makeup, transfer, and operation, is specific for each type of molten salt. For example, even though the constituents of the molten fluoride salts used in the Oak Ridge Molten Salt Reactor Experiment were available in very pure grades, purification by a hydrogen/hydrogen fluoride (H_2/HF) gas purge for 20 h was necessary (Ref 3). For nitrates with a melting point of approximately 220 °C (430 °F), purging with argon flowing above and through the salt at 250 to 300 °C (480 to 570 °F) removes significant amounts of water vapor (Ref 4). Another purification method used for this same type of salt consisted of bubbling pure dry oxygen gas through the 350- °C (660- °F) melt for 2 h and then bubbling pure dry nitrogen for 30 min to remove the oxygen (Ref 5). All metals that contact the molten salt during purification must be carefully selected to avoid contamination from transfer tubes, thermocouple wells, the makeup vessel, and the container itself. This selection process may be an experiment in itself.

Nitrates / Nitrites

Nitrate mixtures have probably been studied and used more than any other molten salt group. This is perhaps because of the low operating temperatures possible (200 to 400 °C, or 390 to 750 °F). Steels of varying types are generally chosen for these systems.

As shown in Fig. 1, the E versus pO^{2-} diagram for iron indicates regions of corrosion, immunity, passivity, and passivity breakdown at temperatures of 240 to 400 °C (465 to 750 °F) (Ref 6). In general, the basicity of the melt prevents iron corrosion. Protection by passive films is less reliable, because oxide ion discharge may breakdown the passive film.

Electropolished iron spontaneously passivates in molten sodium nitrate-potassium nitrite in the temperature range of 230 to 310 °C (445 to 590 °F) at certain potentials (Ref 7). A magnetite (Fe_3O_4) film is formed, along with a reduction of nitrite or any trace of oxygen gas dissolved in the melt. At higher potentials, all reactions occur on the passivated iron. Above the passivation potentials, dissolution occurs with ferric ion soluble in the melt. At even higher potentials, nitrogen oxides are evolved, and nitrate ions dissolve in the nitrite melt. At higher currents, hematite (Fe_2O_3) is formed as a suspension, and NO_2 is detected. Carbon steel in molten sodium nitrate-potassium nitrate ($NaNO_3$-KNO_3) at temperatures ranging from 250 to 450 °C (480 to 840 °F) forms a passivating film consisting mainly of Fe_3O_4 (Ref 5).

Iron anodes in molten alkali nitrates and nitrites at temperatures ranging from 240 to 320 °C (465 to 610 °F) acquire a passive state in both melts. In nitrate melts, the protective Fe_3O_4 oxidizes to Fe_2O_3, and the gaseous products differ for each melt (Ref 8).

An interesting study was conducted on the corrosion characteristics of several eutectic molten salt mixtures on such materials as carbon steel, stainless steel, and Inconel in the temperature range of 250 to 400 °C (480 to 750 °F) in a nonflowing system (Ref 9). The salt mixtures and corrosion rates are given in Table 1. As expected, the corrosion rate was much higher for carbon steel than for stainless steel in the same mixture. Low corrosion rates were found for both steels in mixtures containing large amounts of alkaline nitrate. The nitrate ions had a passivating effect.

Table 1 Corrosion rates of iron-base alloys in eutectic molten salt mixtures

Salt mixture	Corrosion rate			
	Carbon steel		Stainless steel	
	μm/yr	**mils/yr**	**μm/yr**	mils/yr
$NaNO_3$-NaCl-Na_2SO_4 (86.3,8.4,5.3 mol%, respectively)	15	0.6	1	**0.03**
KNO_3-KCl (94.6 mol%, respectively)	23	0.9	7.5	**0.3**
LiCl-KCl (58.42 mol%, respectively)	**63**	**2.5**	**20**	**0.8**

Electrochemical studies showed high resistance to corrosion by Inconel. Again, the sulfate-containing mixture caused less corrosion because of passivating property of the nitrate as well as the preferential adsorption of sulfate ions.

Surface analysis by Auger electron spectroscopy indicated varying thicknesses of iron oxide layers and nickel and chromium layers. The Auger analysis showed that an annealed and air-cooled stainless steel specimen exposed to molten lithium chloride (LiCl)-potassium chloride (KCl) salt had corrosion to a depth five times greater than that of an unannealed stainless steel specimen. Chromium carbide precipitation developed during slow cooling and was responsible for the increased corrosion. The mechanism of corrosion of iron and steel by these molten eutectic salts can be described by the following reactions:

$$Fe \rightleftharpoons Fe^{2+} + 2e^- \quad \textbf{(Eq 1)}$$

$$LiCl + H_2O \rightleftharpoons LiOH + HCl \quad \textbf{(Eq 2)}$$

$$H^+ + e^- \rightleftharpoons \frac{1}{2}H_2 \; H_2O + 2e^- \rightleftharpoons O^{2-} + H_2 \quad \textbf{(Eq 3)}$$

$$\frac{1}{2}O_2 + 2e^- \rightleftharpoons O^{2-} \quad \textbf{(Eq 4)}$$

$$Fe^{3+} + e^- \rightleftharpoons Fe^{2+} \quad \textbf{(Eq 5)}$$

$$Fe^{2+} + O^{2-} \rightleftharpoons FeO \quad \textbf{(Eq 6)}$$

$$3FeO + O^{2-} \rightleftharpoons Fe_3O_4 + 2e^- \quad \textbf{(Eq 7)}$$

$$2Fe_3O_4 + O^{2-} \rightleftharpoons 3Fe_2O_3 + 2e^- \quad \textbf{(Eq 8)}$$

In an actual flowing operating system of KNO_3-NaO_2-NaO_3 (53, 40, and 7 mol%, respectively) at temperatures to 450 °C (840 °F), carbon or chromium-molybdenum steels have been used (Ref 10). For higher temperatures and longer times, nickel or austenitic stainless steels are used. Weld joints are still a problem in both cases.

Alloy 800 and types 304, 304L, and 316 stainless steels were exposed to thermally convective $NaNO_3$-KNO_3 salt (draw salt) under argon at 375 to 600 °C (705 to 1110 °F) for more than 4500 h (Ref 4). The exposure resulted in the growth of thin oxide films on all alloys and the dissolution of chromium by the salt. The weight change data for the alloys indicated that the metal in the oxide film constituted most of the metal loss, that the corrosion rate, in general, increased with temperature, and that, although the greatest metal loss corresponded to a penetration rate of 25 μm/yr (1 mil/yr), the rate was less than 13 μm/yr (0.5 mil/yr) in most cases. These latter rates are somewhat smaller than those reported for similar loops operated with the salt exposed to the atmosphere (Ref 11, 12), but are within a factor of two to five. Spalling had a significant effect on metal loss at intermediate temperatures in the type 304L stainless steel loop. Metallographic

examinations showed no evidence of intergranular attack or of significant cold-leg deposits. Weight change data further confirmed the absence of thermal gradient mass transport processes in these draw salt systems.

Raising the maximum temperature of the type 316 stainless steel loop from 595 to 620 °C (1105 to 1150 °F) dramatically increased the corrosion rate (Ref 11, 12). Thus, 600 °C (1110 °F) may be the limiting temperature for use of such alloys in draw salt.

Fluorides

Because of the Oak Ridge Molten Salt Reactor Experiment, a large amount of work was done on corrosion by molten fluoride salts (Ref 3). Because these molten salts were to be used as heat transfer media, temperature gradient mass transfer was very important. Very small amounts of corrosion can result in large deposits, given that the solubility of the corrosion product changes drastically in the temperature range in question. Many other variables can also cause this phenomenon. Thus, a corrosion rate in itself does not provide complete information about corrosion.

Because the products of oxidation of metals by fluoride melts are quite soluble in the corroding media, passivation is precluded, and the corrosion rate depends on other factors, including the thermodynamic driving force of the corrosion reactions. The design of a practicable system utilizing molten fluoride salts, therefore, demands the selection of salt constituents, such as lithium fluoride (LiF), beryllium fluoride (BeF_2), uranium tetrafluoride (UF_4), and thorium fluoride (ThF_4), that are not appreciably reduced by available structural metals and alloys whose components (iron, nickel, and chromium) can be in near thermodynamic equilibrium with the salt.

A continuing program of experimentation over many years has been devoted to defining the thermodynamic properties of many corrosion product species in molten LiF-BeF_2 solutions. Many of the data have been obtained by direct measurement of equilibrium pressures for such reactions as:

$$H_2(g) + FeF_2(d) \rightleftharpoons Fe(c) + 2HF(g) \qquad \textbf{(Eq 9)}$$

and

$$2HF(g) + BeO(c) \rightleftharpoons BeF_2(l) + H_2O(g) \qquad \textbf{(Eq 10)}$$

where g, c, and d represent gas, crystalline solid, and solute, respectively, using the molten fluoride (denoted 1 for liquid) as the reaction medium. All of these studies have been reviewed, and the combination of these data with those of other studies has yielded tabulated thermodynamic data for many species in molten LiF-BeF_2 (Table 2). From these data, one can assess the extent to which a uranium trifluoride (UF_3) bearing melt will disproportionate according to the reaction:

$$4UF_3(d) \rightleftharpoons 3UF_4(d) + U(d) \qquad \textbf{(Eq 11)}$$

Table 2 Standard Gibbs free energies (ΔG^f) of formation for species in molten 2LiF-BeF_2

Temperature range: 733-1000 K

Material[(a)]	**-ΔG^f (kcal/mol)**	-ΔG^f (1000 K) (kcal/mol)
Lif(l)	$141.8\text{-}16.6 \times 10^{-3}\ T$ K	**125.2**

$CrF_2(d)$	171.8-21.4 × 10^{-3} *T* K	**75.2**
$MoF_6(g)$	**370.9-69.6 × 10^{-3} *T* K**	**50.2**

Source: Ref 13

(a) The standard state for LiF and BeF_2 is the molten 2LiF-BeF_2 liquid. That for $MoF_6(g)$ is the gas at 1 atm. That for all species with d is that hypothetical solution with the solute at unit mole fraction and with the activity coefficient it would have at infinite dilution.

For the case in which the total uranium content of the salt is 0.9 mol%, as in the Oak Ridge Molten Salt Reactor Experiment, the activity of metallic uranium (referred to the pure metal) is near 10^{-15} with 1% of the UF_4 converted to UF_3 and is near 2×10^{-10} with 20% of the UF_4 so converted (Ref 14). Operation of the reactor with a small fraction (usually 2%) of the uranium present as UF_3 is advantageous insofar as corrosion and the consequences of fission are concerned. Such operation with some UF_3 present should result in the formation of an extremely dilute (and experimentally undetectable) alloy of uranium with the surface of the container metal. Operation with 50% of the uranium as UF_3 would lead to much more concentrated (and highly deleterious) alloying and to formation of uranium carbides. All evidence to date demonstrates that operation with relatively little UF_3 is completely satisfactory.

The data gathered to date reveal clearly that in reactions with structural metals, M:

$$2UF_4(d) + M(c) \leftrightharpoons 2UF_3(d) + MF_2(d) \qquad \textbf{(Eq 12)}$$

chromium is much more readily attacked than iron, nickel, or molybdenum (Ref 14, 15).

Nickel-base alloys, more specifically Hastelloy N (Ni-6.5 Mo-6.9Cr-4.5Fe) and its modifications, are considered the most promising for use in molten salts and have received the most attention. Stainless steels, having more chromium than Hastelloy N, are more susceptible to corrosion by fluoride melts, but can be considered for some applications.

Oxidation and selective attack may also result from impurities in the melt:

$$M + NiF_2 \leftrightharpoons MF_2 + Ni \qquad \textbf{(Eq 13)}$$

$$M + 2HF \leftrightharpoons MF_2 + H_2 \qquad \textbf{(Eq 14)}$$

or oxide films on the metal:

$$NiO + BeF_2 \leftrightharpoons NiF_2 + BeO \qquad \textbf{(Eq 15)}$$

followed by reaction of nickel fluoride (NiF_2) with M.

The reactions given in Eq 13, 14, and 15 will proceed essentially to completion at all temperatures. Accordingly, such reactions can lead (if the system is poorly cleaned) to a rapid initial corrosion rate. However, these reactions do not give a sustained corrosive attack.

On the other hand, the reaction involving UF_4 (Eq 12) may have an equilibrium constant that is strongly temperature dependent; therefore, when the salt is forced to circulate through a temperature gradient, a possible mechanism exists for mass transfer and continued attack. Equation 12 is of significance mainly in the case of alloys containing relatively large amounts of chromium.

If nickel, iron, and molybdenum are assumed to form regular or ideal solid solutions with chromium (as is approximately true) and if the circulation rate is very rapid, the corrosion process for alloys in fluoride salts can be simply described. At high flow rates, uniform concentrations of UF_3 and chromium fluoride (CrF_2) are maintained throughout the fluid circuit. Under these conditions, there exists some temperature (intermediate between the maximum and minimum temperatures of the circuit) at which the initial chromium concentration of the structural metal is at equilibrium with the fused salt. This temperature, T_{BP}, is called the balance point.

Because the equilibrium constant for the chemical reaction with chromium increases with temperature, the chromium concentration in the alloy surface tends to decrease at temperatures higher than T_{BP} and tends to increase at temperatures lower than T_{BP}. At some point, the dissolution process will be controlled by the solid-state diffusion rate of chromium from the matrix to the surface of the alloy.

In some melts (NaF-LiF-KF-UF_4, for example), the equilibrium constant for Eq 12 with chromium changes sufficiently as a function of temperature to cause the formation of dendritic chromium crystals in the cold zone. For LiF-BeF_2-UF_4-type mixtures, the temperature dependence of the mass transfer reaction is small, and the equilibrium is satisfied at reactor temperature conditions without the formation of crystalline chromium. Thus, the rate of chromium removal from the salt stream by deposition at cold-fluid regions is controlled by the rate at which chromium diffuses into the cold-fluid wall; the chromium concentration gradient tends to be small, and the resulting corrosion is well within tolerable limits. A schematic of the temperature gradient mass transfer process is shown in Fig. 3.

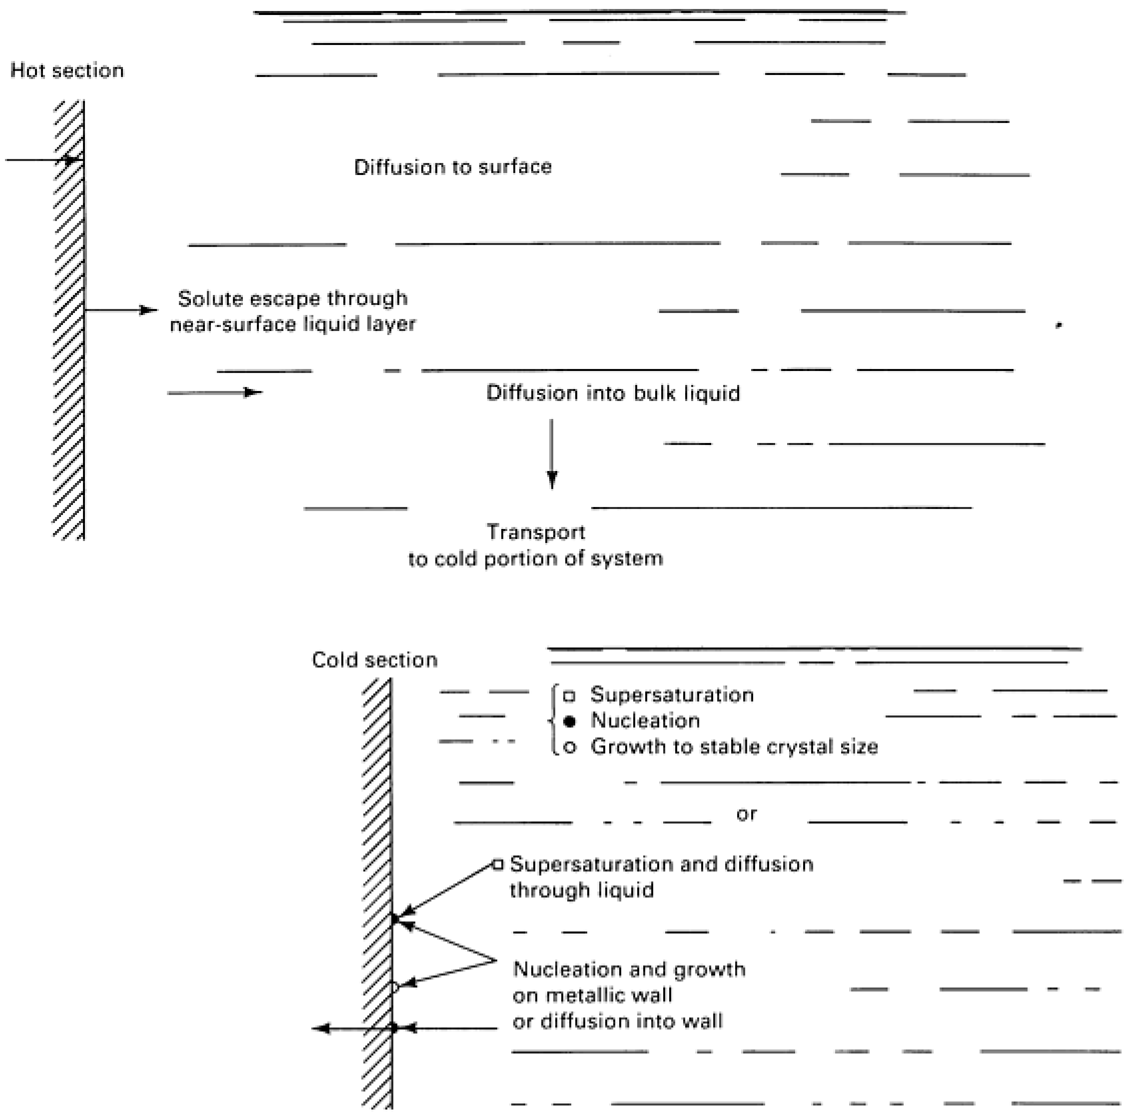

Fig. 3 Temperature-gradient mass transfer

Lithium fluoride-beryllium fluoride salts containing UF_4 or ThF_4 and tested in thermal convection loops showed temperature gradient mass transfer, as noted by weight losses in the hot leg and weight gains in the cold leg (Fig. 4). Hastelloy N was developed for use in molten fluorides and has proved to be quite compatible. The weight changes of corrosion specimens increased with temperature and time (Fig. 5 and 6). Electrochemical methods were used to determine the oxidation potential of molten fluoride salts in thermal convection loops. The values obtained correlated well with specimen weight change data (Fig. 7).

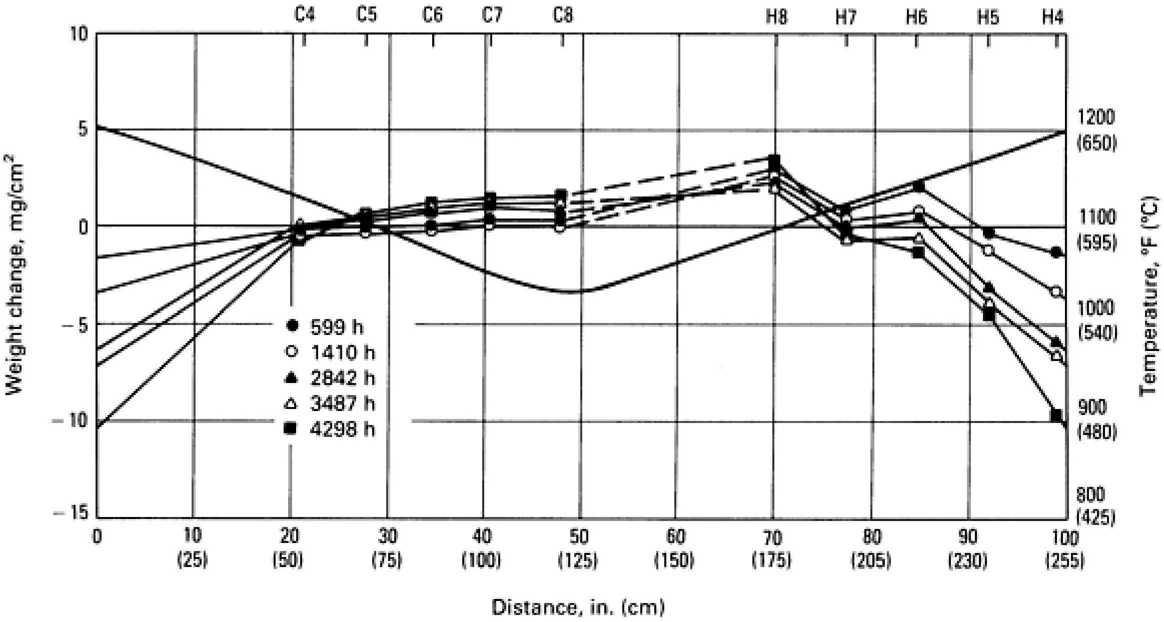

Fig. 4 Weight changes of type 316 stainless steel specimens exposed to LiF-BeF$_2$-ThF$_4$-UF$_4$ (68, 20, 11.7, and 0.3 mol%, respectively) as a function of position and temperature

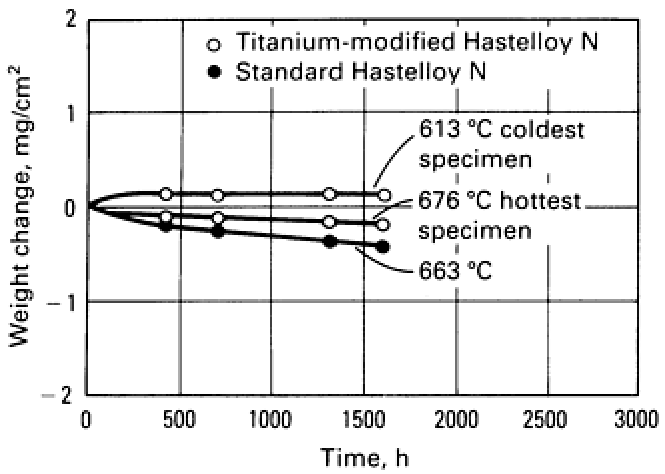

Fig. 5 Weight changes of Hastelloy N specimens versus time of operation in LiF-BeF^2-ThF$_4$ (73, 2, and 25 mol%, respectively)

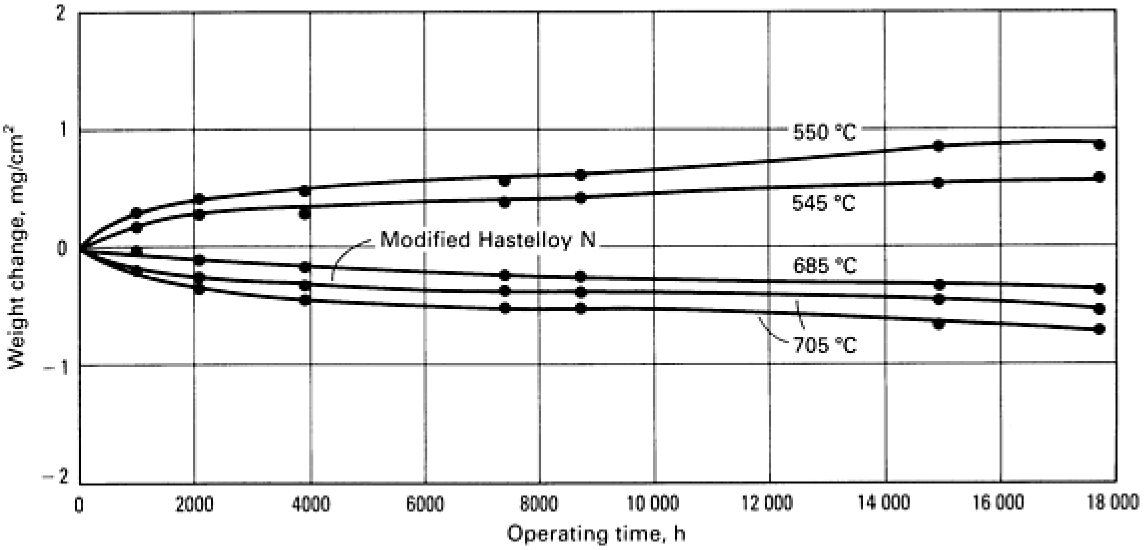

Fig. 6 Weight changes of Hastelloy N exposed to LiF-BeF$_2$-ThF$_4$-UF$_4$ (68, 20, 11.7, and 0.3 mol%, respectively) for various times

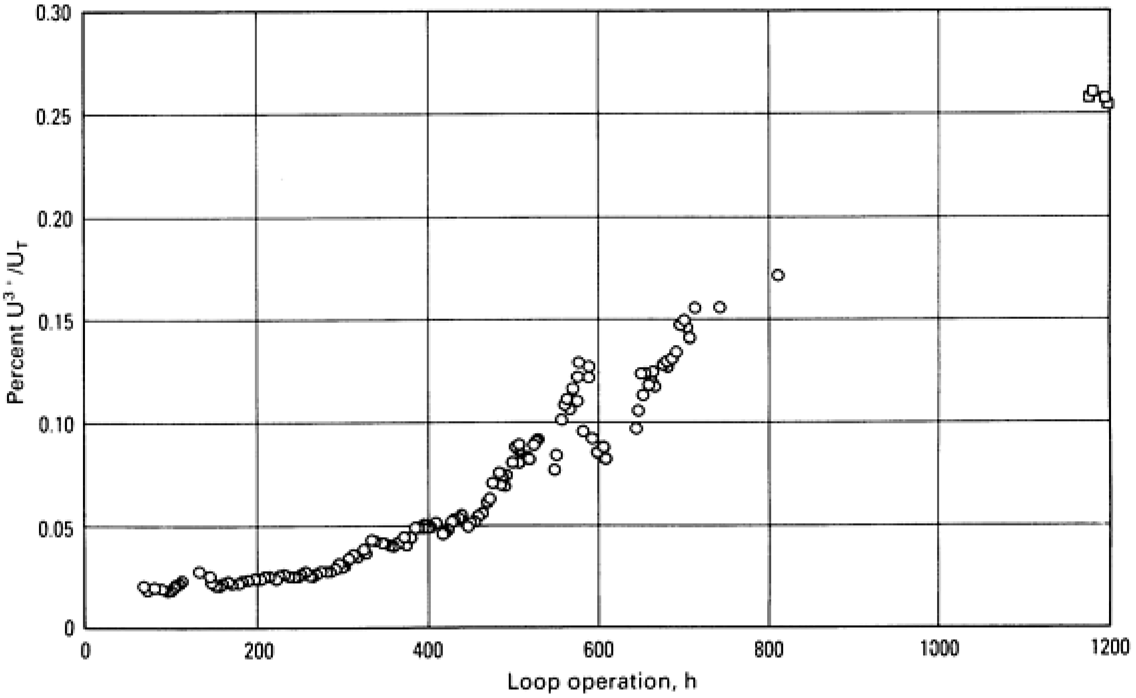

Fig. 7 Uranium (III) in fuel salt

A type 304L stainless steel exposed to a fuel salt for 9.5 years in a type 304L stainless steel loop showed a maximum uniform corrosion rat of 22 μm/yr (0.86 mil/yr). Voids extended into the matrix for 250 μm (10 mils), and chromium depletion was found (Fig. 8 and 9).

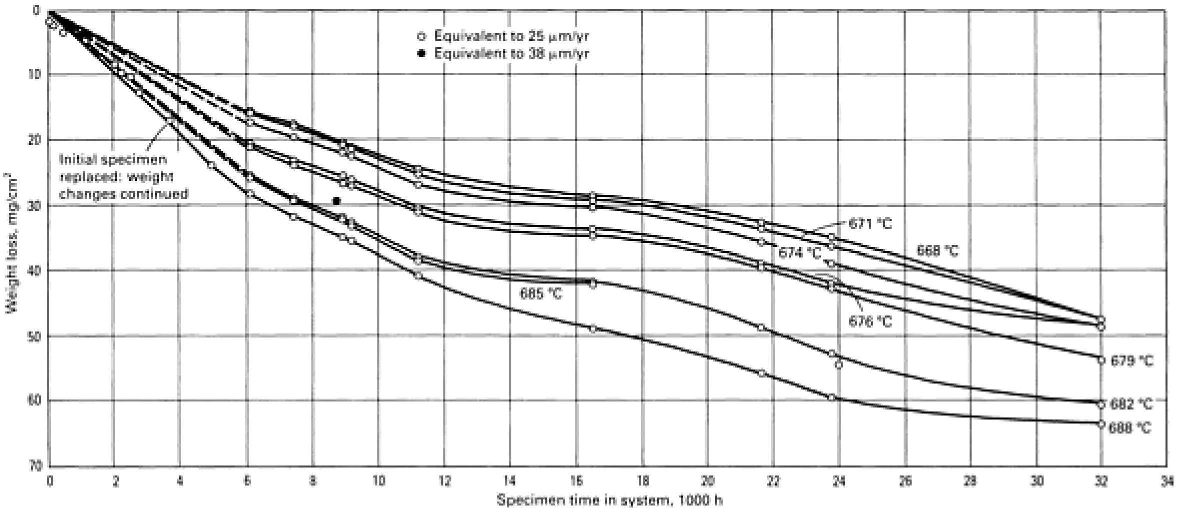

Fig. 8 Weight changes of type 304L stainless steel specimens exposed to $LiF-BeF_2-ZrF_4-ThF_4-UF_4$ (70, 23, 5, 1, and 1 mol%, respectively) for various times and temperatures

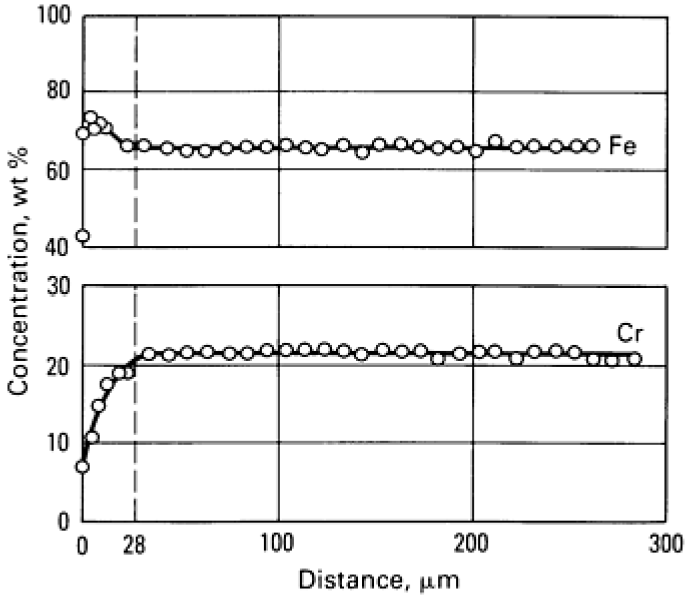

Fig. 9 Chromium and iron concentration gradient in a type 304L stainless steel specimen exposed to $LiF-BeF_2-ZrF_4-ThF_4-UF_4$ (70, 23, 5, 1, and 1 mol%, respectively) for 5700 h at 688 °C (1270 °F)

The corrosion resistance of a maraging steel (Fe-12Ni-5Cr-3Mo) at 662 °C (1224 °F) was better than that of type 304L stainless steel, but was worse than that of a Hastelloy N under equivalent conditions. As shown in Table 3, the uniform corrosion rate was 14 μm (0.55 mil/yr). Voids were seen in the microstructure of the specimens after 5700 h, and electron microprobe analysis disclosed a definite depletion of chromium and iron.

Table 3 Comparison of weight losses of alloys at approximately 663 °C (1225 °F) in similar flow fuel salts in a temperature gradient system

Alloy	**Weight loss, mg/cm^2**		Average corrosion	
	2490 h	**3730 h**	**μm/yr**	mils/yr
Maraging steel	3.0	4.8	14	**0.55**
Type 304 stainless steel	6.5	10.0	28	**1.1**
Hastelloy N	**0.4**	**0.6**	**1.5**	**0.06**

Type 316 stainless steel exposed to a fuel salt in a type 316 stainless steel loop showed a maximum uniform corrosion rate of 25 μm/yr (1 mil/yr) for 4298 h. Mass transfer did occur in the system.

For selected nickel- and iron-base alloys, a direct correlation was found between corrosion resistance in molten fluoride salt and chromium and iron content of an alloy. The more chromium and iron in the alloy, the less the corrosion resistance.

Literature on Molten Salt Corrosion

A vast number of publications are noteworthy in connection with molten salt corrosion. Those mentioned below represent sources of information that are particularly helpful. Janz and Tompkins provide an extensive bibliography with over 400 references (Ref 16). Inman and Lovering give an excellent survey of the field with over 200 references (Ref 1). Allen and Janz discuss safety and health hazards (Ref 17). Gale and Lovering provide an overview for researchers considering working with molten salts (Ref 18).

Summary

In order to study the corrosion of molten salts or to determine what materials are compatible with a certain molten salt, the following questions must be answered. What is the purpose of the investigation? Is the researcher interested in basic studies, or is this work for information or work preliminary to assessment for a real system? For basic studies, capsule experiments or information from capsules is sufficient. Otherwise, flow systems or information from flow systems will be needed at some point to assess temperature gradient mass transfer. Salts to be used in either case need to be purified, and the same purity must be used in each experiment unless this factor is a variable. Analytical facilities must be used for the chemistry of the salt, including impurity content and surface analysis of the metals in question.

Vast amounts of useful information can be obtained from capsule and flow experiments. It is hoped that the preceding information on specific systems will provide an appreciation of the problems involved and the material that can be obtained from various experiments.

Fundamentals of High-Temperature Corrosion in Liquid Metals

P.F. Tortorelli, Oak Ridge National Laboratory

Introduction

CONCERN ABOUT CORROSION of solids exposed to liquid-metal environments, that is, liquid-metal corrosion, dates from the earliest days of metals processing, when it became necessary to handle and contain molten metals. Corrosion considerations also arise when liquid metals are used in applications that exploit their chemical or physical properties. Liquid metals serve as high-temperature reducing agents in the production of metals (such as the use of molten magnesium to produce titanium) and because of their excellent heat transfer properties, they have been used or considered as coolants in a variety of power-producing systems. Examples of such applications include molten sodium for liquid-metal fast breeder reactors and central receiver solar stations as well as liquid lithium for fusion and space nuclear reactors. In addition, tritium breeding in deuterium-tritium fusion reactors necessitates the exposure of lithium atoms to fusion neutrons. Breeding fluids of lithium or lead-lithium are attractive for this purpose. Molten lead or bismuth can serve as neutron multipliers to raise the tritium breeding yield if other types of lithium-containing breeding materials are used. Liquid metals can also be used as two-phase working fluids in Rankine cycle power conversion devices (molten cesium or potassium) and in heat pipes (potassium, lithium, sodium, sodium-potassium). Because of their high thermal conductivities, sodium-potassium alloys, which can be any of a wide range of sodium-potassium combinations that are molten at or near room temperature, have also been used as static heat sinks in automotive and aircraft valves.

Whenever the handling of liquid metals is required, whether in specific uses as discussed above or as melts during processing, a compatible containment material must be selected. At low temperatures, liquid-metal corrosion is often insignificant, but in more demanding applications, corrosion considerations can be important in selecting the appropriate containment material and/or operating parameters. Thus, liquid-metal corrosion studies in support of heat pipe technology and aircraft, space, and fast breeder reactor programs date back many years and, more recently, are being conducted as part of the fusion energy technology program. In this article, the principal corrosion reactions and important parameters that control such processes will be briefly reviewed for materials (principally metals) exposed to liquid-metal environments. Only corrosion phenomena will be covered; liquid-metal cracking and environmental effects on mechanical properties are described in the article "Environmentally Induced Cracking" in this Volume (see in particular the sections "Liquid-Metal Embrittlement" and "Solid-Metal Embrittlement"). Furthermore, the discussion will be limited to corrosion under single-phase (liquid) conditions.

Corrosion Reactions in Liquid-Metal Environments

Liquid-metal corrosion can manifest itself in various ways. In the most general sense, the following categories can be used to classify relevant corrosion phenomena:

- Dissolution
- Impurity and interstitial reactions
- Alloying
- Compound reduction

Definitions and descriptions of these types of reactions are given below. However, it is important to note that this classification is somewhat arbitrary, and as will become clear during the following discussion, the individual categories are not necessarily independent of one another.

Dissolution

The simplest corrosion reaction that can occur in a liquid-metal environment is direct dissolution. Direct dissolution is the release of atoms of the containment material into the melt in the absence of any impurity effects. Such a reaction is a simple solution process and therefore is governed by the elemental solubilities in the liquid metal and the kinetics of the rate-controlling step of the dissolution reaction. The net rate, J, at which an elemental species enters solution, can be described as:

$$J = k(C - c) \qquad \textbf{(Eq 1)}$$

where k is the solution rate constant for the rate-controlling step, C is the solubility of the particular element in the liquid metal, and c is the actual instantaneous concentration of this element in the melt. Under isothermal conditions, the rate of this dissolution reaction would decrease with time as c increases. After a period of time, the actual elemental concentration becomes equal to the solubility, and the dissolution rate is then 0. Therefore, in view of Eq 1, corrosion by the direct dissolution process can be minimized by selecting a containment material whose elements have low solubilities in the liquid metal of interest and/or by saturating the melt before actual exposure. However, if the dissolution kinetics are relatively slow, that is, for low values of k, corrosion may be acceptable for short-term exposures. The functional dependence and magnitude of the solution rate constant, k, depend on the rate-controlling step, which in the simplest cases can be a transport across the liquid-phase boundary layer, diffusion in the solid, or a reaction at the phase boundary. Measurements of weight changes as a function of time for a fixed $C - c$ (see discussion below) yield the kinetic information necessary for determination of the rate-controlling mechanism.

Corrosion resulting from dissolution in a nonisothermal liquid-metal system is more complicated than the isothermal case. Although Eq 1 can be used to describe the net rate at any particular temperature, the movement of liquid--for example, due to thermal gradients or forced circulation--tends to make c the same around the liquid-metal system. Therefore, at temperatures where the solubility (C) is greater than the bulk concentration (c), dissolution of an element into the liquid metal will occur, but at lower temperatures in the circuit where $C < c$, a particular element will tend to come out of solution and be deposited on the containment material (or it may remain as a suspended particulate). A schematic of such a mass transfer process is shown in Fig. 1. If net dissolution or deposition is measured by weight changes, a mass transfer profile such as the one shown in Fig. 2 can be established. Such mass transfer processes under nonisothermal conditions can be of prime importance when, in the absence of dissimilar-metal effects (see below), forced circulation (pumping) of liquid metals used as heat transfer media exacerbates the transport of materials from hotter to cooler parts of the liquid-metal circuit. Normally, the concentration in the bulk liquid, c, rapidly becomes constant with time such that, at given temperature, the concentration driving force ($C - c$, Eq 1) is then also constant. However, much more elaborate analyses based on Eq 1 are required to describe nonisothermal mass transfer precisely. Such treatments must take into account the differences in k around the circuit as well as the possibility that the rate constant for dissolution (or deposition) may not vary monotonically with temperature because of changes in the rate-controlling step within the temperature range of dissolution (deposition). The presence of more than one elemental species in the containment material further complicates the analysis; the transfer of each element typically has to be handled with its own set of thermodynamic and kinetic parameters. Although a thermal gradient increases the amount of dissolution, plugging of coolant pipes by nonuniform deposition of dissolved species in cold zones often represents a more serious design problem than metal loss from dissolution (which sometimes may be handled by corrosion allowances. The most direct way to control deposition, however, is usually to minimize dissolution in the hot zone by use of more corrosion-resistant materials and/or inhibition techniques.

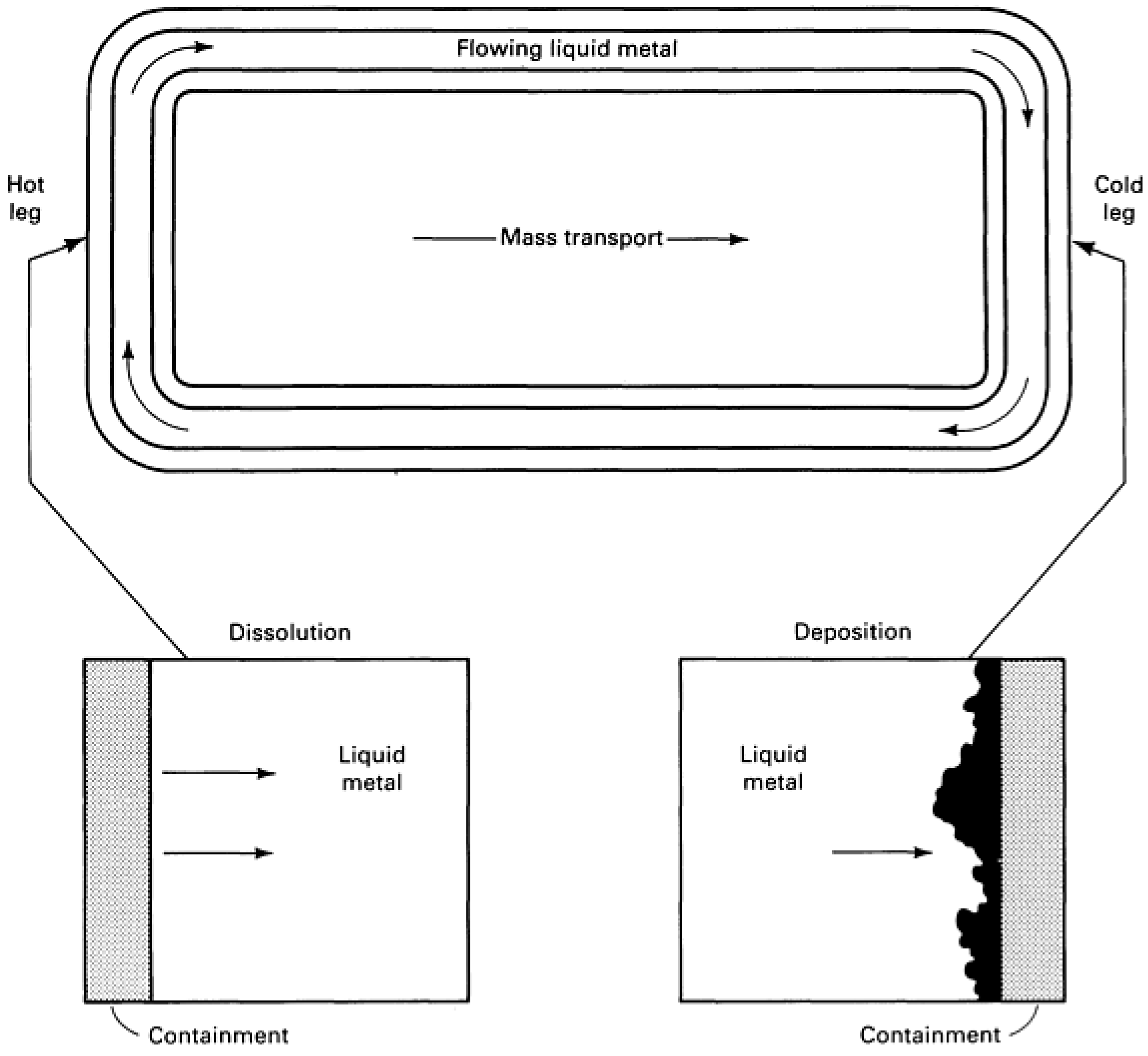

Fig. 1 Schematic of thermal gradient mass transfer in a liquid-metal circuit. Source: Ref 1

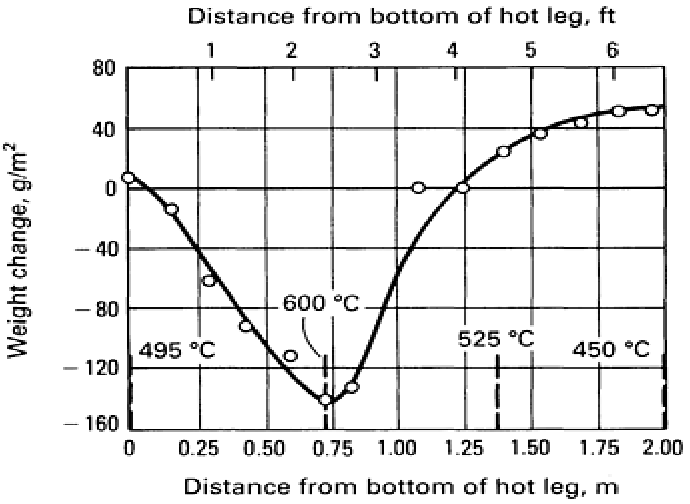

Fig. 2 Mass transfer as characterized by the weight changes of type 316 stainless steel coupons exposed around a nonisothermal liquid lithium type 316 stainless steel circuit for 9000 h. Source: Ref 2

Mass transfer may even occur under isothermal conditions if an activity gradient exists in the system. Under the appropriate conditions, dissolution and deposition will act to equilibrate the activities of the various elements in contact with the liquid metal. Normally, such a process is chiefly limited to interstitial element transfer between dissimilar metals, but transport of substitutional elements can also occur. Elimination (or avoidance) of concentration (activity) gradients across a liquid-metal system is the obvious and, most often, the simplest solution to any problems arising from this type of mass transport process.

Under certain conditions, dissolution of metallic alloys by liquid metals can lead to irregular attack (Fig. 3). Although such localized corrosive attack can often be linked to impurity effects (see discussion below) and/or compositional inhomogeneities in the solid, this destabilization of a planar surface is due to preferential dissolution of one or more elements of an alloy exposed to a liquid metal. Indeed, the type of attack illustrated in Fig. 3 is thought to be caused by the preferential dissolution of nickel from an Fe-17Cr-11Ni (wt%) alloy (type 316 stainless steel). As such, this process resembles the dealloying phenomenon sometimes observed in aqueous environments (see the article "Metallurgically Influenced Corrosion" in this Volume for a description of dealloying corrosion). In contrast, an Fe-12Cr-1Mo steel, which did not undergo preferential dissolution of any of its elements, corroded uniformly when exposed under the same environmental conditions (Fig. 4)

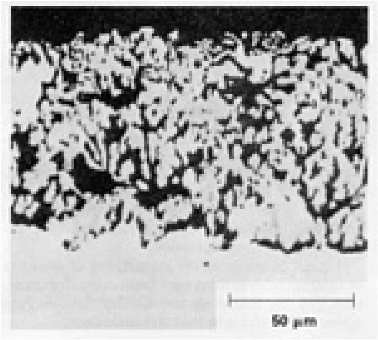

Fig. 3 Polished cross section of type 316 stainless steel exposed to thermally convective Pb-17at.%Li at 500 °C (930 °F) for 2472 h. Source: Ref 3

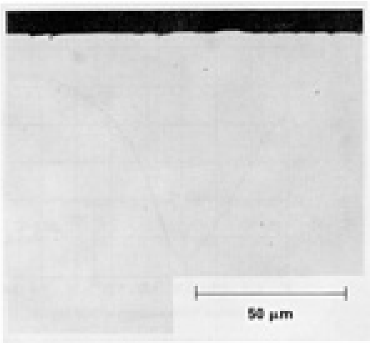

Fig. 4 Polished cross section of Fe-12Cr-1MoVW steel exposed to thermally convective Pb-17at.%Li at 500 °C (930 °F) for 2000 h. Source: Ref 3

Apart from possible effects on morphological development, the changes in surface composition due to preferential elemental dissolution from an alloy into a liquid metal are important in themselves. For example, in austenitic stainless steels exposed to sodium or lithium, the preferential dissolution of nickel causes a phase transformation to a ferritic structure in the surface region. In many cases, an equilibrium surface composition is achieved such that the net elemental fluxes into the liquid metal are in the same proportion as the starting concentrations of these elements in the alloy. Such a phenomenon has been rigorously treated and characterized for sodium-steel systems.

Impurity and Interstitial Reactions

For this discussion, impurity or interstitial reactions refer to the interaction of light elements present in the containment material (interstitials) or the liquid metal (impurities). Examples of such reactions include the decarburization of steel in lithium and the oxidation of steel in sodium or lead of high oxygen activity. In many cases, when the principal elements of the containment material have low solubilities in liquid metals (for example, refractory metals in sodium, lithium, and lead), reactions involving light elements such as oxygen, carbon, and nitrogen dominate the corrosion process. Impurity or interstitial reactions can be generally classified into two types: corrosion product formation and elemental transfer of such species.

Corrosion Product Formation. The general form of a corrosion product reaction is:

$$xL + yM + zI = L_xM_yI_z \quad \textbf{(Eq 2)}$$

where L is the chemical symbol for a liquid-metal atom, M is one species of the containment material, and I represents an interstitial or impurity atom in the solid or liquid ($x, y, z > 0$). The $L_xM_yI_z$ corrosion product that forms by such a reaction may be soluble or insoluble in the liquid metal. If it is soluble, the I species would cause greater dissolution weight losses and would result in an apparently higher solubility of M in L (Eq 1). This is a frequent cause of erroneous solubility measurements and is a good illustration of how dissolution and impurity reactions can be interrelated. Furthermore, if a soluble corrosion product forms at selected sites on the surface of the solid, localized attack will result. Under conditions in which a corrosion product is insoluble, a partial or complete surface layer will form. However, this does not necessarily mean that it can be observed. The product may be unstable outside the liquid metal environment or may dissolve in the cleaning agent used to remove the solidified residue of liquid metal from the exposed containment material.

A good example of the importance of impurity or interstitial reactions that form corrosion products can be found in the sodium-steel-oxygen system. It is thought that the reaction:

$$3Na_2O(l) + Fe(s) = (Na_2O)_2 \cdot FeO(s) + 2Na(l) \quad \textbf{(Eq 3)}$$

increases the apparent solubility of iron in sodium at higher oxygen activities, while the interaction of oxygen, sodium, and chromium can lead to the formation of surface corrosion products, for example:

$$2Na_2O(l) + Cr(s) = NaCrO_2(s) + 3Na(l) \quad \textbf{(Eq 4)}$$

This second type of reaction (Eq 4) is of primary importance in the corrosion of chromium-containing steels by liquid sodium. It can be controlled by reducing the oxygen concentration of the sodium to less than about 3 ppm and/or by modifying the composition of the alloy through reduction of the chromium concentration of the steel.

Such corrosion product reactions can also be observed in lithium-steel systems, in which nitrogen can increase the corrosiveness of the liquid-metal environment. In particular, the reaction:

$$5Li_3N(\text{in } l) + Cr(s) = Li_9CrN_5(s) + 6Li(l) \quad \textbf{(Eq 5)}$$

or an equivalent one with iron, can play an important role in corrosion by liquid lithium. The Li_9CrN_5 corrosion product tends to be localized at the grain boundaries of exposed steels. Such reaction products can probably also be formed when there is sufficient nitrogen in the solid; experimental observations have indicated that nitrogen can increase corrosion by lithium, whether it is in the liquid metal or in the steel.

Corrosion product formation is also important when certain refractory metals are exposed to molten lithium. Despite their low solubilities in lithium, niobium and tantalum can be severely attacked when exposed to lithium if the oxygen activities of these metals are not low. At temperatures below approximately 900 °C (1650 °F), the lithium reacts rapidly with the oxygen and niobium or tantalum (and their oxides and suboxides) to form a ternary oxide corrosion product. Such reactions result in localized penetration along grain boundaries and selected crystallographic planes. This form of corrosive attack can be eliminated, however, by minimizing the oxygen concentration of these refractory metals (Fig. 5)

and by using alloying additions that form oxides that do not react with the lithium and that minimize the amount of uncombined oxygen in the material (1 to 2 at % Zr in niobium and hafnium in tantalum).

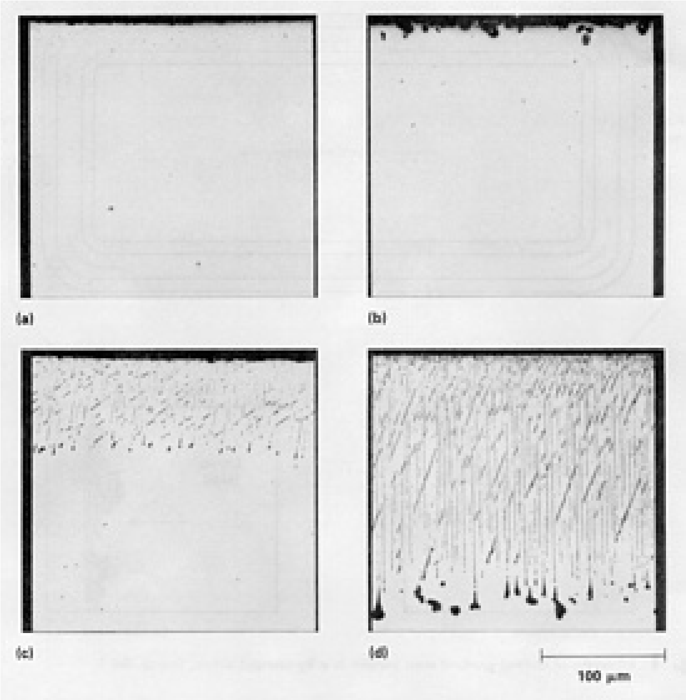

Fig. 5 Effect on initial oxygen concentration (150 to 1700 ppm) in niobium on the depth of attack by lithium. Polished and etched cross sections of niobium exposed to isothermal lithium at 816 °C (1500 °F) for 100 h. (a) 150 ppm. (b) 500 ppm. (c) 1000 ppm. (d) 1700 ppm. Etched with HF-HNO_3-H_2SO_4-H_2O. Source Ref 4

A final example of a corrosion product reaction that can occur in a liquid-metal environment is the oxidation of a solid metal or alloy exposed to molten lead. In some cases, this reaction may actually be beneficial by providing a protective barrier against the highly aggressive lead. This barrier can act in a manner analogous to the behavior observed for the protective oxides formed in high-temperature oxidizing gases. However, this surface product will form and then heal only when the oxygen activity of the melt is maintained at a high level or when oxide formers, such as aluminum or silicon, have been added to the containment alloy to promote protection by the formation of alumina- or silica-containing surface products. Furthermore, reactions of additives to the melt with nitrogen in steel to form nitride surface films are thought to be the cause of reduced corrosion in lead and lead-bismuth systems.

Elemental Transfer of Impurities and Interstitials. The second general type of impurity or interstitial reaction is that of elemental transfer. In contrast to what is defined as corrosion product formation, elemental transfer manifests itself as a net transfer of interstitials or impurities to, from, or across a liquid metal. Although compounds may form or dissolve as a result of such transfer, the liquid-metal atoms do not participate in the formation of stable products by reaction with the containment material. For example, because lithium is such a strong thermodynamic sink for oxygen, exposure of oxygen-containing metals and alloys to this liquid often results in the transfer of oxygen to the melt. Indeed, for oxygen-contaminated niobium and tantalum, high-temperature lithium exposures result in the rapid movement of oxygen into the lithium.

The thermodynamic driving force for light element transfer between solid and liquid metals is normally expressed in terms of a distribution (or partitioning) coefficient. This distribution coefficient is the equilibrium ratio of the concentration of an element, such as oxygen, nitrogen, carbon, or hydrogen, in the solid metal or alloy to that in the liquid. Such coefficients can be calculated from knowledge or estimates of free energies of formation and activities based on equilibrium between a species in the solid and liquid. An example of this approach is its application to decarburization/carburization phenomena in a liquid-metal environment. Carbon transfer to or from the liquid metal can cause decarburization of iron-chromium-molybdenum steels, particularly lower-chromium steels, and carburization of refractory metals and higher-chromium alloys. There have been many studies of such reactions for sodium-steel systems. Although less work has been done in the area of lithium-steel carbon transfer, the same considerations apply. Specifically,

the equilibrium partitioning of the carbon between the iron-chromium-molybdenum steel and the lithium can be described as:

$$\frac{C_C(s)}{C_C(Li)} = (a_{Cr})^{x/y}\left[\frac{C^{\circ}_C(s)}{C^{\circ}_C(Li)}\right]\exp\left(\frac{+\Delta F^{\circ}_{1/2Li_2C_2}}{RT}\right)\exp\left(\frac{-\Delta F^{\circ}_{(1/y)Cr_xC_y}}{RT}\right) \quad \textbf{(Eq 6)}$$

where $C_C(s)$, $C_C(Li)$ is the concentration of carbon in the steel and lithium, respectively; a_{Cr} is the chromium activity of the steel; $C^{\circ}_C(s)$, and $C^{\circ}_C(Li)$ represent the solubilities of carbon in the steel and lithium, respectively; ΔF° represents the free energies of formation of the indicated compounds; x, y is the stoichiometry of the chromium carbide; R is the gas constant; and T is the absolute temperature (in degrees Kelvin).

Equation 6 indicates that in order to decrease the tendency for decarburization of an alloy--that is, to increase the partitioning coefficient, $C_C(s)/C_C(Li)$--the chromium activity of the alloy must be increased or the free energy of formation of the matrix carbide(s) must be lowered (made more negative) by alloy manipulation or thermal treatment to form a more stable carbide dispersion. Experiments in lithium and sodium have shown that these factors have the desired effect. Tempering of iron-chromium-molybdenum steels to yield more stable starting carbides can significantly reduce decarburization by these two liquid metals. With very unstable microstructures, the steel can be severely corroded because of rapid lithium attack of the existing carbides. Furthermore, alloying additions, such as niobium, form very stable carbides and can dramatically reduce decarburization. In addition, as shown by Eq 6, increasing the chromium level of a steel effectively decreases the tendency for carbon loss. With higher-chromium steels, for example, austenitic stainless steels, carburization can then become a problem. If two dissimilar steels of significantly differing chromium activities and/or microstructures are exposed to the same liquid metal, the melt can act as a conduit for the relatively rapid redistribution of carbon between the two solids. Similar considerations would apply for any light element transfer across a liquid metal in contact with dissimilar materials; this can be further complicated by concentration (activity) gradient mass transfer of substitutional elements, as discussed above.

Alloying

Reactions between atoms of the liquid metal and those of the constituents of the containment material may lead to the formation of a stable product on the solid without the participation of impurity or interstitial elements:

$$xM + yL = MxLy \quad \textbf{(Eq 7)}$$

This is not a common form of liquid-metal corrosion particularly with the molten alkali metals, but it can lead to detrimental consequences if it is not understood or expected. Alloying reactions, however, can be used to inhibit corrosion by adding an element to the liquid metal to form a corrosion-resistant layer by reaction of this species with the contaminant material. An example is the addition of aluminum to a lithium melt contained by steel. A more dissolution-resistant aluminide surface layer forms, and corrosion is reduced.

Compound Reduction

Attack of ceramics exposed to liquid metals can occur because of reduction of the solid by the melt. In very aggressive situations, such as when most oxides are exposed to molten lithium, the effective result of such exposure is the loss of structural integrity by reduction-induced removal of the nonmetallic element from the solid. The tendency for reaction under such conditions can be qualitatively evaluated by consideration of the free energy of formation of the solid oxide relative to the oxygen/oxide stability in the liquid metal. Similar considerations apply to the evaluation of potential reactions between other nonmetallic compounds (nitrides, carbides, and so on) and liquid metals.

Considerations in Materials Selection

The above types of corrosion reactions must be considered in materials selection for liquid-metal containment. In many cases, particularly at low temperature or with less aggressive liquids (such as molten steel), liquid-metal corrosion is not an important factor, and many materials, both metals and ceramics, would suffice. Under more severe conditions, however, an understanding of the various types of liquid-metal corrosion is necessary to select or develop a compatible containment material. For example, for applications in high-temperature molten lithium, most oxides would be unstable with respect to this liquid metal, low-chromium steels would decarburize, and alloys containing large amounts of nickel or manganese would suffer extensive preferential dissolution and irregular attack. Materials selection would then be limited to higher-chromium ferritic/martensitic steels or high-purity refractory metals and alloys.

A general summary of the types of the most common corrosion reactions and guidelines for materials selection and/or development is given in Table 1, which also includes typical examples for each category. Because two or more concurrent corrosion reactions are possible, and because consideration of all of the applicable materials consequences may lead to opposite strategies, materials selection for liquid-metal environments can become quite complex and may require optimization of several factors rather than minimization of any particular one. In addition, an assessment of the suitability of a given material for liquid-metal service must be based on the knowledge of its total corrosion response. As in many corrosive environments, a simple numerical rate is not an accurate measurement of the susceptibility of a material when reaction with the liquid metal results in more than one of the modes of attack shown in Fig. 6 and discussed above. Under such circumstances, a measurement reflecting total corrosion damage is much more appropriate for judging the ability of a material to resist corrosion by a particular liquid metal. Additional examples of liquid-metal corrosion can be found in the article "General Corrosion" (see the section "Liquid-Metal Dissolution") in this Volume.

Table 1 Guidelines for materials selection and/or alloy development based on liquid-metal corrosion reactions

Corrosion reaction	**Guidelines**	Example
Direct dissolution	Lower activity of key elements.	**Reduce nickel in lithium, lead, or sodium systems.**
Corrosion product formation	Lower activity of reacting elements.	**Reduce chromium and nitrogen in lithium systems.**
	In case of protective oxide, add elements to promote formation.	**Add aluminum or silicon to steel exposed to lead.**
Elemental transfer	Increase (or add) elements to decrease transfer tendency.	**Increase chromium content in steels exposed to sodium or lithium.**
	Minimize element being transferred.	**Reduce oxygen content in metals exposed to lithium.**
Alloying	Avoid systems that form stable compounds.	**Do not expose nickel to molten aluminum.**
	Promote formation of corrosion-resistant layers by alloying.	**Add aluminum to lithium to form surface aluminides.**
Compound reduction	**Eliminate solids that can be reduced by liquid metal.**	**Avoid bulk oxide-lithium couples.**

Fundamentals of Corrosion in Gases

Samuel A. Bradford, Department of Mining, Metallurgical and Petroleum Engineering, University of Alberta

Introduction

ENGINEERING METALS react chemically when exposed to air or to other more aggressive gases. Whether they survive or not depends on how fast they react. For a few metals, the reaction is so slow that they are virtually unattacked, but for others, the reaction can be disastrous. High-temperature service is especially damaging to most metals because of the exponential increase in reaction rate with temperature.

The most common reactant is oxygen in the air; therefore, all gas-metal reactions are usually referred to as oxidation, using the term in its broad chemical sense whether the reaction is with oxygen, water vapor, hydrogen sulfide (H_2S), or whatever the gas might be. Throughout this article, the process will be called oxidation, and the corrosion product will be termed oxide.

Corrosion in gases differs from aqueous corrosion in that electrochemical principles do not help greatly in understanding the mechanism of oxidation. For gaseous reactions, a fundamental knowledge of the diffusion processes involved is much more useful. The principles of high-temperature oxidation began to be understood only in the 1920s, whereas electrochemistry and aqueous corrosion principles were developed approximately 100 years earlier. The first journal devoted to corrosion in gases (*Oxidation of Metals*) began publication less than 20 years ago.

In this article, a short summary of thermodynamic concepts is followed by an explanation of the defect structure of solid oxides and the effect of these defects on conductivity and diffusivity. The commonly observed kinetics of oxidation will be described and related to the corrosion mechanisms. These mechanisms are shown schematically in Fig. 1. The gas first adsorbs on the metal surface as atomic oxygen. Oxide nucleates at favorable sites and most commonly grows laterally to form a complete thin film. As the layer thickens, it provides a protective scale barrier to shield the metal from the gas. For scale growth, electrons must move through the oxide to reach the oxygen atoms adsorbed on the surface, and oxygen ions, metal ions, or both must move through the oxide barrier. Oxygen may also diffuse into the metal.

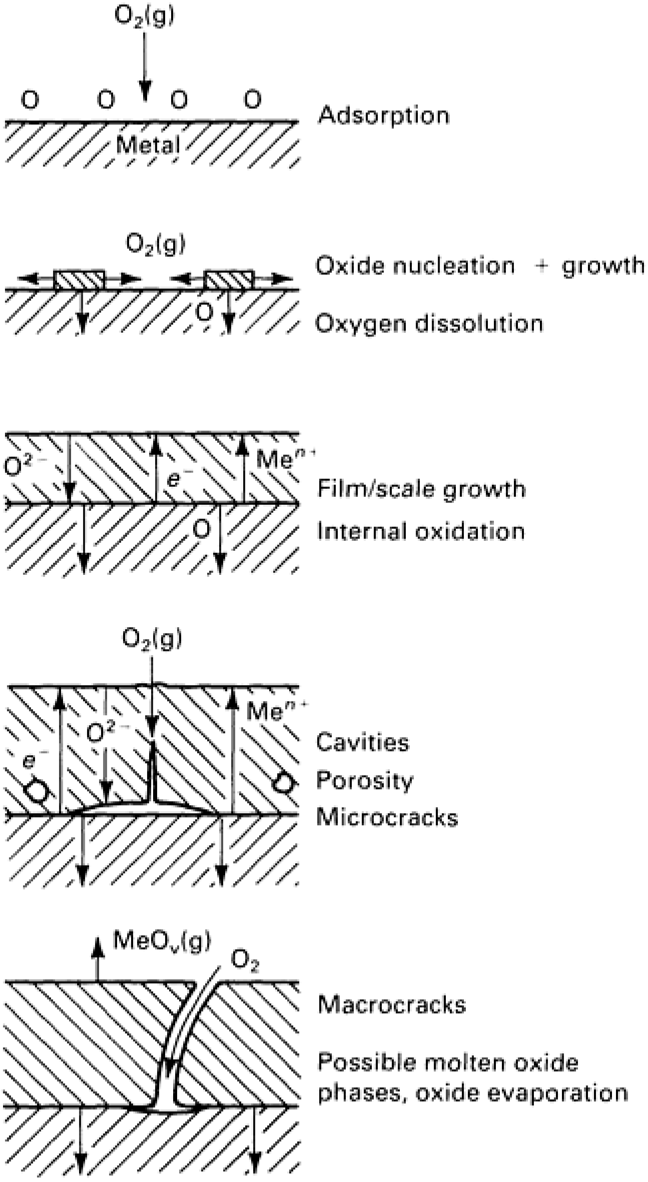

Fig. 1 Schematic illustration of the principal phenomena taking place during the reaction of metals with oxygen. Source: Ref 1

Growth stresses in the scale may create cavities and microcracks in the scale, modifying the oxidation mechanism or even causing the oxide to fail to protect the metal from the gas. Improved oxidation resistance can be achieved by developing better alloys and by applying protective coatings. The basic principles of alloy oxidation, discussed in the section "Alloy Oxidation: The Doping Principle" in this article, are applicable to both alloy development and use of metallic coatings for protection against corrosive gases.

Fundamental Data. Essential to an understanding of the gaseous corrosion of a metal are the crystal structure and the molar volume of the metal on which the oxide builds, both of which may affect growth stresses in the oxide. For high-temperature service the melting point of the metal, which indicates the practical temperature limits, and the structural changes that take place during heating and cooling, which affect oxide adherence, must be known. These data are presented in Table 1 for pure metals. For the oxides, their structures, melting and boiling points, molar volume, and oxide/metal volume ratio (Pilling-Bedworth ratio) are shown in Table 2. The structure data were taken from many sources.

Table 1 Structures and thermal properties of pure metals

Thermodynamics of High-Temperature Corrosion in Gases

Free Energy of Reaction. The driving force for reaction of a metal with a gas is the Gibbs energy change, Δ*G*. For the usual conditions of constant temperature and pressure, Δ*G* is described by the Second Law of Thermodynamics as:

$$\Delta G = \Delta H - T\Delta S \qquad \textbf{(Eq 1)}$$

where Δ*H* is the enthalpy of reaction, *T* is the absolute temperature, and Δ*S* is the entropy change. No reaction will proceed spontaneously unless Δ*G* is negative. If Δ*G* = 0, the system is at equilibrium, and if Δ*G* is positive, the reaction is thermodynamically unfavorable; that is, the reverse reaction will proceed spontaneously.

The driving force Δ*G* for a reaction such as aA + bB = cC + dD can be expressed in terms of the standard Gibbs energy change, ΔG^o by:

$$\Delta G = \Delta G^\circ + RT \ln \frac{a_C^c \, a_D^d}{a_A^a \, a_B^b} \qquad \textbf{(Eq 2)}$$

where the chemical activity, *a,* of each reactant or product is raised to the power of its stoichiometric coefficient, and *R* is the gas constant. For example, in the oxidation of a metal by the reaction:

$$xM + \frac{y}{2} O_2 = M_xO_y$$

M is the reacting metal, M_xO_y is its oxide, and *x* and *y* are the moles of metal and oxygen, respectively, in 1 mol of the oxide.

The Gibbs energy change for the reaction is:

$$\Delta G = \Delta G^\circ + RT \ln \left[\frac{a_{M_xO_y}}{(a_M)^x \cdot (a_{O_2})^{y/2}}\right] \qquad \textbf{(Eq 3)}$$

In most cases, the activities of the solids (metal and oxide) are invarient; that is, their activities = 1 for pure solids, and for the relatively high temperatures and moderate pressures encountered in oxidation reactions, a_{O_2} can be approximated by its pressure. Therefore, at equilibrium where Δ*G* = 0:

$$\Delta G^\circ = -RT \ln \left[\frac{a_{prod}}{a_{react}}\right] = +\frac{y}{2} RT \ln p_{O_2} \qquad \textbf{(Eq 4)}$$

where p_{O_2} is the partial pressure of oxygen.

In solid solutions, such as an alloy, the partial molar Gibbs energy of a substance is usually called its chemical potential μ. If 1 mol of pure A is dissolved in an amount of solution so large that the solution concentration remains virtually unchanged, the Gibbs energy change for the mole of A is:

$$\Delta\overline{G}_A = \mu_A - \mu^\circ_A = RT \ln a_A \qquad \textbf{(Eq 5)}$$

where μ°_A is the chemical potential of 1 mol of pure A, the chemical potential μ_A is the value in the solution, and a_A is the activity of A in the solution.

Metastable Oxides. Thermodynamically unstable oxides are often formed in corrosion by gases. The Gibbs energy of formation of the oxide, ΔG, is less negative than for a stable oxide, but in fact an unstable oxide can often exist indefinitely with no measurable transformation.

A common example is wustite (FeO), which is formed during the hot rolling of steel. Thermodynamically, it is unstable below 570 °C (1060 °F), but it remains the major component of mill scale at room temperature because the decomposition kinetics is extremely slow.

As another example, rapid kinetics can favor the formation of less stable oxide on an alloy. An alloy AB could oxidize to form oxides AO and BO, but if BO is more stable than AO, then any AO formed in contact with B should in theory convert to BO by the reaction:

$$B + AO \rightarrow BO + A$$

Nevertheless, if AO grows rapidly compared with BO and the conversion reaction is slow, AO can be the main oxide found on the alloy.

Thermodynamically unstable crystal structures of oxides are also sometimes found. A growing oxide film tends to try to align its crystal structure in some way with that of the substrate from which it is growing. This epitaxy can cause the formation of an unstable structure that fits the substrate best. For example, cubic aluminum oxide (Al_2O_3) may form on aluminum alloys instead of the stable rhombohedral Al_2O_3.

Free Energy-Temperature Diagrams. Metal oxides become less stable as temperature increases. The relative stabilities of oxides are usually shown on a Gibbs energy-temperature diagram, sometimes called an Ellingham diagram (Fig. 2), for common metals in equilibrium with their oxides. Similar diagrams are available for sulfides, nitrides, and other gas-metal reactions. In Fig. 2, the reaction plotted in every case is:

$$\frac{2x}{y} M + O_2 = \frac{2}{y} M_xO_y$$

That is, 1 mol of O_2 gas is always the reactant so that:

$$\Delta G^o = RT \ln p_{O_2} \qquad \textbf{(Eq 6)}$$

For example, the Gibbs energy of formation of Al_2O_3 at 1000 °C (1830 °F), as read from Fig. 2, is approximately -840 kJ (-200 kcal) for $\frac{2}{3}$ mol of Al_2O_3.

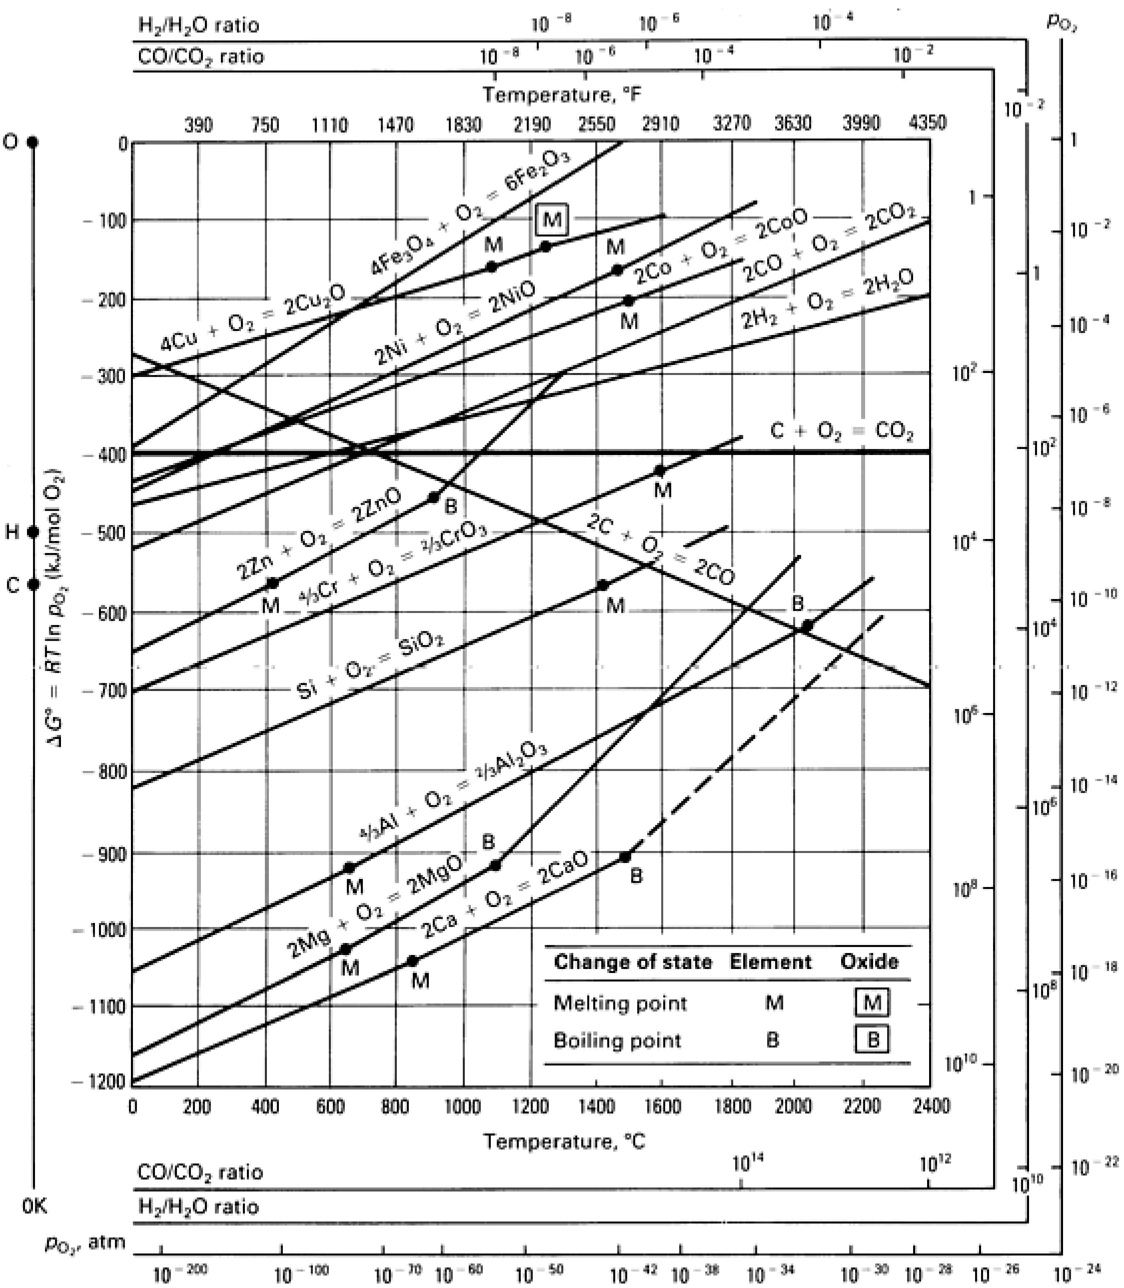

Fig. 2 Standard Gibbs energies of formation of selected oxides as a function of temperature. Source: Ref 4

The equilibrium partial pressure of O_2 is:

$$p_{O_2} = \exp\left(\frac{\Delta G^\circ}{RT}\right) \qquad \textbf{(Eq 7)}$$

and can also be read directly from Fig. 2 without calculation by use of the pO_2 scale along the bottom and right side of the diagram. A straight line drawn from the index point labeled O at the upper left of the diagram, through the 1000 °C (1830 °F) point on the Al/Al_2O_3 line intersects the pO_2 scale at approximately 10^{-35} atm, which is the O_2 partial pressure in equilibrium with aluminum and Al_2O_3 at 1000 °C (1830 °F). This means that any O_2 pressure greater than 10^{-35} atm tends to oxidize more aluminum, while Al_2O_3 would tend to decompose to Al + O_2 only if the pressure could be reduced to below 10^{-35} atm. Obviously, Al_2O_3 is an extremely stable oxide.

The oxidation of a metal by water vapor can be determined in the same way. The reaction is:

$$xM + yH_2O = M_xO_y + yH_2$$

The equilibrium pH_2/pH_2O ratio for any oxide at any temperature can be found by constructing a line from the H index point on the left side of Fig. 2. For example, for the reaction:

$$2Al(l) + 3H_2O(g) = A_2O_3(s) + 3H_2(g)$$

at 1000 °C (1830 °F), the equilibrium H_2/H_2O ratio is 10^{10}. A ratio greater than this will tend to drive the reaction to the left, reducing Al_2O_3 to the metal. A ratio less than 10^{10} produces more oxide.

Similarly, the oxidation of metals by carbon dioxide (CO_2) is also shown on Fig. 2. For the reaction:

$$xM + yCO_2 = M_xO_y + yCO$$

the equilibrium carbon monoxide (CO)/CO_2 ratio is found from the index point marked C on the left side of the diagram. Oxidation of aluminum by CO_2 has an equilibrium CO/CO_2 ratio approximately 10^{10} at 1000 °C (1830 °F).

Isothermal Stability Diagrams. For situations that are more complicated than a single metal in a single oxidizing gas, it is common to fix the temperature at some practical value and plot the other variables of gas pressures or alloy composition against each other. This produces isothermal stability diagrams, or predominance area diagrams, which show the species that will be most stable in any set of circumstances.

One Metal and Two Gases. These diagrams, often called Kellogg diagrams, are constructed from the standard Gibbs energies of formation, ΔG^o, of all elements and compounds likely to be present in the system. For example, for the Ni-O-S system, the ΔG^o values of nickel monoxide (NiO) (s), nickel monosulfide (NiS) (l), nickel sulfate ($NiSO_4$ (s), sulfur dioxide (SO_2 (g), sulfur trioxide (SO_3 (g), and S (l) are needed.

In Fig. 3, the boundary between the Ni (s) and NiO (s) regions represents the equilibrium Ni (s) + $\frac{1}{2}O_2$ (g) = NiO (s); therefore, the diagram shows that at 1250 K any O_2 pressure above about 10^{-11} atm will tend to form NiO from metallic nickel if pS_2 is low. Similarly, S_2 gas pressure greater than about 10^{-7} atm will form NiS from nickel at low pO_2. Also a mixed gas of 10^{-5} atm each of S_2 and O_2 should form nearly the equilibrium ratio of NiO (s) and $NiSO_4$ (s).

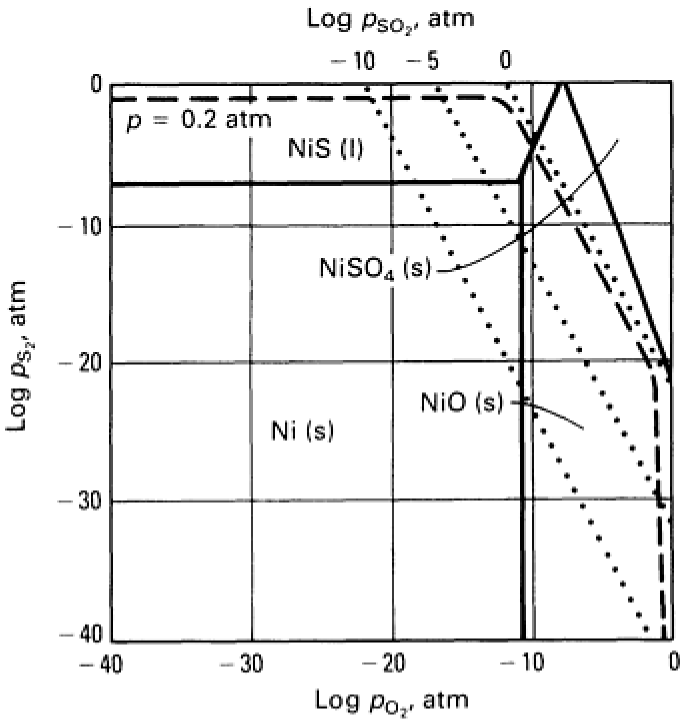

Fig. 3 The Ni-O-S system at 1250 K. Source: Ref 5

If the principal gases of interest were SO_2 and O_2, the same ΔG^o data could be used to construct a diagram of log pO_2 versus pSO_2, or as in Fig. 3, pSO_2 isobars can be added to the figure (the dotted lines). Thus, a mixed gas of 10^{-5} atm each of SO_2 and O_2 will form only NiO at 1250 K, with neither the sulfide nor sulfate being as stable.

When nickel metal is heated to 1250 K in the open air with sulfur-containing gases, $pSO_2 + pS_2 + pO_2 \approxeq 0.2$ atm. The situation is shown by the dashed line in Fig. 3 labeled p = 0.2 atm.

An Alloy System and a Gas. Isothermal stability diagrams for oxidation of many important alloy systems have been worked out, such as that for the Fe-Cr-O system shown in Fig. 4. In this diagram, the mole fraction of chromium in the alloy is plotted against log pO_2 so that for any alloy composition the most stable oxide or mixture of oxides is shown at any gas pressure.

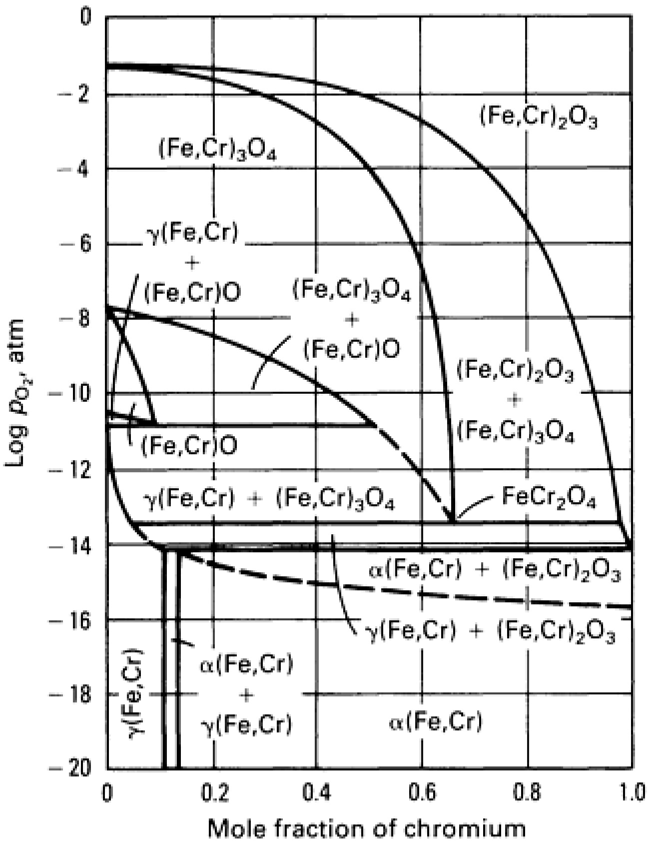

Fig. 4 Stability diagram for the Fe-Cr-O system at 1300 °C (2370 °F)

For an alloy system in gases containing more than one reactive component, the pressures of all but one of the gases must be fixed at reasonable values to be able to draw an isothermal stability diagram in two dimensions. Figure 5 shows an example of such a situation: the Fe-Zn system in equilibrium with sulfur and oxygen-containing gases with SO_2 pressure set at 1 atm and temperature set at 1164 K.

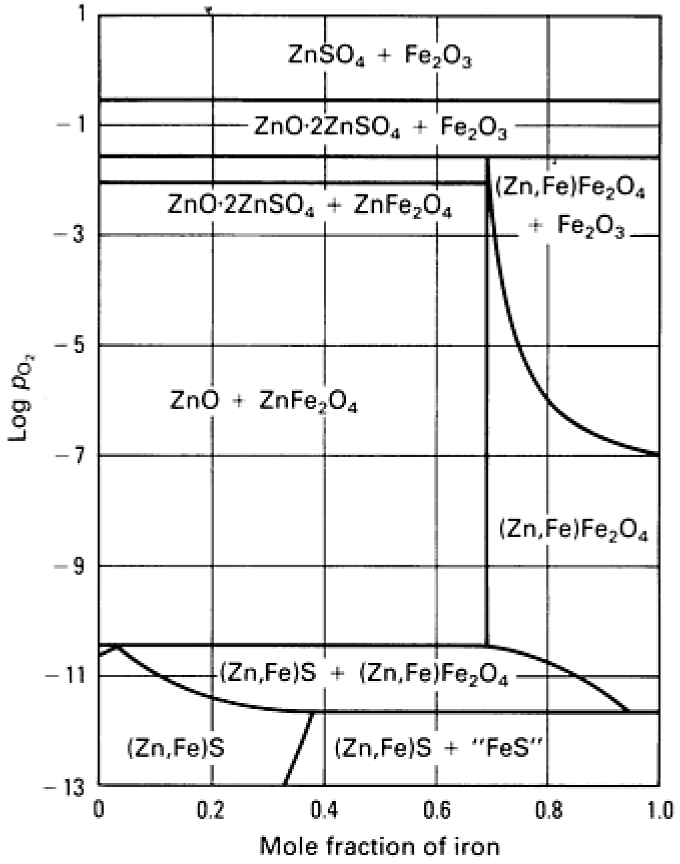

Fig. 5 The Fe-Zn-S-O system for p_{SO_2} = 1 atm at 1164 K. Source: Ref 6

Limitations of Predominance Area Diagrams. Isothermal stability diagrams, like all predominance area diagrams, including Pourbaix potential-pH diagrams, must be read with an understanding of their rules:

- Each area on the diagram is labeled with the predominant phase that is stable under the specified conditions of pressure or temperature. Other phases may also be stable in that area, but in smaller amounts
- The boundary line separating two predominance areas shows the conditions of equilibrium between the two phases.

Also, the limitations of the diagrams must be understood to be able to use them intelligently:

- The diagrams are for the equilibrium situation. Equilibrium may be reached quickly in high-temperature oxidation, but if the metal is then cooled, equilibrium is often not reestablished
- Microenvironments, such as gases in voids or cracks, can create situations that differ from the situations expected for the bulk reactant phases
- The diagrams often show only the major components, omitting impurities that are usually present in industrial situations and may be important
- The diagrams are based on thermodynamic data and do not show rates of reaction

Kinetics of Corrosion in Gases

Mechanisms of Oxidation. In 1923, N.B. Pilling and R.E. Bedworth classified oxidizable metals into two groups: those that formed protective oxide scales and those that did not (Ref 7). They suggested that unprotective scales formed if the volume of the oxide layer was less than the volume of metal reacted. For example, in the oxidation of aluminum:

$$2Al + \frac{3}{2}O_2 \rightarrow Al_2O_3$$

the Pilling-Bedworth ratio is:

$$\frac{\text{Volume of 1 mol of } Al_2O_3}{\text{Volume of 2 mol of Al}}$$

where the volumes can be calculated from molecular and atomic weights and the densities of the phases.

If the ratio is less than 1, as is the case for alkali and alkaline earth metals, the oxide scales are usually unprotective, with the scales being porous or cracked due to tensile stresses and providing no efficient barrier to penetration of gas to the metal surface. If the ratio is more than 1, the protective scale shields the metal from the gas so that oxidation can proceed only by solid-state diffusion, which is slow even at high temperatures. If the ratio is much over 2 and the scale is growing at the metal/oxide interface, the large compressive stresses that develop in the oxide as it grows thicker may eventually cause the scale to spall off, leaving the metal unprotected.

Exceptions to the Pilling-Bedworth theory are numerous, and it has been roundly criticized and rejected by many. Its main flaw is the assumption that metal oxides grow by diffusion of oxygen inward through the oxide layer to the metal. In fact, it is much more common for metal ions to diffuse outward through the oxide to the gas. Also, the possibility of plastic flow by the oxide or metal was not considered. Nevertheless, historically, Pilling and Bedworth made the first step in achieving understanding of the processes by which metals react with gases. And although there may be exceptions, the volume ratio, as a rough rule-of-thumb, is usually correct. The Pilling-Bedworth volume ratios for many common oxides are listed in Table 2.

Defect Structure of Ionic Oxides. Ionic compounds can have appreciable ionic conductivity due to Schottky defects and/or Frenkel defects. Schottky defects are combinations of cation vacancies and anion vacancies in the proper ratio necessary to maintain electrical neutrality. Figure 6(a) illustrates a Schottky defect in a stoichiometric ionic crystal. With Schottky defects, the ions must diffuse into the appropriate adjacent vacancies to allow mass transfer and ionic electrical conductivity.

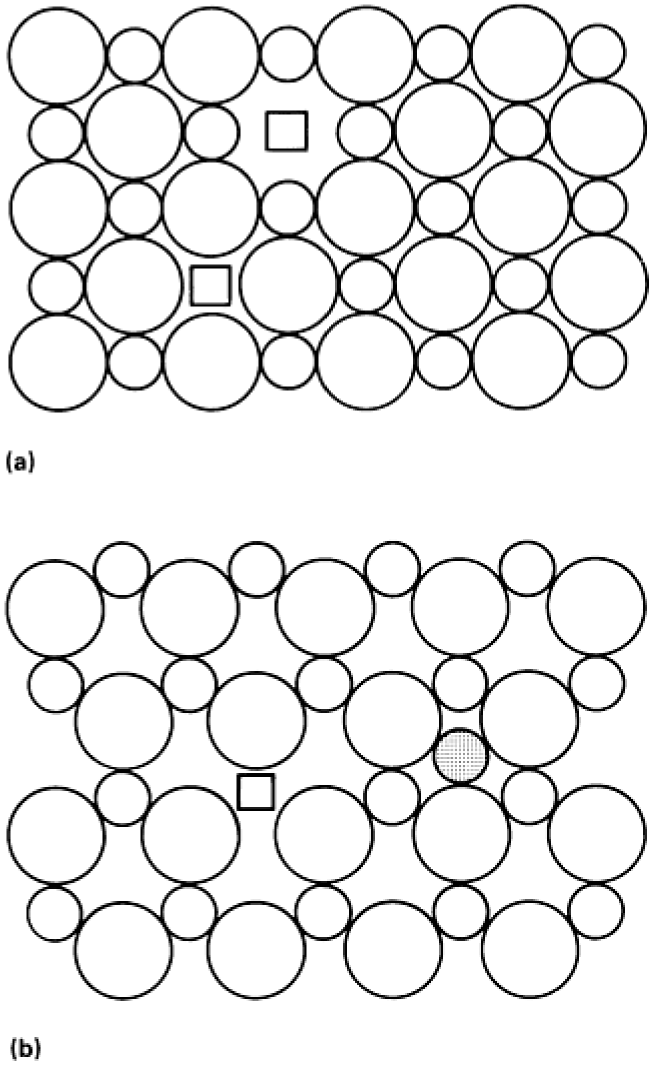

Fig. 6 Defects in ionic crystals. (a) Schottky defect. (b) Frenkel defect. Vacancies are indicated by open squares. Interstitial ion is shown as shaded circle.

Frenkel defects are also present in ionic crystals in such a way that electrical neutrality and stoichiometry are maintained (Fig. 6b). This type of defect is a combination of a cation vacancy and an interstitial cation. Metal cations are generally much smaller than the oxygen anions. Limited ionic electrical conductivity is possible in such crystals by diffusion of cations interstitially and by diffusion of cations into the cation vacancies.

Metallic oxides are seldom, if ever, stoichiometric and cannot grow by mere diffusion by Schottky and Frenkel defects. For oxidation to continue when a metal is protected by a layer of oxide, electrons must be able to migrate from the metal, through the oxide, to adsorbed oxygen at the oxide/gas interface. Nevertheless, Schottky and Frenkel defects may provide the mechanism for ionic diffusion necessary for oxide growth.

Defect Structure of Semiconductor Oxides. Oxides growing to provide protective scales are electronic semiconductors that also allow mass transport of ions through the scale layer. They may be conveniently categorized as *p*-type, *n*-type, and amphoteric semiconductors. Examples of the three types are listed in Table 3 (Ref 8).

Table 3 Classification of electrical conductors: oxides, sulfides, and nitrides

Metal-excess semiconductors (*n*-type)
BeO, MgO, CaO, SrO, BaO, BaS, ScN, CeO_2, ThO_2, UO_3, U_3O_8, TiO_2, TiS_2, (Ti_2S_3), TiN, ZrO_2, V_2O_5, (V_2S_3), VN, Nb_2O_5, Ta_2O_5, (Cr_2S_3), MoO_3, WO_3, WS_2, MnO_2, Fe_2O_3, $MgFe_2O_4$, $NiFe_2O_4$, $ZnFe_2O_4$, $ZnCo_2O_4$, ($CuFeS_2$), ZnO, CdO, CdS, HgS(red), Al_2O_3, $MgAl_2O_4$, $ZnAl_2O_4$, Tl_2O_3, (In_2O_3), SiO_2, SnO_2, PbO_2
Metal-deficit semiconductors (*p*-type)
UO_2, (VS), (CrS), Cr_2O_3, (<1250 °C, or 2280 °F), $MgCr_2O_4$, $FeCr_2O_4$, $CoCr_2O_4$, $ZnCr_2O_4$, (WO_2), MoS_2, MnO, Mn_3O_4, Mn_2O_3, ReS_2, FeO, FeS, NiO, NiS, CoO, (Co_3O_4), PdO, Cu_2O, Cu_2S, Ag_2O, $CoAl_2O_4$, $NiAl_2O_4$, (Tl_2O), Tl_2S, (GeO), SnS, (PbO), (Sb_2S_3), (Bi_2S_3)
Amphoteric conductors
TiO[(a)], Ti_2O_3[(a)], VO[(a)], Cr_2O_3 (>1250 °C, or 2280 °F), MoO_2, FeS_2, (OsS_2), (IrO_2), RuO_2, PbS

Source: Ref 8

(a) Metallic conductors.

The p-type metal-deficit oxides are nonstoichiometric with cation vacancies present. They will also have some Schottky and Frenkel defects that add to the ionic conductivity. A typical example is NiO, a cation-deficient oxide that provides the additional electrons needed for ionic bonding and electrical neutrality by donating electrons from the 3*d* subshells of a fraction of the nickel ions. In this way, for every cation vacancy present in the oxide, two nickelic ions (Ni^{3+}) will be present (Fig. 7). Each Ni^{3+} has a low-energy positively charged electron hole that electrons from other nickelous ions (Ni^{2+}) can easily move into. The positive or *p*-type semiconductors carry most of their current by means of these positive holes.

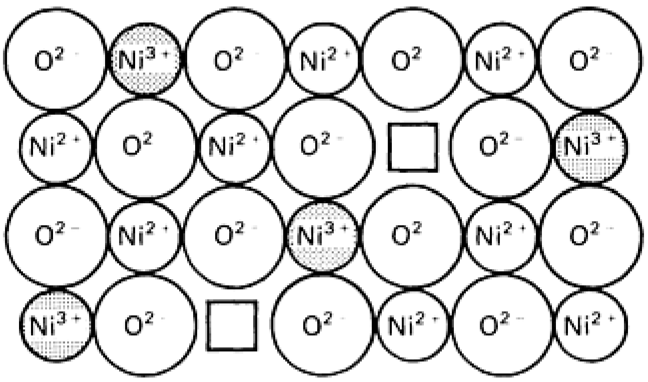

Fig. 7 Illustration of the ionic arrangement in *p*-type NiO scale. Cation vacancies are indicated as open squares. The N^{3+} cations are shaded.

Cations can diffuse through the scale from the Ni/NiO interface by cation vacancies, to the NiO/ gas interface where they react with adsorbed oxygen. Electrons migrate from the metal surface, by electron holes, to the adsorbed oxygen atoms,

which then become oxygen anions. In this way, while Ni^{2+} cations and electrons move outward through the scale toward the gas, cation vacancies and electron holes move inward toward the metal. Consequently, as the scale thickens, the cation vacancies tend to accumulate to form voids at the Ni/NiO interface.

The n-type semiconductor oxides have negatively-charged free electrons as the major charge carriers. They may be either cation excess or anion deficient. Beryllium oxide (BeO) typifies the cation-excess oxides because the beryllium ion (Be^{2+}) is small enough to move interstitially through the BeO scale. Its structure is shown in Fig. 8.

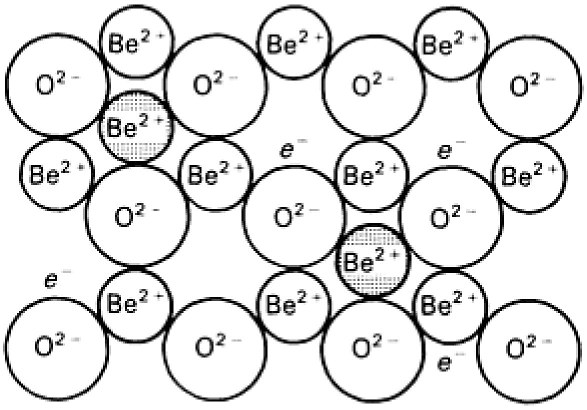

Fig. 8 Illustration of the ionic arrangement in *n*-type cation-excess BeO. Interstitial cations are shaded; free electrons are indicated as *e*$^-$.

Oxygen in the gas adsorbs on the BeO surface and picks up free electrons from the BeO to become adsorbed O^{2-} ions, which then react with excess Be^{2+} ions that are diffusing interstitially from the beryllium metal. The free electrons coming from the metal surface as the beryllium ionizes travel rapidly through vacant high-energy levels. As with *p*-type oxides, the cation-excess *n*-type oxides grow at the oxide/gas interface as cations diffuse outward through the scale.

Another group of *n*-type semiconducting oxides is anion deficient, as exemplified by zirconium dioxide (ZrO_2). In this case, although most of the cations are contributing four electrons to the ionic bonding, a small fraction of the zirconium cations only contributes two electrons to become the zirconium ion Zr^{2+}. Therefore, to maintain electrical neutrality, an equal number of anion vacancies must be present in the oxide. This arrangement is shown in Fig. 9. The oxide grows at the metal/oxide interface by inward diffusion of O^{2-} through the anion vacancies in the oxide.

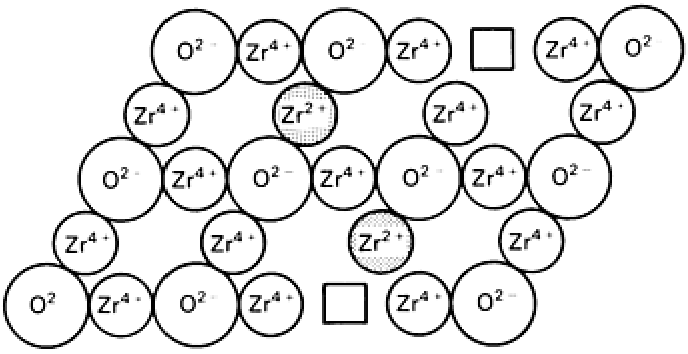

Fig. 9 Illustration of the ionic arrangement in *n*-type anion-deficient ZrO_2. Anion vacancies are indicated as open squares; Zr^{2+} ions are shaded.

Amphoteric Oxides. A number of compounds can be nonstoichiometric with either a deficiency of cations or a deficiency of anions. An example is lead sulfide (PbS), which has a minimum in electrical conductivity at the stoichiometric composition. Thus, if the composition is $Pb_{<1}S$, it is *p*-type and if it is $PbS_{<1}$, it is *n*-type.

Similarly, intrinsic semiconductors, such as cupric oxide (CuO), have a few electron holes in their valence band and an equal number of free electrons in their nearly vacant conduction band. Current is carried both by migration of electron holes in the low-energy bonding levels and by free electrons in the higher-energy conduction levels.

Oxide Texture: Amorphous Oxides. In the very early stages of oxidation and especially at low temperatures, some oxides appear to grow with an amorphous structure. In general, these oxide glasses contain more oxygen than metal in their formulas so that oxygen triangles or tetrahedra form around each of the metal ions. The random network ring structures that result allow large anions or molecular oxygen to move through them more readily than the smaller cations do. Amorphous oxides tend to crystallize as they age. Examples are silicon dioxide (SiO_2), Al_2O_3, tantalum pentoxide (Ta_2O_5), and niobium pentoxide (Nb_2O_5).

In contrast, oxides with M_2O and MO formulas have structures in which the small cations can move readily. They are apparently always crystalline. Examples are NiO, cuprous oxide (Cu_2O), and zinc oxide (ZnO).

Oxide Texture: Epitaxy. As a crystalline oxide grows on a metal surface, it often aligns its crystal structure to be compatible with the structure of the metal substrate. This epitaxy finds the best fit, not a perfect fit, between the two crystal structures. For example, either (111) or (001) planes of Cu_2O grow parallel to the Cu (001) plane with the <110> directions of Cu_2O parallel to the <110> of copper (Ref 9).

Stress develops in an epitaxial oxide layer as it grows because of the slight misfit between the oxide and metal crystals. The stress is likely to produce dislocation arrays in the oxide that would be paths of easy diffusion for mass transport through the film. A mosaic structure may develop in the oxide because of the growth stresses. The mosaic structure consists of small crystallites with orientations very slightly tilted or twisted with respect to each other. The boundaries between the crystallites are dislocation arrays that serve as easy diffusion paths.

Stresses in epitaxial layers increase as the films grow thicker until at some point the bulk scale tends to become polycrystalline and epitaxy is gradually lost. Epitaxy may last up to about 50 nm in many cases, but it is seldom strong much over 100 nm.

Oxide Texture: Preferred Orientation. As oxidation produces thicker layers, the oxide grain size increases. Crystals that are favorably oriented for growth will grow at the expense of their neighboring grains until the oxide surface consists of a few large grains with similar orientation. The variation in growth rate of different oxide grains produces the roughening of the scaled surface that is commonly observed.

Linear Oxidation Reaction Rates. If the metal surface is not protected by a barrier of oxide, the oxidation rate usually remains constant with time, and one of the steps in the oxidation reaction is rate controlling rather than a transport process being rate controlling. This situation is to be expected if the Pilling-Bedworth ratio is less than 1, if the oxide is volatile or molten, if the scale spalls off or cracks due to internal stresses, or if a porous, unprotective oxide forms on the metals.

The linear oxidation rate is:

$$\frac{dx}{dt} = k_L \qquad \textbf{(Eq 8)}$$

where x is the mass or thickness of oxide formed, t is the time of oxidation, and k_L is the linear rate constant. The rate constant is a function of the metal, the gas composition and pressure, and the temperature.

Integrated, the linear oxidation equation is:

$$x = k_L t \qquad \textbf{(Eq 9)}$$

The oxidation never slows down; after long times at high temperatures, the metal will be completely destroyed. Figure 10 shows the relationship between oxide mass and time for linear oxidation.

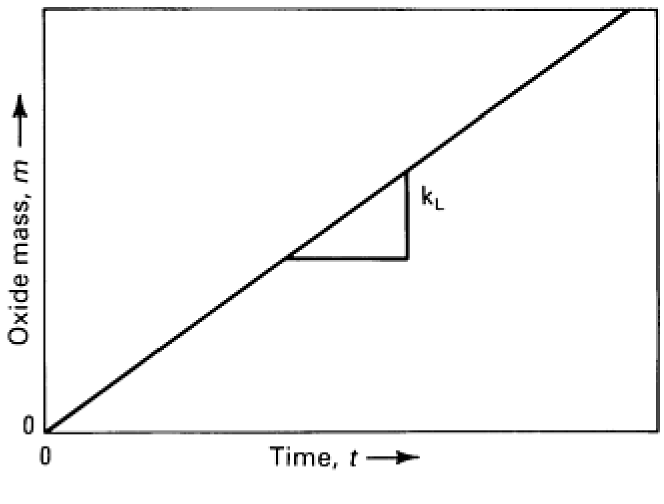

Fig. 10 Linear oxidation kinetics

Logarithmic and Inverse Logarithmic Reaction Rates. At low temperatures when only a thin film of oxide has formed (for example, under 100 nm), the oxidation is usually observed to follow either logarithmic or inverse logarithmic kinetics. Transport processes across the film are rate controlling, with the driving force being electric fields across the film. The logarithmic equations is:

$$x = k_e \log (at + 1) \qquad \textbf{(Eq 10)}$$

where k_e and a are constants.

The inverse logarithmic equation is:

$$\frac{1}{x} = b - k_i \log t \qquad \textbf{(Eq 11)}$$

where b and k_i are constants. Under the difficult experimental conditions involved in making measurements in the thin film range, it is nearly impossible to distinguish between logarithmic and inverse logarithmic oxidation. Both equations have two constants that can be adjusted to fit the data quite well. Metals oxidizing with logarithmic or inverse log kinetics reach a limiting film thickness at which oxidation apparently stops. Figure 11 shows the curves for both logarithmic and inverse logarithmic kinetics.

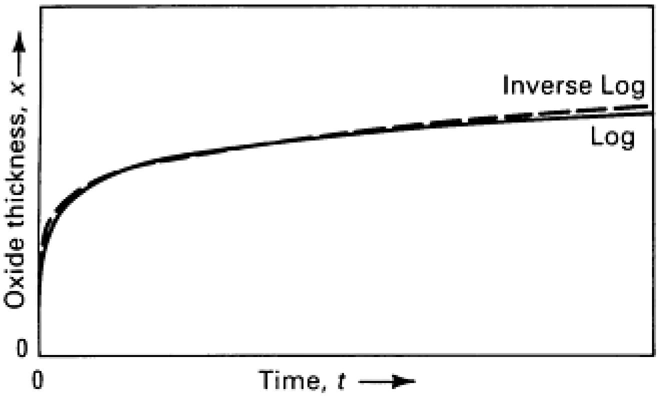

Fig. 11 Logarithmic and inverse logarithmic oxidation kinetics

Parabolic Kinetics. When the rate-controlling step in the oxidation process is the diffusion of ions through a compact barrier layer of oxide with the chemical potential gradient as the driving force, the parabolic rate law is usually observed. As the oxide grows thicker, the diffusion distance increases, and the oxidation rate slows down. The rate is inversely proportional to the oxide thickness, or:

(Eq 12)

Upon integration, the parabolic equation is obtained:

(Eq 13)

where k_p is the parabolic rate constant. Figure 12 shows the parabolic oxidation curve.

Fig. 12 Parabolic oxidation kinetics

Other Reaction Rate Equations. A number of other kinetics equations have been fitted to the experimental data, but it is believed that they describe a combination of the mechanisms described above, rather than any new basic process. A cubic relationship:

$$x^3 = k't \quad \textbf{(Eq 14)}$$

has often been reported. It can be shown mathematically to be an intermediate stage between logarithmic and parabolic kinetics.

Initial Oxidation Processes: Adsorption and Nucleation. To begin oxidation, oxygen gas is chemisorbed on the metal surface until a complete two-dimensional invisible oxide layer forms. Some atomic oxygen also dissolves into the metal at the same time. After the monolayer forms, discrete nuclei of three-dimensional oxide appear on the surface and begin expanding laterally at an ever-increasing rate. The nuclei may originate at structural defects, such as grain

boundaries, impurity particles, and dislocations. The concentration of nuclei depends primarily on the crystal orientation of the metal, with more nuclei forming at high pressures and low temperatures.

These oxide islands grow outward rapidly by surface diffusion of adsorbed oxygen until a complete film three or four monolayers thick covers the metal. The oxidation rate then drops abruptly. If chemisorption were still the rate-controlling (slow) step in oxidation after the thin film is completed, a logarithmic rate law should be observed. A logarithmic rate law is found, but it is more likely the result of the strong electric field across the film that affects the oxidation.

Thin-Film Mechanisms. A large number of theories have been proposed to explain the oxidation mechanism at low temperatures or in the early stages of high-temperature oxidation where logarithmic kinetics is commonly observed. None of the theories is completely accepted yet, and perhaps none is completely correct, but they have common threads of agreement that indicate reasonably well what is happening. Some of the most important theories will be briefly described.

The Cabrera-Mott theory, probably the best established theory of thin film oxidation, applies to films up to about 10 nm thick (Ref 10). It proposes that electrons from the metal easily pass through the thin film by tunneling to reach adsorbed oxygen at the oxide/gas surface and form oxygen anions. A potential of approximately 1 V is set up between the external oxide surface and the metal. For a film 1 nm thick, the field strength would be 10^7 V/cm, powerful enough to pull cations from the metal and through the film. The rate-controlling step is the transfer of cations (or anions) into the oxide or the movement of the ions through the oxide. The electric field reduces this barrier. The structure of the oxide determines whether cations or anions migrate through the oxide. As the film grows thicker, the field strength decreases until it has so little effect on the ions that the rate-controlling mechanism changes.

N. Cabrera and N.F. Mott developed an inverse logarithmic kinetic equation to describe the mechanism. A logarithmic equation is more commonly observed, but it can be derived from the Cabrera-Mott mechanism if the activation energy for ionic migration is a function of film thickness. Such a situation would exist if the oxide film were initially amorphous and became more crystalline with aging, giving a constant field strength through the film instead of a constant voltage.

The Hauffe-Ilschner theory, a modification of Mott's original concept of a space charge developed across the oxide film, proposes that quantum-mechanical tunneling of electrons is the rate-controlling step (Ref 11). After the film thickness reaches about 10 nm, tunneling becomes increasingly difficult, and the observed reaction rate decreases greatly. For film thicknesses up to perhaps 20 nm, a logarithmic equation results. For films from 20 to 200 nm thick, the inverse logarithmic relationship holds. Potentials across thin films have been measured; a change in sign of the potential is interpreted as a change from electronic transport control to ionic transport control.

The Grimley-Trapnell theory (Ref 12). T.B. Grimley and B.M.W. Trapnell used the Cabrera-Mott model, but assumed a constant electric field instead of a constant potential. They assumed that the adsorbed oxygen layer would always be complete, even at high temperatures and low pressure. The adsorbed oxygen would take electrons from cations in the oxide, not from the metal, so that a space charge would develop at the MO/O^-_{ads} interface and be independent of the oxide thickness. If the rate-controlling step is diffusion of cations through vacancies, logarithmic kinetics should be observed. If some other process is rate controlling, linear kinetics is most likely.

The Uhlig theory, developed by H.H. Uhlig and amplified by Fromhold, also predicts logarithmic kinetics at temperatures up to 600 K (Ref 13). The rate-controlling step is the thermal emission of electrons from the metal into the oxide (or electron holes from the adsorbed O^- to the oxide) under the combined effects of induced potential and applied field. The field is created by the diffusing ions. Because growth of the film depends on the electronic work function of the metal, the theory explains oxidation rate changes at crystal and magnetic transformations; most other theories do not.

Solid-State Diffusion. Diffusion processes in solids play a key role in the oxidation of metals. Mass transfer may be the result of diffusion of metal ions from the metal surface through the oxide layer to the adsorbed oxygen anions at the oxide/gas interface or the result of the diffusion of anions inward through the oxide to the metal. The diffusion of atomic oxygen into the metal from the oxide or the gas can also be involved. Within an alloy, the diffusion of oxidizable metal atoms toward the surface and the back diffusion of unreactive atoms from the metal surface inward to the unaltered alloy can occur.

Diffusion Mechanisms. Atoms or ions diffuse through solids by any of several mechanisms. The most common is vacancy diffusion. A metal crystal always contains large numbers of vacancies, while ionic oxides contain Schottky and Frenkel defects that also involve vacancies. An atom or ion sitting on a regular lattice site can diffuse by jumping to a

vacant identical site nearby (Fig. 13a). For metal atoms, this is relatively easy because the jump distances are short. For ionic crystals, the jump distances are much longer because cation sites are surrounded by anion sites, and vice versa.

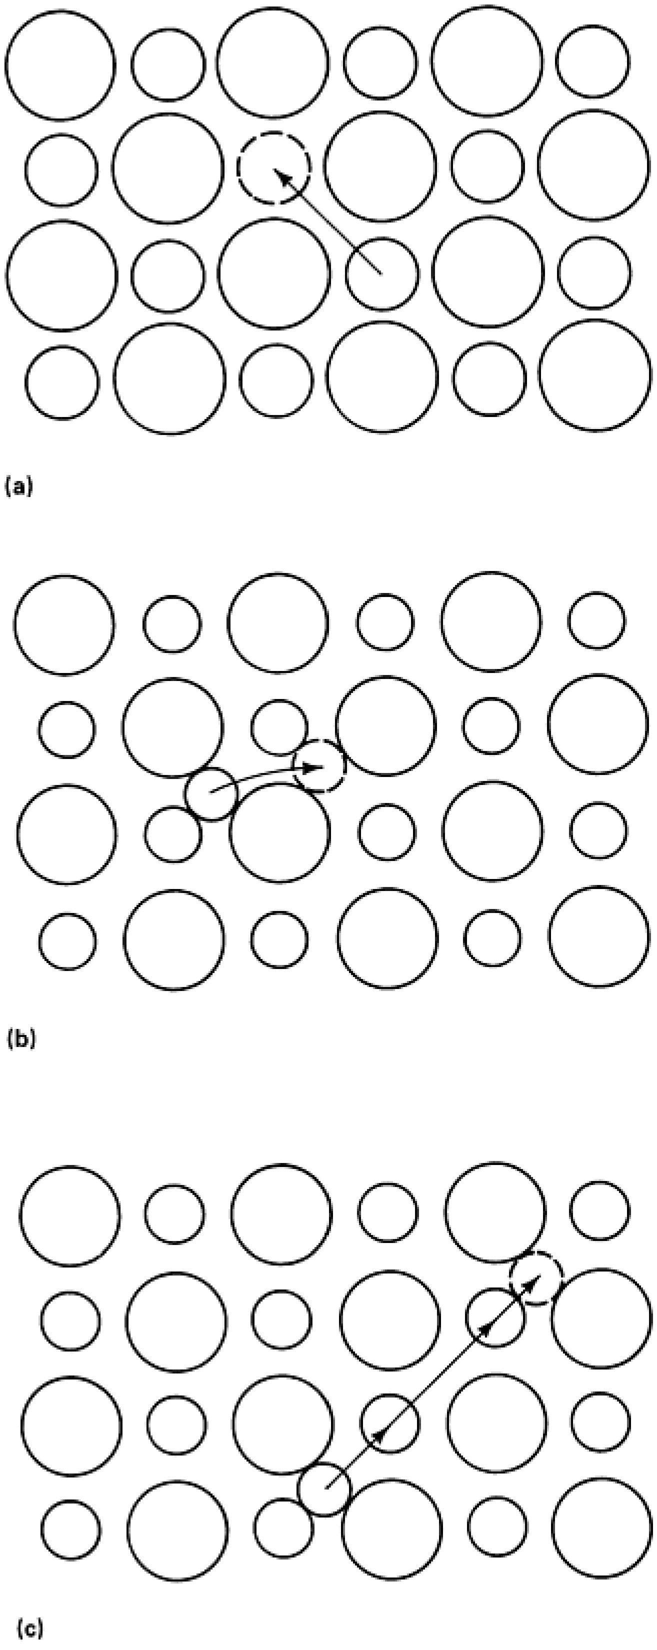

Fig. 13 Diffusion mechanisms. (a) Vacancy diffusion. (b) Interstitial diffusion. (c) Crowdion diffusion

Small interstitial atoms diffuse readily from one interstitial position to another. In ionic oxides, the cations may diffuse interstitially, but the anions are usually not small enough to do so. Interstitial diffusion is shown in Fig. 13(b).

In ionic crystals, an interstitial ion may crowd into a regular lattice site, displacing an ion, which is forced to move into an interstitial position or to the next lattice site. This "crowdion" effect may extend for several atomic spacings along a line or equivalent direction. Figure 13(c) shows "crowdion" diffusion.

Fick's law. In 1855, A. Fick formulated his two laws of diffusion for the simplest sort of diffusion system: a binary system at constant temperature and pressure, with net movement of atoms in only one direction. This is the usual situation for diffusion through an oxide growing on a pure metal.

Fick's first law states that the rate of mass transfer is proportional to the concentration gradient. Mathematically:

$$J = -D\left(\frac{\partial c}{\partial x}\right) \qquad \textbf{(Eq 15)}$$

where J is the flux or mass diffusing per second through a unit cross section in the concentration gradient ($\partial c/\partial x$), and D is the diffusion coefficient, or diffusivity in square centimeters per second, which is a function of the diffusing atoms, the structure through which they are diffusing, and the temperature. For diffusion of cations through a protective oxide, the entry of cations into the oxide at the metal/oxide interface will very nearly equal the flux of cations delivered to the oxygen at the oxide/gas interface.

For diffusion of oxygen into the metal, the concentration of oxygen changes with time inside the metal. Fick's second law describes this change as:

$$\frac{\partial c}{\partial t} = \frac{\partial}{\partial x}\left(D\frac{\partial c}{\partial x}\right) \qquad \textbf{(Eq 16)}$$

Equation 16 must be solved for the particular geometry and boundary conditions involved (flat or round specimens, and so on). For oxygen atoms diffusing inward from a flat surface, with a constant diffusivity and a constant interfacial concentration, the solution to Eq 16 for the concentration of oxygen at any distance × from the metal surface is:

$$\frac{C_M - C_X}{C_M - C_O} = \text{erf}\left(\frac{x}{2\sqrt{Dt}}\right) \qquad \textbf{(Eq 17)}$$

(assuming D is independent of composition) where C_M is the oxygen concentration at the metal/oxide interface, C_x is the concentration at time t and distance x from the surface, and C_O is the initial constant concentration at any distance x when $t = 0$. The error function, erf, is tabulated in many books on probability. Figure 14 shows the variation of C_x with x.

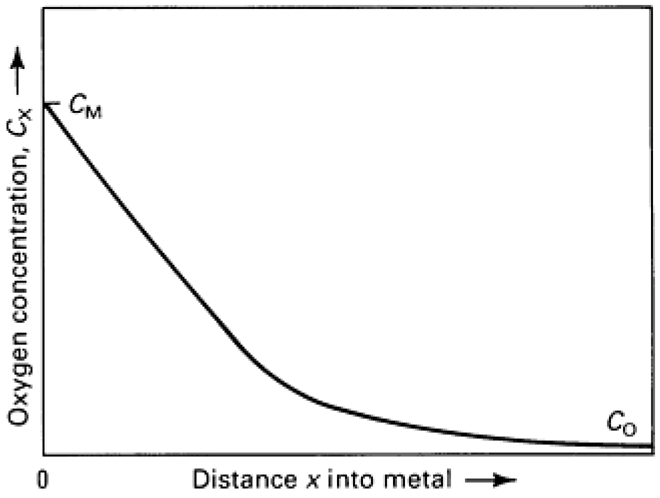

Fig. 14 Nonsteady-state diffusion. Fick's second law

As oxidation proceeds, C_M and C_O remain constant; therefore, for any fixed value of C_x, Eq 17 reduces to:

$$X \propto \sqrt{t} \qquad \textbf{(Eq 18)}$$

The Diffusion Coefficient. The diffusion coefficient D in rather stoichiometric compounds can usually be assumed to be proportional to the defect concentration. The diffusion coefficient can also vary with crystal orientation in noncubic crystals. For oxides that are epitaxial or have a preferred orientation, the diffusivity can be several times more or less than it would be for a random polycrystalline oxide. The diffusion coefficient D is independent of orientation in cubic crystals. Temperature has a major effect on the diffusion coefficient; D increases exponentially with temperature according to the Arrhenius equation:

$$D = D_o \exp\left(\frac{-Q}{RT}\right) \qquad \textbf{(Eq 19)}$$

where D_o is a constant called the frequency factor that is a function of the diffusing species and the diffusion medium, Q is the activation energy for diffusion, R is the gas constant, and T is the absolute temperature. Activation energies for interstitial diffusion are much lower than those for vacancy diffusion.

The activation energy is a measure of the temperature dependence of a diffusion process. A high value of Q means that the diffusion proceeds much more rapidly at high temperatures, but very much slower at low temperatures. Typical values of D_o and Q for diffusion in oxides are listed in Table 4.

Table 4 Selected diffusion data in metal oxides

Metal oxide	Temperature		Frequency factor[(a)] cm^2/s	Activation energy for diffusion	
	°C	°F		kJ/mol	BTU/mol
Copper in Cu_2O	800-1050	1470-1920	0.12	151.0	**143**
Nickel in NiO	740-1400	1365-2550	0.017	234	**222**
Oxygen in Fe_2O_3	1150-1250	2100-2280	10^{11}	610	**578**
Iron in Fe_3O_4	750-1000	1380-1830	5.2	230	**218**
Iron in $Fe_{0.92}O$	690-1010	1275-1850	0.014	126.4	**120**
Chromium in Cr_2O_3	1000-1350	1830-2460	4000	420	**398**
Oxygen in UO_2	450-600	840-1110	2.6 × 10-5$_{-5}$	124	**118**
Magnesium in MgO	**1400-1600**	**2550-2910**	**0.25**	**330**	**313**

Source: Ref 6

(a) The frequency factor, D_o, is a function of the diffusing species and the diffusion medium. See Eq 19 and corresponding text.

If the diffusivity D is plotted on a natural logarithm (base e) scale as a function of $1/T$, the slope of the resulting straight line is $-Q/R$. If the graph shows two intersecting lines, it indicates that one diffusion mechanism is operative at low temperatures, such as grain-boundary diffusion, and that another mechanism with a higher activation energy, such as volume diffusion, has gained control at high temperatures.

Effect of Impurities. All oxides contain some substitutional impurity cations from the alloy before oxidation or from the gas phase during oxidation. Although the solubility limit for foreign ions is low, they can have a great effect on diffusivity in the oxide, and consequently on oxidation rate.

In *p*-type oxides, such as NiO, any substitutional cation with a valence greater than the Ni^{2+} ion it replaces tends to increase the concentration of cation vacancies. Two aluminum ions (Al^{3+}) replacing two Ni^{2+} ions in the structure also supply two extra valence electrons to the oxygen so that an additional cation vacancy in the oxide structure will be necessary to maintain the balance of charge between anions and cations. Additional cation vacancies in the NiO increase the diffusivity of Ni^{2+} cations through the oxide. Conversely, substitutional cations with a valence lower than +2 should reduce diffusion in NiO, reducing the number of cation vacancies. Cations with a +2 valence should have little effect on diffusion if substituting for Ni^{2+} ions.

For *n*-type oxides, the effect is reversed, if Al^{3+} is substituted for some titanium ions (Ti^{4+}) in titanium dioxide (TiO_2), more anion vacancies will be present in the oxide. For every two Al^{3+} ions substituted, one additional O^{2-} vacancy must be present in the oxide to maintain the electronic charge balance. Diffusion of oxygen ions inward then increases because of

the increase in anion vacancy concentration. Higher valent impurity ions would decrease oxygen diffusion in *n*-type oxides.

The impurity effect is especially important for diffusion at low temperatures at which the native defect concentration is low; therefore, the activation energy is associated with only the movement of ions. At high temperatures, the activation energy increases because it involves formation of defects as well as the motion of the ions.

Short-Circuit Diffusion. The activation energies for diffusion along line and surface defects in solids are much less than those for volume diffusion. Dislocations, grain boundaries, porosity networks, and external surfaces offer rapid diffusion paths at low temperatures at which volume diffusion has virtually stopped. In metals, diffusion along dislocations is more important than volume diffusion below about one-half of the absolute melting point. At high temperatures, of course, volume diffusion predominates in both metals and oxides.

Wagner Theory of Oxidation. C. Wagner derived the parabolic rate equation for scale growth on a metal in which diffusion of ions or electrons is rate controlling. Before the full derivation is presented, a simplified treatment will be given to emphasize the main features of diffusion-controlled oxidation.

It was assumed that a pure metal is oxidizing and that growth of a dense single-phase oxide occurs by a single diffusion mechanism, for example, the diffusion of cations outward through a *p*-type oxide. The rate of growth in oxide thickness, dx/dt, is then proportional to the flux of metal ions J_M by Fick's first law (Eq 15):

$$\frac{dx}{dt} = k'J_M = -k'D_M \frac{(C_M - C_O)}{x} \qquad \textbf{(Eq 20)}$$

or

$$\frac{dx}{dt} = \frac{\text{Constant}}{x} \qquad \textbf{(Eq 21)}$$

Integrating with the limit that at time $t = 0$ the oxide thickness $x = 0$, the parabolic equation results:

$$x^2 = kt \qquad \textbf{(Eq 22)}$$

The Wagner Derivation. The flow of ions in the x direction through a growing oxide layer depends on the concentration of ions and their drift velocity. The ion flux J_i is:

$$J_i = C_i u_i \text{ mol/cm}^2 \cdot \text{s} \qquad \textbf{(Eq 23)}$$

where C_i is the molar concentration per cubic centimeter, and u_i is the average drift velocity. The drift velocity depends on the mobility of the ions and the force acting on them. The mobility B_i is the terminal ion velocity when it is acted upon by a unit force per ion.

A charged ion (valence z_i) moving through the oxide is acted upon by two forces: the chemical potential gradient, $d\mu_i/dx$, and an electric potential gradient, dE/dx. The flux is then:

$$J_i = \frac{-C_i B_i}{N} \left(\frac{d\mu_i}{dx} + z_i F \frac{dE}{dx} \right) \qquad \textbf{(Eq 24)}$$

where N is Avogadro's number, and F is Faraday's constant.

Equation 24 can be used to calculate the oxidation rate in terms of more easily measured quantities, such as electrical conductivity or diffusivity of the ions. In terms of electrical conductivity:

$$\frac{C_i B_i}{N} = \frac{\sigma_i}{z_i^2 F^2} \qquad \textbf{(Eq 25)}$$

where σ_i is the partial electrical conductivity due to the movement of the particular type of ion being considered. The total conductivity, σ, of the oxide would be the sum of the conductivity due to movement of cations (σ_c), the conductivity due to movement of anions (σ_a), and the conductivity due to movement of electrons or electron holes (σ_e):

$$\sigma = \sigma_c + \sigma_a + \sigma_c \qquad \textbf{(Eq 26)}$$

In oxides with predominant electronic conduction: $\sigma_e \gg (\sigma_c + \sigma_a)$.

Substituting Eq 25 into Eq 24 yields:

$$J_i = \frac{-\sigma_i}{z_i^2 F^2}\left(\frac{d\mu_i}{dx} + z_i F \frac{dE}{dx}\right) \qquad \textbf{(Eq 27)}$$

As the oxide forms, the flow of positive ions outward through the scale must be balanced by the flow of negative ions and electrons to maintain a charge balance, or:

$$zJ_c - J_e = z_a J_a \qquad \textbf{(Eq 28)}$$

where the subscripts c, a, and e refer to cations, anions, and electrons respectively. Wagner derived Eq 28 in a general form in which all these fluxes were considered (Ref 14). In most actual oxidation processes, the cation diffusion controls the scale growth, while anion diffusion is negligible; therefore, the diffusion equation will be derived for that situation, as demonstrated in Ref 4. It could be derived for anion diffusion in the same manner.

From Eq 27, the cation flux is:

$$J_c = \frac{-\sigma_c}{z_c^2 F^2}\left(\frac{d\mu_c}{dx} + z_c F \frac{dE}{dx}\right) \qquad \textbf{(Eq 29)}$$

the anion flux is essentially zero, and the electron flux or electron hole flux is:

$$J_e = \frac{-\sigma_e}{F^2}\left(\frac{d\mu_e}{dx} - F \frac{dE}{dx}\right) \qquad \textbf{(Eq 30)}$$

Combining Eq 28, 29, and 30 to solve for the electric potential gradient yields:

$$\frac{dE}{dx} = \frac{-1}{F(\sigma_c + \sigma_e)}\left(\frac{\sigma_c d\mu_c}{z_c dx} - \sigma_e \frac{d\mu_e}{dx}\right) \qquad \textbf{(Eq 31)}$$

Eliminating *dE*/*dx* from Eq 29 by substituting Eq 31 gives:

$$J_c = \frac{-\sigma_c \sigma_e}{z_c^2 F^2 (\sigma_c + \sigma_e)} \left(\frac{d\mu_c}{dx} + z_c \frac{d\mu_e}{dx} \right) \qquad \textbf{(Eq 32)}$$

Everywhere throughout the oxide, the equilibrium:

$$M = M_c^{z+} + z_c e^-$$

is established almost instantly; therefore, the chemical potential of the metal is:

$$\mu_M = \mu_c + z_c \mu_c \qquad \textbf{(Eq 33)}$$

Thus, Eq 32 can be rewritten as:

$$J_c = \frac{-\sigma_c \sigma_e}{z_c^2 F^2 (\sigma_c + \sigma_e)} \frac{d\mu_M}{dx} \qquad \textbf{(Eq 34)}$$

which can be integrated over the entire scale thickness *x* from the inner, or metal/oxide, surface at which the metal chemical potential is $\overset{i}{\mu}_M$ to $\overset{o}{\mu}_M$ at the outer, or oxide/gas, surface. This gives a cation flux of:

$$J_c = \frac{-1}{z_c^2 F^2 x} \int_{\overset{i}{\mu}_M}^{\overset{o}{\mu}_M} \frac{\sigma_c \sigma_e}{(\sigma_c + \sigma_e)} \, d\mu_M \qquad \textbf{(Eq 35)}$$

Because the oxide is an electronic semiconductor with $\sigma_c \ll \sigma_e \simeq 1$, Eq 35 can be rewritten as:

$$J_c = \frac{-1}{z_c^2 F^2 x} \int_{\overset{i}{\mu}_M}^{\overset{o}{\mu}_M} \sigma_c \, d\mu_M \qquad \textbf{(Eq 36)}$$

From Eq 23, the flux is also:

$$J_c = C_c \frac{dx}{dt} \ \mathrm{mol/cm^2 \cdot s} \qquad \textbf{(Eq 37)}$$

if the cation concentration C_c is expressed in moles per cubic centimeter. The rate-determining drift velocity of the cations, *dx*/*dt* is therefore also the growth rate of the scale. The growth rate is then:

$$\frac{dx}{dt} = \left[\frac{-1}{z_c^2 F^2 C_c} \int_{\overset{i}{\mu}_M}^{\overset{o}{\mu}_M} \sigma_c \, d\mu_M \right] \frac{1}{x} \qquad \textbf{(Eq 38)}$$

where the bracketed term is the parabolic rate constant k_p, which can be mathematically evaluated. Agreement between calculated and experimental measurements of k_p has been found to be quite close for numerous oxidation systems.

If anion diffusion predominates when metal M reacts with nonmetal A so that $\sigma_a \gg \sigma_c$, the parabolic rate equation will be:

$$\frac{dx}{dt} = \left[\frac{1}{z_a^2 F^2 C_A} \int_{\mu_A^i}^{\mu_A^o} \sigma_A d\mu_A\right] \frac{1}{x} \qquad \textbf{(Eq 39)}$$

Equation 23 can also be evaluated in terms of diffusivities *D* instead of conductivities by means of the Nernst-Einstein equation:

$$D_i = \frac{B_i RT}{N} \qquad \textbf{(Eq 40)}$$

where B_i, is the absolute mobility of the particle, *R* is the gas constant, and *T* is the absolute temperature. Comparison of Eq 40 with Eq 25 gives:

$$D_i = \frac{\sigma_i RT}{z_i^2 F^2 C_i} \qquad \textbf{(Eq 41)}$$

so that Eq 38 can be rewritten as:

$$\frac{dx}{dt} = \left[\frac{-1}{RT} \int_{\mu_M^i}^{\mu_M^o} D_c d\mu_M\right] \frac{1}{x} \qquad \textbf{(Eq 42)}$$

and Eq 39 becomes:

$$\frac{dx}{dt} = \left[\frac{1}{RT} \int_{\mu_A^i}^{\mu_A^o} D_a d\mu_A\right] \frac{1}{x} \qquad \textbf{(Eq 43)}$$

The good agreement between parabolic rate constants calculated from conductivities or diffusivities and the rate constants measured in oxidation experiments indicates that Wagner's assumptions are generally valid. The principal assumptions about the scale are (Ref 4):

- The oxide scale is completely compact and adherent.
- Diffusion of ions through the scale is the rate-controlling process
- Thermodynamic equilibrium exists at both the metal/oxide and oxide/gas interfaces
- Thermodynamic equilibrium exists locally throughout the scale
- The oxide deviates only slightly from stoichiometry

Effects of Temperature and Pressure. The parabolic oxidation rate (Eq 12) increases exponentially with temperature, following the Arrhenius equation:

$$k_p = k_o \exp \frac{-Q}{RT} \qquad \textbf{(Eq 44)}$$

where k_o is a constant that is a function of the oxide composition and the gas pressure. For cation-deficient or cation-excess oxides where $D_c \gg D_a$, the activation energy *Q* for oxide growth has been found to be the same as the activation energy for diffusion of cations in the oxide. For anion-deficient oxides, such as ZrO_2, where $D_a \gg D_c$, the activation

energy for oxide growth is the same as that for anion diffusion, verifying that ionic diffusion is the rate-controlling process.

The activity of oxygen can be approximated by its partial pressure so that the chemical potential of oxygen becomes:

$$d\mu_o = \frac{1}{2} RT\, d \ln pO_2 \qquad \textbf{(Eq 45)}$$

Equation 45 can be used to modify Eq 39 to:

$$\frac{dx}{dt} = \left[\frac{RT}{2z_a^2 F^2 C_A} \int_{p^i_{O_2}}^{p^o_{O_2}} \sigma_o \, d \ln p_{O_2}\right] \frac{1}{x} \qquad \textbf{(Eq 46)}$$

where $p^o_{O_2}$ is the oxygen gas pressure, and $p^i_{O_2}$, is the dissociation pressure of the oxide in equilibrium with the metal. Equation 46 can be used if the variation in ionic conductivity with pressure is known.

For a cation-deficient *p*-type oxide, such as NiO, growth occurs at the oxide/gas interface where:

$$O_2 + 2Ni = 2NiO + 2V''_{Ni} + 4\dot{h}$$

The symbol V''_{Ni} stands for a doubly charged cation vacancy, and $\dot{h}$ represents an electron hole. Thermodynamic equilibrium is established at the interface so that at any time the equilibrium constant K is:

$$K = \frac{[V''_{Ni}]^2[\dot{h}]^4}{p_{O_2}} \qquad \textbf{(Eq 47)}$$

where the brackets indicate the concentration (approximately the activity) of the species enclosed; thus, $[V''_{Ni}]$ is the concentration of cation vacancies. The solids nickel and NiO can be assumed not to change in concentration at the interface. Because there must be two electron holes for every cation vacancy, or $2[V''_{Ni}] = [\dot{h}]$, then:

$$pO_2 \propto [V''_{Ni}]^2 [\dot{h}]^4 \propto [\dot{h}]^6 \qquad \textbf{(Eq 48)}$$

The oxide conductivity σ is proportional to the hole concentration, so that:

$$\sigma \propto p_{O_2}^{1/6} \qquad \textbf{(Eq 49)}$$

for a *p*-type oxide with divalent cations. In general, for any *p*-type oxide,

$$\sigma \propto p_{O_2}^{1/n} \qquad \textbf{(Eq 50)}$$

where, theoretically, *n* is generally a number between 5 and 8 that depends on the metal valence.

Substituting into Eq 46, the oxidation rate is:

$$\frac{dx}{dt} \propto [(p^{o}_{O_2})^{1/n} - (p^{i}_{O_2})^{1/n}] \quad \textbf{(Eq 51)}$$

In most cases, the ambient oxygen pressure $p^{o}_{O_2}$ is much greater than the oxide dissociation pressure $p^{i}_{O_2}$ so that:

$$\frac{dx}{dt} \propto (p^{o}_{O_2})^{1/n} \quad \textbf{(Eq 52)}$$

for *p*-type oxides.

For *n*-type oxides, such as BeO, in which the oxide grows at the oxide/gas interface the reaction is:

$$O_2 + 2Be^{2+}_{i} + 4\,e^{-} = 2BeO$$

where Be^{2+}_{i} is an interstitial cation, and e^{-} is a free electron. The equilibrium established will be:

$$K = \frac{1}{p_{O_2}[Be^{2+}_{i}]^2[e^{-}]^4} \quad \textbf{(Eq 53)}$$

For every Be^{2+} released into the oxide, two electrons are also freed so that $[e^{-}] = 2\,[Be^{2+}_{i}]$. The oxygen pressure is:

$$p_{O_2} \propto \frac{1}{[Be^{2+}_{i}]^2[e^{-}]^4} \propto \frac{1}{[e^{-}]^6} \propto \frac{1}{\sigma^6} \quad \textbf{(Eq 54)}$$

making the oxidation rate:

$$\frac{dx}{dt} \propto [(p^{i}_{O_2})^{-1/n} - (p^{o}_{O_2})^{-1/n}] \quad \textbf{(Eq 55)}$$

Because $p^{i}_{O_2} \ll p^{o}_{O_2}$, the oxidation rate should be practically independent of the ambient oxygen pressure for *n*-type oxides. In fact, this prediction has not been observed experimentally, because the oxides are invariably doped by electrically active impurity atoms.

Properties of Scales

Multiple Scale Layers. A pure metal that can oxidize to more than one valence will form a series of oxides, usually in separate layers. For example, iron has valences of +2 and +3 at high temperatures and forms wustite FeO, magnetite ($FeO \cdot Fe_2O_3$, commonly written as Fe_3O_4), and hematite (Fe_2O_3) scale layers. The layers will be arranged with the most metal-rich oxide next to the metal, progressively less metal in each succeeding layer, and finally the most oxygen-rich layer on the outside. Within each layer a concentration gradient exists with higher metal ion concentration closest to the metal.

If the oxygen partial pressure in the gas is so low that it is below the dissociation pressures of the outer oxygen-rich oxides, then only the thermodynamically stable, inner oxides will form. In general, the lowest valence, inner oxide will usually be *p*-type because of the ease with which electron holes and cation vacancies can form. The outermost oxide is

often *n*-type because of its anion vacancies. A scale consisting of an inner layer with cations diffusing outward and an outer layer with anions diffusing inward will grow at the oxide/oxide interface.

Relative Thickness. When diffusion is rate controlling, the relative thickness of the layers is proportional to the relative diffusion rates if no porosity develops in the layers. For compact layers growing by a single diffusion mechanism, the ratio of thicknesses should be related to the ratio of the parabolic rate constants by:

$$\frac{x_1}{x_2} = \left(\frac{k_{p1}}{k_{p2}}\right)^{1/2} \quad \textbf{(Eq 56)}$$

where subscripts 1 and 2 refer to layers 1 and 2. The thickness ratio, consequently, is a constant and does not change with time. Because the ions diffusing through the various layers are likely to be different and because the crystal structures of the layers are certainly different, the thickness ratio is commonly found to be quite far from unity. One layer is usually much thicker than the others.

When diffusion controls the growth of each layer, the entire scale will appear to follow the parabolic oxidation equation with an effective parabolic rate constant k_p. However, this effective parabolic rate constant does not follow the Arrhenius equation (Eq 44) unless the thickness ratios remain far from unity throughout the temperature range, that is, unless one layer predominates at all temperatures. If an inner scale predominates, its growth is independent of oxygen pressure, but if the outermost scale is the major part of the scale, the rate constant will vary with oxygen pressure.

Paralinear Oxidation. With some metals, the oxidation begins as parabolic, but the protective scale gradually changes to a nonprotective outer layer. If the inner protective layer remains at a constant thickness, then the diffusion through the layer of constant thickness results in a linear rate of oxidation. The outer layer may become unprotective by sublimation, transformation to a porous layer, fracture, and so on. This type of oxidation behavior that is initially parabolic and gradually transforms to linear is termed paralinear oxidation (Fig. 15). The mass of a metal *m* consumed at time *t* can be calculated from:

$$m = \frac{k_p}{k_l} \ln \frac{k_p}{k_p - k_l(m - k_l t)} \quad \textbf{(Eq 57)}$$

where k_p is the parabolic rate constant for formation of the inner layer, and k_1 is the linear rate constant for formation of the outer layer (Ref 15).

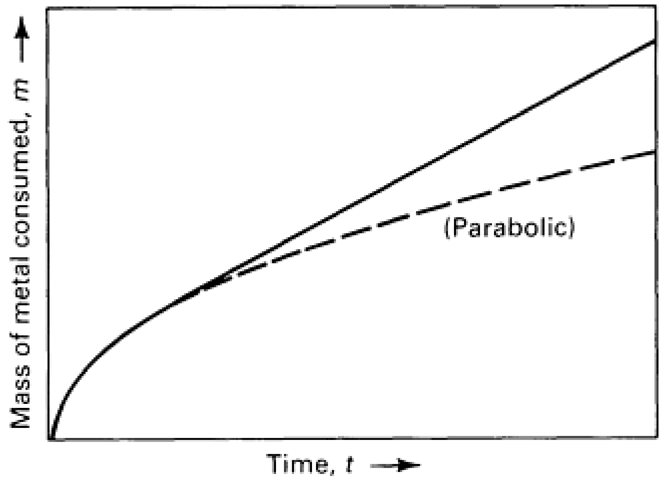

Fig. 15 Paralinear oxidation. Linear region is tangential to initial parabolic curve

Oxide Evaporation. At very high temperatures, the evaporation of a protective oxide may limit its protective qualities or remove the oxide entirely, because evaporation rates increase exponentially with temperature. The platinum metals and refractory metals in particular tend to have volatile oxides. Suboxides and unusual valences are also often found at high temperatures; aluminum, for example, forms only one stable solid oxide, Al_2O_3, but it vaporizes as Al_2O and AlO. Evaporation may be much worse in gases containing water or halide vapor if volatile hydroxides (hydrated oxides) or oxyhalides form.

Theoretically, the evaporation rate should be directly proportional to the sublimation vapor pressure of the oxide if no evaporating molecules return to the surface, but at gas pressures above 10^{-3} to 10^{-4} atm, a gaseous stagnant boundary layer slows the escape of evaporated oxide molecules. The boundary layer becomes thinner at higher gas velocities, leading to higher evaporation losses.

As evaporation removes material from the oxide layer, diffusion through the oxide increases until the two rates finally become equal. The oxide thickness then remains constant, and the metal has oxidized paralinearly. If more than one oxide layer protects the metal, the higher-valent outermost oxide always has the higher vapor pressure and is the more volatile.

Stresses in Scales. As oxide scales grow, stresses develop that influence the protective properties of the scale. During growth, recrystallization may occur in either the metal or oxide to alter the stress situation radically. Changes in temperature usually have a great effect on the stress state for metals in engineering service. Stress relief, if it damages the scale, will result in partial or complete loss of oxidation protection.

Growth Stresses. The magnitude of growth stresses is not well defined by the Pilling-Bedworth ratio (discussed earlier in the section "Kinetics of Corrosion in Gases" in this article), indicating other factors also play a major role. Crystalline oxides will attempt to grow on a metal substrate with an epitaxial relationship. However, because the fit of the oxide crystal on the metal crystal is never perfect, the stresses that develop tend to limit the epitaxy to about the first 50 nm of oxide. Therefore, the stresses in thick scales are not greatly affected by the original epitaxy.

Polycrystalline oxides develop stresses along their grain boundaries because of more rapid growth of grains oriented in preferred directions. Short-circuit diffusion along oxide grain boundaries may lead to oxide formation at the boundaries that increases compressive stresses. Furthermore, any second phases or foreign inclusions in a metal may oxidize at a rate different from that of the parent metal and create high stresses within the oxide.

The compositional variation across a scale due to deviations from stoichiometry also create stresses within the oxide. Wustite is an important example, varying from $Fe_{0.95}O$ in equilibrium with the metal to as little as $Fe_{0.84}O$ in equilibrium with Fe_3O_4 at 1370 °C (2500 °F).

Composition will also tend to vary in a metal alloy in which one component is preferentially oxidized. If diffusion in the alloy is too slow to maintain a constant composition at the metal/oxide interface, stress develops in the metal. Similarly, any diffusion of oxygen into the metal from the oxide creates compressive stresses in the metal.

Surface geometry will contribute an additional effect to the growth stresses in an adherent oxide. Whether the contribution is compressive or tensile depends on whether the surface profile is convex or concave and whether the scale grows at the oxide/gas interface or at the metal/oxide interface. Figure 16 shows the four possibilities for changes in stress state in an oxide scale as it grows, assuming that the original growth stresses are compressive (Ref 16).

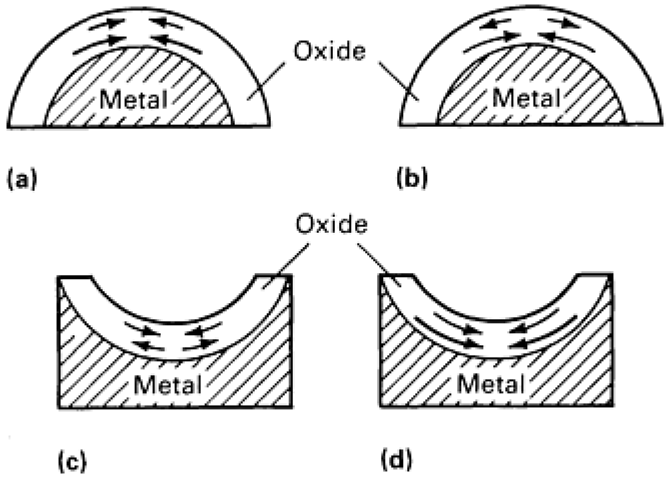

Fig. 16 Stress development on curved surfaces. (a) Oxide grows by cation diffusion on a convex surface. (b) Oxide grows by anion diffusion on a convex surface. (c) Oxide grows by cation diffusion on a concave surface. (d) Oxide grows by anion diffusion on a concave surface.

In Fig. 16(a), for a convex surface on which oxide grows at the oxide/gas interface by cation diffusion outward through the scale, the metal surface will gradually recede, increasing the compressive stresses at the metal/oxide interface as long as adhesion is maintained. Figure 16(b) shows oxidation of a convex surface on which the oxide grows at the metal/oxide interface by anion diffusion inward. The compressive stresses that develop at the metal/oxide interface are due only to the volume change of the reaction. Oxide that is pushed away from the growth area will gradually reduce its compressive stress until the outer surface may even be in tension.

For concave surfaces, Fig. 16(c) illustrates oxide growth at the oxide/gas interface by outward diffusion of cations. As the metal surface recedes, the compressive growth stresses are reduced and may eventually even become tensile if oxidation continues long enough. Figure 16(d) shows growth on a concave surface by anion diffusion inward for reaction at the metal/oxide interface. Very high compressive stresses develop during growth until they exceed the cohesive strength of the oxide.

Transformation Stresses. Preferential oxidation of one component in an alloy may alter the alloy composition to the point that a crystallographic phase transformation occurs. A change in temperature could also cause crystallographic transformation of either metal or oxide. The volume change accompanying a transformation creates severe stresses in both the metal and the oxide. Some oxides form initially in an amorphous structure and gradually crystallize as the film grows thicker. The tensile stress created by volume contraction may partially counteract the compressive growth stresses usually present.

Thermal Stresses. A common cause of failure of oxide protective scales is the stress created by cooling from the reaction temperature. The stress generated in the oxide is directly proportional to the difference in coefficients of linear expansion between the oxide and the metal. Examples of the coefficients are listed in Table 5 for a few important metal/oxide systems. In most cases, the thermal expansion of the oxide is less than that of the metal; therefore, compressive stress develops in the oxide during cooling. Multilayered scales will develop additional stresses at the oxide/oxide interface.

Table 5 Coefficients of linear thermal expansion of metals and oxides

System	**Oxide coefficient, m/m·K**	**Metal coefficient, m/m·K**	Temperature range	
			°C	°F
Fe/FeO	12.2×10^{-6}	15.3×10^{-6}	100-900	**212-1650**
Fe/Fe_2O_3	14.9×10^{-6}	15.3×10^{-6}	20-900	**70-1650**
Ni/NiO	17.1×10^{-6}	17.6×10^{-6}	20-1000	**70-1830**
Co/CoO	15.0×10^{-6}	14.0×10^{-6}	25-350	**75-660**
Cr/Cr_2O_3	7.3×10^{-6}	9.5×10^{-6}	100-1000	**212-1830**
Cu/Cu_2O	4.3×10^{-6}	18.6×10^{-6}	20-750	**70-1380**
Cu/CuO	$\mathbf{9.3 \times 10^{-6}}$	$\mathbf{18.6 \times 10^{-6}}$	**20-600**	**70-1110**

Stress Relief. Stresses develop in oxide scale during growth or temperature change. The oxide may develop porosity as it grows. If temperatures are high, the stress may reach the yield strength of either the metal or the oxide so that plastic deformation relieves the stress. A brittle oxide may crack. A strong oxide may remain intact until the internal stresses exceed the adhesive forces between metal and oxide so that the oxide pulls loose from the metal. The ways in which stresses can be relieved are discussed below.

Porosity. For oxides that grow by cation diffusion outward through cation vacancies (*p*-type oxides, such as NiO), the vacancies are created at the oxide/gas interface and diffuse inward through the scale as they exchange places with an equal number of outward-diffusing cations. The vacancies are annihilated within the oxide, at the metal/oxide interface, or within the metal, depending on the system.

In some oxides, the vacancies collect together within the oxide to form approximately spherical cavities. The preferred sites for cavity formation are along paths of rapid diffusion, such as grain boundaries and dislocation lines.

Vacancies that are annihilated at the metal/oxide interface may cause detachment of the scale because voids that form there reduce adhesion of oxide to metal. If detachment is only partial, the oxidation rate slows down because the cross-sectional area available for diffusion decreases.

Plastic Flow of Oxide. Dislocations form in the oxide as it grows epitaxially on the metal because of the crystallographic lattice mismatch between oxide and metal. As the growth continues, these glissile slip dislocations move out into the oxide by the process of glide. Once out in the oxide, they become sessile growth dislocations.

Although dislocations are present in the oxide, slip is not an important process in relieving growth stress (Ref 17). Plastic deformation of the oxide occurs only at high temperatures at which creep mechanisms become operative. The three important creep mechanisms in oxides are grain-boundary sliding. Herring-Nabarro creep, and climb. Grain-boundary sliding allows relative motion along the inherently weak boundaries. Herring-Nabarro creep allows grain elongation by diffusion of ions away from grain-boundary areas in compression over to boundaries in tension. Within the grains, dislocation climb is controlled by diffusion of the slower moving ions. The creep rate increases with amount of porosity in the oxide.

Cracking of Oxide. Tensile cracks readily relieve growth stresses in the oxide scale. As shown in Fig. 16(b) and 16(c), tensile stresses may eventually develop in oxide growing on curved surfaces and cause fracture. In the case of anion diffusion inward on convex surfaces, if oxygen diffuses on into the metal, the tensile stresses near the oxide/gas interface develop much more quickly.

Shear cracks can form in oxide having high compressive stresses near the metal surface, as shown in Fig. 16(a) and 16(d), if the scale cohesion is weak and adhesion to the metal is strong. If the metal/oxide interface is planar, a shear crack initiating at the interface can extend rapidly across the surface. However, if the interface is rough because oxidation has concentrated at the grain boundaries of the metal and keyed the oxide into the metal, rapid crack extension may be prevented and scale adherence may be improved.

Periodic cracking of a protective oxide results in the parabolic oxidation being interrupted by a sudden increase in rate when the gas can react directly with the bare metal surface. As oxide begins to cover the metal surface again, parabolic oxidation is resumed. A typical oxidation curve for this repeated process is shown in Fig. 17. The time periods between successive parabolic steps are sometimes fairly uniform, because a critical scale thickness is reached that causes cracks to be initiated. The overall oxidation of the metal becomes approximately a slow linear process.

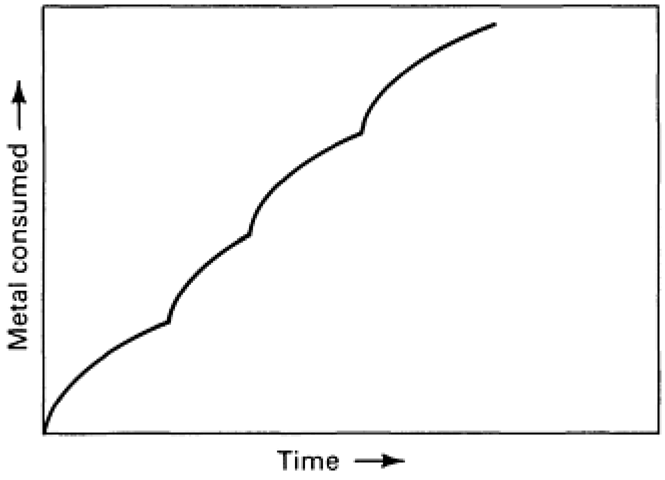

Fig. 17 Periodic cracking of scale

Occasionally, a metal oxidizes parabolically until the scale cracks or spalls off, and from that time on, the oxidation is linear. The oxide, originally protective, completely loses its protective properties. The breakaway oxidation (Fig. 18) commonly occurs if many cracks form continuously and extend quickly through the oxide. It can also occur for alloys that have had one component selectively oxidized. When the protective scale spalls off, the metal surface is so depleted in the component that the same protective scale cannot re-form. Breakaway oxidation leaves bare metal continually exposed, unlike paralinear oxidation (Fig. 15), in which an inner protective scale always remains.

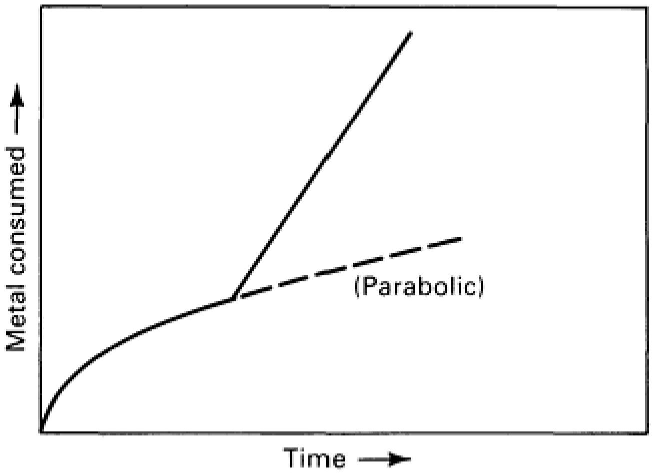

Fig. 18 Breakaway oxidation

Decohesion and Double-Layer Formation. For scale growth by cation diffusion, a protective scale may eventually reach a thickness at which it can no longer deform plastically to conform to the receding metal surface. At this point, decohesion begins at some places along the metal/oxide interface. However, oxidation continues at the oxide/gas interface because cations continue to diffuse outward through the detached scale, driven by the chemical potential gradient across the scale.

At the inner scale surface, the cation concentration decreases, thus increasing the chemical potential of oxygen there. The increased chemical potential of oxygen has associated with it an increased pressure of O_2 gas that will form in the space between the scale and the metal. The O_2 then migrates to the metal surface, and because its pressure is greater than the dissociation pressure of oxide in equilibrium with metal, an inner layer of oxide begins to form on the metal.

The inner oxide layer forms a porous fine-grain structure, although it has essentially the same composition as the compact outer layer. Initially, it started forming as mounds from the nucleation sites. If the growth of these mounds were controlled by cation diffusion, the inner oxide would quickly thicken in the areas where it was thinnest and where diffusion distances were shortest. However, in this situation, the diffusion of O_2 from the outer layer to the inner layer is rate controlling so that the inner layer grows mainly at its high points and forms a porous scale (Ref 18). Figure 19 shows the mechanism of the double-layer scale.

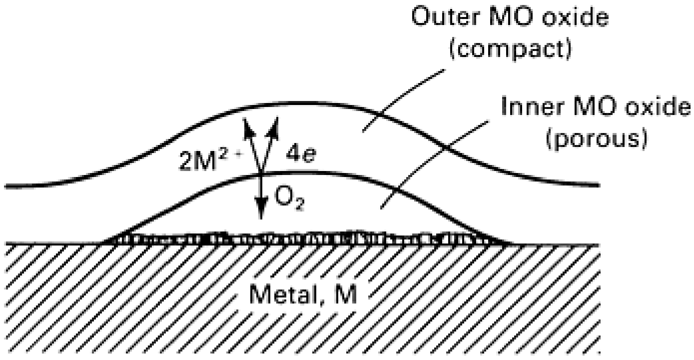

Fig. 19 Structure of double-layer single-phase scale

Deformation of Metal. Foils and thin-wall tubes are often observed to deform during oxidation, thus relieving the oxide growth stresses. At high temperatures, slip and creep mechanisms can both be operative in metals while the temperature is still too low for plastic deformation of the oxide. The deformation processes are facilitated by accumulation of porosity in the metal, which is caused by cation diffusion outward from the metal and by selective oxidation of one component of an alloy.

Logarithmic Oxidation of Scales. A logarithmic rate law for thick oxide scales has been developed for situations in which cavities or precipitates hinder the diffusion so that only part of the oxide is available for diffusion (Ref 19). The equation developed for logarithmic thick scale growth should not be confused with thin-film logarithmic behavior, which has an entirely different mechanism.

Even where the whole oxide scale originally serves as a diffusion path for ions or vacancies, the area available for diffusion may reduce with time. This can occur where vacancies collect at the metal/oxide interface to cause partial detachment or cavity formation, or in the case of an A-B alloy, it can occur where particles of a very stable but slow-growing BO oxide form and restrict the growth of a much faster growing AO oxide layer. It has even been suggested that the mechanism might hold when growth stresses are so high that they cause the scale to crack in short cracks that run parallel to the metal surface.

The equation developed for these situations will approximate the standard logarithmic equation:

$$m = \mathrm{k} \log (\mathrm{a}t + 1) \qquad \textbf{(Eq 58)}$$

where m is the mass increase per unit area, and k and a are constants. The oxidation begins rapidly but then almost comes to a stop as the cross-sectional area available for diffusion decreases.

Catastrophic Oxidation. Although many oxidation failures can be described as catastrophies, the term catastrophic oxidation is reserved for the special situation in which a liquid phase is formed in the oxidation process. This can occur either when the metal is exposed to the vapors of a low-melting oxide or during oxidation of an alloy having a component that forms a low-melting oxide. The low-melting oxides that have commonly caused catastrophic oxidation are listed in Table 6.

Table 6 Low-melting oxides

Oxide	Melting point	
	°C	°F
V_2O_3	674	**1245**
MoO_3	795	**1463**
MoO_2-MoO_3, eutectic	778	**1432**
Bi_2O_3	817	**1503**
PbO	885	**1625**

The exact mechanism of catastrophic oxidation is disputed, but the evidence shows that it occurs at the metal/oxide interface. A liquid phase seems to be essential. The liquid usually forms at the oxide/gas surface and penetrates the scale along grain boundaries or pores to reach the metal. The penetration paths can also serve as paths for rapid diffusion of reacting ions. Once at the metal/oxide interface, the liquid spreads out by capillary action, destroying adherence of the solid scale.

Oxidation in the absence of any protective scale proceeds linearly or even at an ever increasing rate if the metal heats up from the exothermic oxidation reaction. The Wagner mechanism clearly does not apply to catastrophic oxidation.

Internal Oxidation. Internal oxidation is the term used to describe the formation of fine oxide precipitates found within an alloy. It is sometimes called subscale formation. Oxygen dissolves in the alloy at the metal/oxide interface or at the bare metal surface if the gas pressure is below the dissociation pressure of the metal oxides. The oxygen diffuses into the metal and forms the most stable oxide that it can. This is usually the oxide of the most reactive component of the alloy. Internal oxides can form only if the reactive element diffuses outward more slowly than the oxygen diffuses inward; otherwise, only surface scale would form.

Because diffusion of oxygen is usually the rate-controlling process in internal oxidation, parabolic behavior is observed. Wagner developed an equation that, with simplifications, is approximately (Ref 20):

$$x = \left(\frac{2N_o^s D_o t}{\nu N_B^i}\right)^{1/2} \quad \textbf{(Eq 59)}$$

where N_o^s is the mole fraction of oxygen in the alloy at its surface, N_B^i is the mole fraction of reactive metal B initially in the alloy, D_o is the diffusion coefficient of oxygen in the alloy, v is the ratio of oxygen atoms to metal atoms in the

oxide compound that forms, and *x* is the subscale thickness at time *t.* It is assumed that counter-diffusion of B atoms is negligible and that oxygen has a very low solubility limit in the alloy.

Because the diffusion coefficients of B atoms and oxygen both vary exponentially with temperature and because their activation energies are different, it is possible that internal oxidation will form in an alloy only in a certain temperature range. Because internal oxide precipitates reduce the cross section available for oxygen diffusion, only surface oxide forms above some critical solute concentration in the alloy.

In an A-B alloy, in which BO is a more stable oxide than AO, a mixed (A,B)O oxide may form as the internal oxide. This will occur if AO and BO have considerable mutual solubility so that the free energy of the system is lowered by precipitation of the mixed oxide. For example, the internal oxide that forms in unalloyed steels is (Fe,Mn)O (Ref 21).

Alloy Oxidation: The Doping Principle (Ref 22). For oxides that form according to the Wagner mechanism and contain wrong-valent impurity cations that are soluble in the oxide, the impurities alter the defect concentration of the scale. Consequently, the oxide growth rate may also be altered by the alloy impurities. Whether oxidation increases or decreases depends on the relative valences of the cations and on the type of oxide.

***p*-type Oxides.** In a *p*-type semiconducting oxide (typified by NiO) the oxidation rate is controlled by cation diffusion through cation vacancies. If the number of cation vacancies can be decreased, the oxidation is slowed. The cation vacancies are present in the first place because a small fraction of the nickel cations have a higher-than-normal valence, contributing more than their share of valence electrons to the oxygen and thus allowing a small fraction of cations to be absent from the structure.

If a few cations with a higher valence are substituted for the regular cations in an oxide, the vacancy concentration is increased. For example, if a small amount of aluminum is alloyed with nickel and then oxidized to form a scale of NiO with a few substitutional Al^{3+} cations, the oxidation rate will be faster than for pure NiO because of the increased cation vacancy concentration. For every two Al^{3+} cations in the oxide, contributing one additional electron each, another cation vacancy V''_{Ni} must be present. For the same reason, adding lower-valent cations, such as lithium ions (Li^+), to the NiO will reduce the cation vacancy concentration. Substituting ions with the same valence as the rest of the cations in the oxide should have little effect.

***n*-type Oxides.** The *n*-type semiconducting oxides behave exactly opposite to the *p*-type oxides. For the oxides that grow by anion diffusion through anion vacancies (typified by ZrO_2), the anion vacancies exist because some cations have a lower-than-normal valence, contributing fewer electrons to the oxygen than required by the structural arrangement. Consequently, anion vacancies are present to facilitate anion diffusion. If additional low-valent cations replace the regular higher-valent cations, the oxidation rate increases. Conversely, substituting higher-valent cations reduces the anion vacancy concentration and reduces the oxidation rate.

For *n*-type oxides that grow by interstitial diffusion of cations, as with BeO, substitution of higher-valent cations, for example, Al^{3+}, for a few of the Be^{3+} ions in the oxide structure leaves the oxide negatively charged with the excess electrons. The free electrons tend to prevent the ionization of the metal:

$$Be \rightarrow Be_i^{2+} + 2e^-$$

at the metal/oxide interface. The concentration of interstitial cations Be_i^{2+} is consequently reduced; therefore, the oxidation rate is reduced. However, if lower-valent cations are substituted in the *n*-type semiconducting oxide, for example, a small amount of Li^+ in BeO, the Li^+ supplies only one valence electron to the oxygen in place of the two electrons that would have been supplied by the replaced Be^{2+}. The oxygen must obtain more electrons from the surface of the metal, increasing the ionization and formation of interstitial Be_i^{2+} cations. Alloying with a metal that forms cations of the same valence as the rest of the cations in the oxide will have little effect.

Alloy Development. As it turns out, the doping principle has been useful in verifying the Wagner mechanism, but it is not very helpful in developing oxidation-resistant alloys. First, the concentration of foreign cations that can be put into solid solution in the oxide is severely restricted by low solubility limits. Second, the choices of foreign ions that could be used is extremely limited by their valence. For *p*-type oxides, the alloying element should have a lower valence than the metal being oxidized in order to slow corrosion, but *p*-type oxides are commonly formed by metals with +1 and +2

valences. The *n*-type oxides form on metals with high valences, but very few alloying elements have even higher valences to slow the oxidation.

For any stoichiometric oxides, nitrides, or sulfides that are ionic conductors instead of semiconducting electronic conductors, the doping principle can be applied in theory to reduce oxidation at room temperature. However, at high temperatures, perhaps all these protective scales carry current principally by free electrons (*n*-type) or electron holes (*p*-type).

Selective Oxidation. An alloy is selectively oxidized if one component, usually the most reactive one, is preferentially oxidized. The simplest case would be a binary alloy with a uniform scale composed entirely of the only oxide that one of the components can form. This situation will be described to illustrate the principles involved. The alloy is formed from metals A and B where B is more reactive than A is; that is, oxide BO is thermodynamically more stable than AO, and AO and BO are immiscible. Which scale, AO or BO, that will form on the A-B alloy depends on the relative nobility of A and B, their concentrations in the alloy, the oxygen pressure, and the temperature.

Alloying With a Noble Metal. An obvious example of selective oxidation would be scale formation on alloy A-B where A is so noble that AO is not thermodynamically stable at the environmental pressure and temperature. That is, the oxygen partial pressure in the gas is less than the equilibrium (dissociation) pressure of AO oxide. Then, only BO scale can form if it is stable.

Both Elements Reactive. For situations in which both A and B are reactive with oxygen at the temperature and gas pressure involved but A is somewhat more noble than B, the alloy composition determines which oxide forms. If the alloy contains some very low concentration of B, the activity of B could be so low that the free energy for formation of BO could actually be positive. That is, for the reaction:

$$B_{(alloy)} + \frac{1}{2}O_2 \rightarrow BO$$

the driving force is:

$$\Delta G = \Delta G^\circ + RT \ln \frac{1}{N'_B \cdot p_{O_2}^{1/2}} \quad \textbf{(Eq 60)}$$

where ΔG is the Gibbs energy change; ΔG^o is the Gibbs energy change under standard conditions; the activity of the pure solid oxide is approximately 1 (invariant); the small mole fraction of B in the alloy is N'_B, which approximates its activity; and the pressure of O_2(p_{O_2}) closely approximates its fugacity. It can be seen that if N'_B is smaller than some critical value N^*_B described below, then the Gibbs energy for formation of BO could be positive even though ΔG^o is negative. Because it is stable. AO will grow on the alloy, while BO cannot.

The situation for selective oxidation of A is illustrated in Fig. 20. Alloying element A becomes depleted as it reacts at the metal/oxide interface. This creates a concentration gradient of A, causing A to diffuse from the interior of the alloy toward the surface. At the same time, depleting A near the metal surface increases the concentration of B so that B should diffuse inward. If the diffusion rates of A and B in the alloy are similar to the rate-controlling diffusion through the oxide, then element A never becomes seriously depleted at the metal/oxide interface and AO continues to form. However, if diffusion through the alloy is much slower than through the oxide, the concentration of B will increase at the alloy surface until it reaches N^*_B, the critical concentration at which formation of BO is thermodynamically favorable. When that time comes, BO will form along with AO.

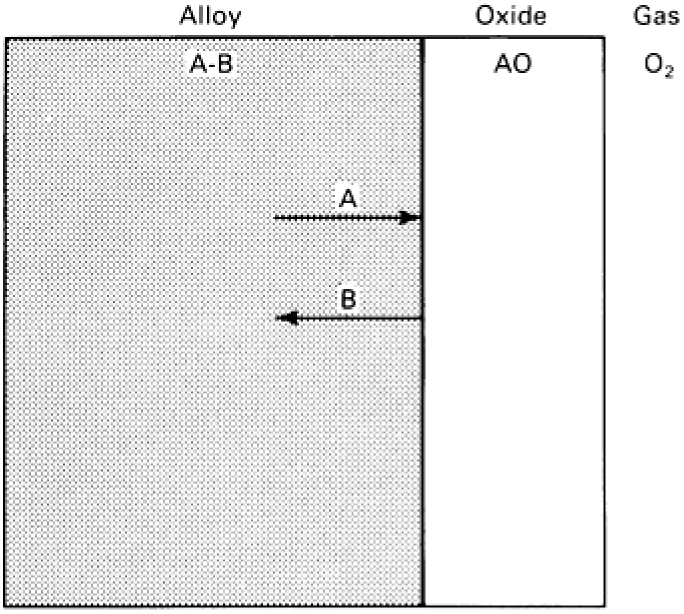

Fig. 20 Selective oxidation of alloy A-B, with oxide AO forming. Directions for diffusion of A and B are indicated.

At a high concentration of B in an alloy, BO forms while A diffuses back into the alloy (Fig. 21). In this case, the mole fraction N_A is less than the minimum or critical concentration N^*_A at which AO oxide could be stable. However, if diffusion into the metal is slow, the concentration of A may eventually build up to N^*_A, and the AO oxide would then begin to form.

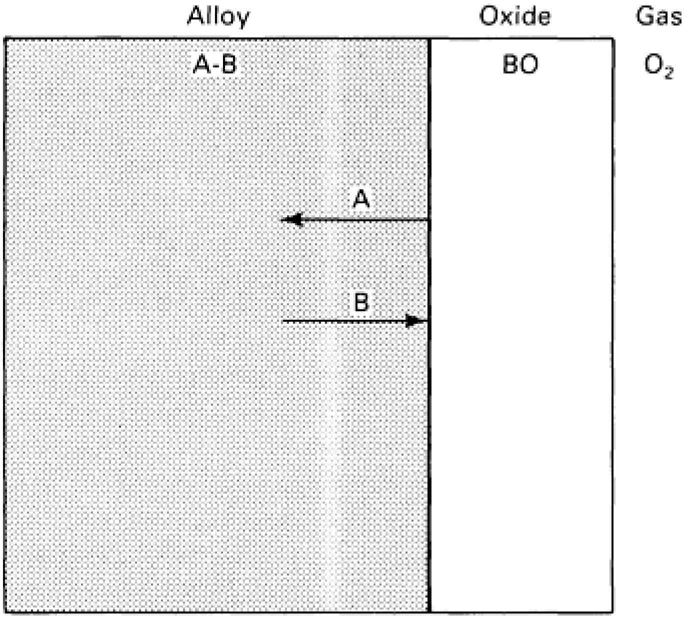

Fig. 21 Selective oxidation of alloy A-B for $N_B > N^*_B$

Reducing Oxidation Rates. It may at first seem that the oxidation rate of a reactive metal could be reduced by alloying it with a noble metal, but this is not always the case. If the concentration of the reactive element is far greater

than the critical concentration needed to form an external scale, that is, if $N_B \gg N^*_B$ alloying with a noble metal will have very little effect on the oxidation rate.

For example, Wagner considered alloying nickel with a noble metal, such as platinum. For oxidation of pure nickel, the rate is proportional to the concentration gradient across the scale (Fick's first law); therefore, the rate constant k is given by:

$$k = \text{Constant } [(p^{o}_{O_2})^{1/n} - (p_d)^{1/n}] \quad \textbf{(Eq 61)}$$

where $p^{o}_{O_2}$ is the oxygen pressure in the gas at the outer surface of the oxide, p_d is the dissociation pressure for NiO in equilibrium with the pure nickel, and n is a constant theoretically equal to 6 for NiO as indicated in Eq 49. Figure 22 shows the concentration gradients of nickel in the alloy and in the scale.

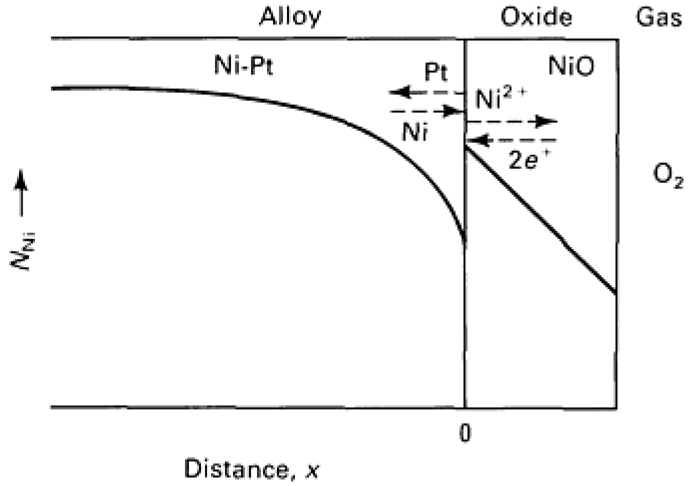

Fig. 22 Schematic diagram of concentration gradients of nickel in nickel-platinum alloy and NiO oxide. Electron holes are indicated as e^+.

Oxidation of nickel-platinum alloy would have a rate constant of:

$$k' = \text{Constant} \cdot [(p^{o}_{O_2})^{1/n} - (p^{i}_{O_2})]^{1/n} \quad \textbf{(Eq 62)}$$

where $p^{i}_{O_2}$ is the equilibrium oxygen pressure for NiO in equilibrium with the nickel-platinum alloy at the inner surface of the oxide. Comparing the oxidation rate of the alloy with the rate for pure nickel yields:

$$\frac{k'}{k} = \frac{(p^{o}_{O_2})^{1/n} - (p^{i}_{O_2})^{1/n}}{(p^{o}_{O_2})^{1/n} - (p_d)^{1/n}} \quad \textbf{(Eq 63)}$$

If activity of nickel in the alloy can be approximated by its concentration, Eq 63 can be written as:

$$\frac{k'}{k} = \frac{1 - (N^*_{Ni}/N^i_{Ni})^{2/n}}{1 - (N^*_{Ni})^{2/n}} \quad \textbf{(Eq 64)}$$

where N^*_{Ni} is the critical concentration of nickel in an alloy in equilibrium with NiO, and N^i_{Ni} is the mole fraction of nickel in the alloy at the metal/oxide interface.

In considering Eq 64, it must be remembered that N^*_{Ni} is extremely small for a reactive metal, such as nickel. Therefore, alloying nickel with a small amount of platinum, but still keeping $N^i_{Ni} \gg N^*_{Ni}$, will have very little effect on the oxidation. Oxide growth will slow to a stop only when enough platinum is added to make N^i_{Ni} approach N^*_{Ni}. The oxidation rate is then no longer controlled by diffusion of nickel through the oxide but by interdiffusion of platinum and nickel in the alloy.

Composite External Scales. Wagner has shown that for an A-B alloy that is forming both AO and BO oxides, the mole fraction of B at the alloy surface must not exceed:

$$N^i_B \leq (1 - N^*_A) = \frac{V}{z_B M_O}\left(\frac{\pi k_p}{D}\right)^{1/2} \qquad \textbf{(Eq 65)}$$

where N^*_A is the minimum concentration of A necessary to form AO, V is the molar volume of the alloy, z_B is the valence of B, M_O is the atomic weight of oxygen, k_p is the parabolic rate constant for growth of BO, and D is the diffusion coefficient of B in the alloy. Equation 65 does not take into account any complications, such as porosity and internal oxidation. If the concentration of B lies anywhere between N^*_B and (1 - N^*_A), thermodynamics predicts that both AO and BO form.

Competing Oxides. When oxides of both metals form, their relative positions and distribution depend on the thermodynamic properties of the oxides and the alloy, the diffusion processes, and reaction mechanisms. This section will discuss the two common situations in which both metals in a binary alloy oxidize to form two separate oxide phases.

The first situation involves immiscible oxides with the more stable oxide growing slowly. With both AO and BO stable but with rapid growth of AO and slow growth of BO, the more stable BO may nucleate first, but gradually becomes overwhelmed and surrounded by fast-growing AO. Figures 23(a) and 23(b) illustrate the situation. If diffusion in the alloy is rapid, the oxidation proceeds to form an AO scale with BO islands scattered through it. However, if diffusion in the alloy is slow, the metal becomes depleted of A near the metal/oxide interface, while the growth of BO continues until it forms a complete layer, undercutting the AO (Fig. 23c). Pockets of AO at the metal/oxide interface will gradually be eliminated by the displacement reaction:

$$AO + B_{(alloy)} \rightarrow BO + A_{(alloy)}$$

because BO is thermodynamically more stable than AO. This reaction continues even if the oxygen supply is cut off.

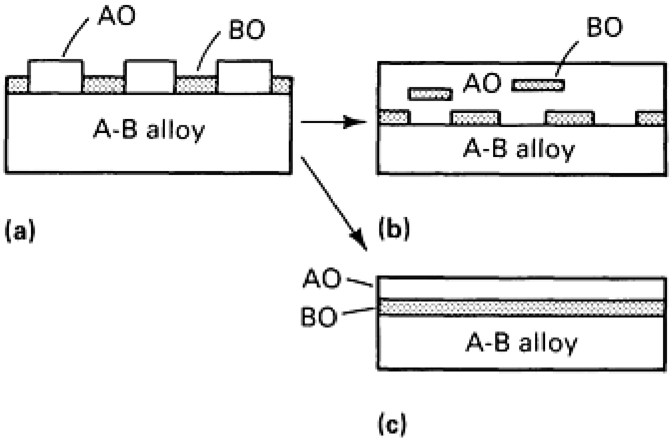

Fig. 23 Simultaneous growth of competing oxides. BO is more stable, but AO grows faster. (a) Early stage with nucleation of both oxides. (b) Later stage if diffusion in alloy is rapid. (c) Final stage if diffusion in alloy is slow

The second situation involves two oxides that are partially miscible. For alloys rich in A, an AO scale will form with some B ions dissolved substitutionally in the AO structure. If the solubility limit is exceeded when B ions continue to diffuse into the scale, BO precipitates as small islands throughout the AO layer. Even if the solubility limit is not reached, the more stable BO may nucleate within the AO scale and precipitate.

For alloys rich in B, a BO layer first forms. If B ions diffuse through the scale faster than A ions do, the concentration of A ultimately builds up in the scale close to the metal/oxide interface. An AO layer then forms underneath the BO. On the other hand, if A ions diffuse through the original BO scale more quickly than the B ions, the AO layer eventually forms on top of the BO layer. In addition, if A ions diffuse rapidly through BO and B ions diffuse rapidly through AO, alternate layers of BO/AO/BO/AO may even form.

Double Oxides. A great deal of research has been directed toward developing alloys that form slow-growing complex oxides. The silicates are particularly important because they can form glassy structures that severely limit diffusion of ions. Therefore, silicide coatings on metals have been very successful. In addition to forming a protective SiO_2 outer layer, much of the silicon diffuses into the underlying alloy, where it gradually oxidizes to ternary silicates.

Spinels often have extremely low diffusion rates. Spinels are double oxides of a metal with +2 valence and a metal with +3 valence, having the general formula $MO{\cdot}Me_2O_3$ and also having the crystal structure of the mineral spinel ($MgO{\cdot}Al_2O_3$). The iron oxide Fe_3O_4 has an inverse spinel structure. On iron-chromium alloys, the spinel phase can be either stoichiometric $FeO{\cdot}Cr_2O_3$ or the solid solution $Fe_{3-x}Cr_xO_4$. Although many ternary oxides tend to be brittle, much research has been devoted to minor alloy additions to improve the high-temperature mechanical properties of those ternary scales that are extremely protective.

Summary Outline of Alloy Oxidation. A schematic diagram has been constructed to show the morphologies of scale growth on binary alloys (Ref 23). It is shown in Fig. 24. The diagram illustrates those types of structures that are known to form, not all those that would be theoretically possible.

Introduction

Bruce Craig, Metallurgical Consultants, Inc.; Steven L. Pohlman, Kennecott Corporation

Introduction

OVER THE YEARS, corrosion scientists and engineers have recognized that corrosion manifests itself in forms that have certain similarities and therefore can be categorized into specific groups. However, many of these forms are not unique but involve mechanisms that have overlapping characteristics that may influence or control initiation or propagation of a specific type of corrosion.

The most familiar and often used categorization of corrosion is probably the eight forms presented by Fontana and Greene (Ref 1): uniform attack, crevice corrosion, pitting, intergranular corrosion, selective leaching, erosion corrosion, stress corrosion, and hydrogen damage. This classification of corrosion was based on visual characteristics of the morphology of attack. Fontana and Greene's introductory remarks in their chapter on forms of corrosion indicate that this classification is arbitrary and that many of the forms are interrelated, making exact distinction impossible. Other prominent corrosion authors such as Uhlig (Ref 2) and Evans (Ref 3) have avoided a classification format and have simply discussed the classical types of corrosion (for example, pitting and crevice corrosion) as they relate to specific metals and alloys.

Substantial advances in the field of corrosion science have begun to define the mechanisms of many forms of corrosion more clearly. However, rather than placing the mechanisms into distinct categories, the overlap between many of the forms has become greater. For example, there is evidence that hydrogen may dominate the crack initiation or crack propagation portion of fracture in some metal/solution systems where stress-corrosion cracking occurs. Additionally, in some metal systems where dealloying (selective leaching) occurs, this form of corrosion may be a precursor to stress-corrosion cracking.

In a similar vein, the magnitude of contribution of stress or corrosion to stress-corrosion cracking, hydrogen damage, or liquid metal embrittlement is not currently understood and can affect whether just pitting or crevice attack occurs or environmental cracking results. The transition from uniform corrosion to highly localized attack is not clearly understood, and there are conditions where a distinction cannot be drawn.

The forms of corrosion presented in this Section were categorized to represent the mechanisms of attack involved rather than to emphasize the visual characteristics. However, as with any classification system, these categories are not distinct or all-inclusive and do not necessarily represent the only mode of attack that may be observed. The forms of corrosion discussed in this Section are categorized in Table 1.

Table 1 Forms of corrosion presented in this Section

General corrosion
Atmospheric corrosion
Galvanic corrosion
Stray-current corrosion
General biological corrosion
Molten salt corrosion

Corrosion in liquid metals
High-temperature corrosion
Oxidation
Sulfidation
Carburization
Other forms[(a)]
Localized corrosion
Filiform corrosion
Crevice corrosion
Pitting corrosion
Localized biological corrosion
Metallurgically influenced corrosion
Intergranular corrosion
Dealloying corrosion
Mechanically assisted degradation
Erosion corrosion
Fretting corrosion
Cavitation and water drop impingement
Corrosion fatigue
Environmentally induced cracking
Stress-corrosion cracking

Hydrogen damage
Liquid metal embrittlement
Solid metal induced embrittlement

(a) Other forms include hydrogen effects and hot corrosion.

General Corrosion. In this Section, general corrosion is defined as corrosive attack dominated by uniform thinning. Although high-temperature attack in gaseous environments, liquid metals, and molten salts may manifest itself as various forms of corrosion, such as stress-corrosion cracking and dealloying, high-temperature attack has been incorporated into the article "General Corrosion" because it is often dominated by uniform thinning. However, subsequent articles in this Volume will discuss cases of highly localized high-temperature attack. Likewise, galvanic corrosion may appear to be highly localized, but if the anodic area were large and a highly conductive electrolyte existed, uniform thinning would occur.

Localized Corrosion. The forms of corrosion in the article "Localized Corrosion" need no explanation, even though other forms could be placed in this category. It should be noted, however, that localized biological corrosion often causes or accelerates pitting or crevice corrosion.

Metallurgically influenced corrosion was so classified as a result of the significant role that metallurgy plays in these forms of attack. It is well understood that metallurgy is important in all forms of corrosion, but this classification is meant to emphasize its role in these specific forms of attack.

Mechanically assisted degradation groups those forms of corrosion that contain a mechanical component, such as velocity, abrasion, and hydrodynamics, that has a significant effect on the corrosion behavior. Corrosion fatigue was included in this category because of the dynamic stress states; however, it could easily be categorized as a form of environmentally induced cracking.

The environmentally induced cracking article follows the current trend in the literature of combining those forms of cracking that are produced by corrosion in the presence of stress. As the introduction to this article explains, there are many differences as well as similarities among these forms of cracking. However, the distinction between each form is not always apparent; it is therefore easier to combine these different forms into one all-encompassing form.

As a result of the arbitrary nature of classifying forms of corrosion and the fact that corrosion science is a dynamic field with ever-changing theories and observations, the distinctions between many forms become highly personalized. Other articles in this Volume will contain variations of these forms of corrosion and are not always self-consistent. This does not imply a misunderstanding of the mechanisms of corrosion, but rather underscores the continuing evolution of corrosion theory.

General Corrosion

Chairman: Steven L. Pohlman, Kennecott Corporation

Introduction

GENERAL CORROSION, as described in this article, refers to corrosion dominated by uniform thinning that proceeds without appreciable localized attack. Weathering steels and copper alloys are good examples of materials that typically exhibit general attack, while passive materials, such as stainless steels or nickel-chromium alloys, are generally subject to localized attack. Under specific conditions, however, each material may vary from its normal mode of corrosion. Examples describing the environmental conditions that promote uniform attack will be discussed throughout this article.

General corrosion has been divided into seven specific types of corrosion in this article. Atmospheric corrosion is probably the most common form of corrosion and may well be the most costly. Galvanic corrosion is an electrochemical form of corrosion that protects cathodic areas at the expense of anodic areas. Stray-current corrosion is similar to galvanic corrosion, but does not rely on electrochemically induced driving forces to cause rapid attack. Biological corrosion is a microbial-assisted form of attack that can manifest itself in a general or a localized form. Moltensalt corrosion and liquid-metal corrosion have become more of a concern as the demand for higher-temperature heat transfer fluids increases. High-temperature (gaseous) corrosion is an area of great concern, particularly for the industrial sector.

As noted in the Introduction to this Section, some of the categories of general corrosion described in this article also manifest themselves as other forms of corrosive attack, such as stress-corrosion cracking, dealloying, or pitting. However, because uniform thinning plays an important role in all of the categories described, each can and will be discussed under general corrosion.

Atmospheric Corrosion

Steven L. Pohlman, Kennecott Corporation

Atmospheric corrosion is defined as the corrosion or degradation of material exposed to the air and its pollutants rather than immersed in a liquid. This has been identified as one of the oldest forms of corrosion and has been reported to account for move failures in terms of cost and tonnage than any other single environment.

Dry Corrosion

Many authors classify atmospheric corrosion under categories of dry, damp, and wet, thus emphasizing the different mechanisms of attack under increasing humidity or moisture. Supplementary information on atmospheric corrosion can be found in the article "Simulated Service Testing" (see the section "Corrosion Testing in the Atmosphere") in this Volume.

Types of Atmospheric Corrosion

In the absence of moisture, most metals corrode very slowly at ambient temperatures. Accelerated corrosion under dry conditions at elevated temperatures is covered in the section "High-Temperature Corrosion" in this article. Dry corrosion at ambient temperature occurs on metals that have a negative free energy of oxide formation and thus form a rapid thermodynamically stable film in the presence of oxygen. Typically, these films are desirable because they are defect free, nonporous, and self-healing and act as a protective barrier to further corrosive attack of the base metal. Metals such as stainless steels, titanium, and chromium develop this type of protective film. Porous and nonadhering films that form spontaneously on nonpassive metals as unalloyed steel are normally not desirable.

Tarnishing of copper and silver in dry air with traces of hydrogen sulfide (H_2S) is an example of a nondesirable film formation at ambient temperatures caused by lattice diffusion. For tarnishing to occur, sulfur impurities must be present. The sulfides increase the likelihood of defects in the oxide-lattice and thus destroy the protective nature of the natural

film, which leads to a tarnished surface. Surface moisture is not necessary for tarnishing to occur, and in some cases, such as copper in the presence of trace amounts of H_2S, moisture can actually retard the process of tarnishing. In general, dry corrosion plays an insignificant part in atmospheric corrosion as a whole.

Damp corrosion requires moisture in the atmosphere and increases in aggressiveness with the moisture content. When the humidity exceeds a critical value, which is around 70% relative humidity, an invisible thin film of moisture will form on the surface of the metal, providing an electrolyte for current transfer. The critical value depends on surface conditions such as cleanliness, corrosion product buildup, or the presence of salts or other contaminants that are hygroscopic and can absorb water at lower relative humidities.

Wet corrosion occurs when water pockets or visible water layers are formed on the metal surfaces because of sea spray, rain, or drops of dew. Crevices or condensation traps also promote the pooling of water and lead to wet atmospheric corrosion even when the flat surfaces of a metal component appear to be dry (Fig. 1).

Fig. 1 Corroded steel formwork on the ceiling of a parking garage. The seams in this corrugated structure act as condensation traps and lead to wet atmospheric corrosion. Courtesy of R.H. Heidersbach, California Polytechnic State University

During wet corrosion, the solubility of corrosion product can affect the corrosion rate. Typically, when the corrosion product is soluble, the corrosion rate will increase. This occurs because the dissolved ions normally increase the conductivity of the electrolyte and thus decrease the internal resistance to current flow, which will lead to an increased corrosion rate. Under alternating wet and dry conditions, the formation of an insoluble corrosion product on the surface may increase the corrosion rate during the dry cycle by absorbing moisture and continually wetting the surface of the metal.

The rusting of iron and steel and the formation of patina on copper are examples of metals experiencing either damp or wet atmospheric corrosion. Figures 1, 2, 3, 4, and 5 show examples of the damp/wet atmospheric corrosion of weathering steel components.

Atmospheric Contaminants

Wet atmospheric corrosion is often controlled by the level of contaminants found in the environment. For example, steel pillars 25 m (80 ft) from the seacoast will corrode 12 times faster than the same steel pillars 250 m (800 ft) further inland. The level of marine salts found at the two locations can explain the difference in the observed corrosion rates. More

detailed information on marine atmospheres and their effect on the corrosivity of metals and alloys can be found in the article "Marine Corrosion" in this Volume.

Industrial atmospheres are more corrosive than rural atmospheres, primarily because of the sulfur compounds produced during the burning of fuels. Sulfur dioxide (SO_2) is selectively absorbed on metal surfaces, and under humid conditions the metal oxide surfaces catalyze the SO_2 to sulfur trioxide (SO_3) and promote the formation of sulfuric acid (H_2SO_4) according to the reaction $H_2O + SO_3 \rightarrow H_2SO_4$. An example of SO_2-induced corrosion of plain carbon steel is shown in Fig. 6.

Fig. 6 Delamination of plain carbon steel due to SO_2 + ash deposit outside the boiler area of a coal-fired power plant. Courtesy of D.M. Berger, Gilbert/Commonwealth

Small additions of copper (0.1%) will increase the resistance of steel to a sulfur polluted environment by enhancing the formation of a tighter, more protective rust film (see the articles "Corrosion of Carbon Steels" and "Corrosion of Alloy Steels" in this Volume). Additions of nickel and chromium will accomplish the same end. Nickel and copper alloys form insoluble sulfates that help to protect the base metal and are therefore used extensively in industrial environments (see the articles "Corrosion of Copper and Copper Alloys" and "Corrosion of Nickel-Base Alloys" in this Volume). The remarkable longevity of ancient iron is probably due to a SO_2-free atmosphere rather than a high degree of resistance to general corrosive attack.

Other major contaminants that promote atmospheric corrosion are nitrogen compounds, H_2S, and dust particles. Nitrogen compounds occur naturally during thunderstorms and are added to the environment by the use of ammonia (NH_3) base fertilizers. Hydrogen sulfide can be generated naturally by the decomposition of organic sulfur compounds or by sulfate-reducing bacteria (SRB) in polluted rivers. Detailed information on SRB and their effect on alloy corrosion behavior can be found in the articles "Effects of Environmental Variables on Aqueous Corrosion" (see the Appendix "Biological Effects") and "Localized Corrosion" (see the section "Localized Biological Corrosion").

Dust particles can be very detrimental to corrosion-resistant metals by adhering to the surface and absorbing water or H_2SO_4, and trapping the solution against the surface. Dust particles may also contain contaminants, such as chlorides, that can break down protective surface films and thus initiate corrosion.

Oxygen is not considered a contaminant, but is an essential element of the corrosion process. The normal cathodic reaction is the reduction of oxygen. In polluted areas with high concentrations of SO_2, the pH of the surface electrolyte may be low enough so that hydrogen reduction is the principal cathodic reaction. Once a suitable surface electrolyte has been formed by water vapor, oxygen will dissolve in the electrolyte solution and promote the cathodic reaction. Because the water layer on the surface of the metal is extremely thin, the diffusion of oxygen to the surface of the metal occurs very rapidly and does not slow the corrosion rate.

Carbon dioxide (CO_2) does not play a significant role in atmospheric corrosion, and in some cases, it will actually decrease corrosion attack.

Atmospheric Variables

Atmospheric variables such as temperature, climatic conditions, and relative humidity, as well as surface shape and surface conditions that affect the time of wetness, are important factors that influence the rate of corrosive attack. Additional information concerning variables is available in the article "Effects of Environmental Variables on Aqueous Corrosion" in this Volume.

Surface temperature is a critical variable. As the surface temperature increases, the corrosion rate will rise sharply to the point at which evaporation of the electrolyte takes place. At this temperature, the corrosion rate will decrease quickly.

Climatic Conditions. Metal surfaces located in areas where they become wet and retain moisture generally corrode more rapidly than surfaces exposed to rain. The rain has a tendency to wash the surface and remove particles of dust that can lead to differential aeration corrosion. Exceptions would be in areas that are subject to acid rain. Exposure of metals in different months of the year can have a pronounced effect on the corrosion rate. Winter exposure is usually the most severe because of increased combustion products in the air. The presence of SO_2 and other sulfur pollutants leads to an aggressive environment and the formation of a less protective corrosion product film on normally passive metals. One should be cautious regarding the month in which outdoor corrosion tests are performed. In locations in which sulfur-containing fuel is not burned during the winter months, the summer months may sometimes lead to higher rates of attack because of the increased surface temperatures.

Time of Wetness/Relative Humidity. Time of wetness is a critical variable with respect to the extent of corrosion experienced. The time of wetness determines the duration of the electrochemical process. The thickness and the chemical composition of the water film are both important.

The critical relative humidity is the humidity below which water will not form on a clean metal surface and thus electrochemical or wet corrosion will not occur. The actual relative humidity will change depending on the surface condition of the metal.

For iron, the critical relative humidity appears to be about 60%; at this level, rust slowly begins to form. At 75 to 80% relative humidity, there is a sharp increase in corrosion rate that is speculated to occur because of the capillary condensation of moisture within the rust corrosion product layer. At 90% relative humidity, there is another increase in the corrosion rate corresponding to the vapor pressure of ferrous sulfate. The critical relative humidity for copper, nickel, and zinc also appears to be between 50 and 70%, depending on surface conditions.

The nature of the corrosion product can greatly affect the time of wetness. If the corrosion product film is microporous in nature, capillary condensation can cause the condensation of moisture well below the critical relative humidity value. This occurs because of the differences in vapor pressure as measured over a curved surface as compared to a flat surface. For example, a 1.5-nm capillary will condense moisture at 50% relative humidity; a 36-nm capillary will condense moisture at 98% relative humidity. This phenomenon accounts for the formation of electrolyte in microcracks and in contact angles between dust particles and metal surfaces. The condensation of moisture on a metal surface can also be enhanced by the formation of a saturated solution, which will lower the equilibrium vapor pressure and allow condensation below 100% relative humidity.

Dew formation on metal surfaces can lead to accelerated corrosion because of the tendency of the dew to be acidic as a result of high SO_2 values near the ground. The dew can form on open or sheltered surfaces and leads to a corrosive attack of galvanized sheet called white rusting.

The thickness of the electrolyte is also an important factor in the corrosion process. Water begins to adhere to a polished metal surface at an estimated 55% relative humidity and will form a thin film, which will increase in thickness as the relative humidity increases. The thin water layers can support an electrochemical reaction, but polarization of the cathodic and anodic sites slows the process as the film thickness decreases and virtually stops at about 60%, the critical relative humidity value. The corrosion rate on a surface reaches a maximum when the water film thickness is above 150 m. Therefore, not only is the time of wetness an important parameter but the thickness and conductivity of the surface electrolyte must also be known.

Atmospheric Corrosion of Specific Metal Systems

Irons and steel, zinc, copper, nickel, and aluminum are the metal systems of major economic importance when dealing with atmospheric corrosion. Table 1 provides an overview of atmospheric corrosion rates of various metals and alloys. Metals that are not particularly resistant to dilute H_2SO_4 such as copper, cadmium, nickel, and iron, show more rapid attack in industrial environments. Metals and alloys that are more resistant to H_2SO_4, such as lead, aluminum, and stainless steels, are less affected in the industrial environments. Copper forms a protective sulfate patina and is therefore more resistant than nickel. Copper also forms a basic copper chloride in seacoast environments. Nickel is very important in marine atmospheres, but is sensitive to the H_2SO_4 found in the industrial environments.

Table 1 Average atmospheric-corrosion rates of various metals for 10- and 20-year exposure times

Corrosion rates are given in mils/yr (1 mil/yr = 0.025 mm/yr). Values cited are one-half reduction of specimen thickness.

Low-alloy steels that resist atmospheric corrosion are called weathering steels (see the section "Weathering Steels" in the article "Corrosion of Carbon Steels" in this Volume). These alloyed steels form a protective rust film in alternating wet and dry environments. The weathering steels do not perform well under conditions of burial or total immersion. The atmospheric attack of wrought iron can sometimes progress along the internal planes formed during rolling and cause swelling of the material. For this reason, it is best not to cut across the grain boundaries and leave the face exposed to the environment. Stainless steels and aluminum alloys are normally very resistant to atmospheric conditions and will resist tarnishing in industrial, urban, and rural environments.

Lead, aluminum, and copper corrode initially, but form a protective film. In an urban atmosphere, nickel does not form a completely protective film and will experience a parabolic corrosion rate. Zinc attack appears to be linear after an initial period of decreasing corrosion rate. The corrosion rate of steel depends on the alloying elements typically attributed to the compact nature of the rust formed because of the alloying elements.

Copper, lead, and nickel form sulfates on the surface when attacked by dilute H_2SO_4. The lead forms a protective film, but the copper and nickel will slough off after a period of time. The protective carbonate film on zinc and cadmium is dissolved, and the metal is readily attacked. The oxide film on iron is formed by the hydrolysis of the ferrous sulfate. More detailed information on each of the metal systems mentioned above can be found in the Section "Specific Alloy Systems" in this Volume.

Prevention of Atmospheric Corrosion

Two approaches can be taken to prevent the onset of atmospheric corrosion. The first is a temporary fix that can be used during transport or storage. This consists of lowering the atmospheric humidity by using a desiccant, heating devices, or by treating the surface with a vapor phase or surface inhibitor. Permanent solutions to atmospheric corrosion can be accomplished by either changing the material or by applying a coating. Organic, inorganic, and metallic coatings have been effectively employed. The use of protective coatings and inhibitors to mitigate corrosion is discussed at length in the Section "Corrosion Protection Methods" in this Volume.

When using an alloy steel, the addition of small amounts of copper, phosphorus, nickel, and chromium are particularly effective in reducing atmospheric corrosion. It has been reported that copper additives are more effective in temperate climates than in tropical marine regions. The combination of minor elements, such as the addition of chromium and nickel with copper and phosphorus, appears to be very effective for all locations. The effects of alloying additions in ferrous alloys (wrought carbon, alloy, and stainless steels, and cast irons and steels) are detailed in the first five articles of the Section "Specific Alloy Systems" in this Volume.

Galvanic Corrosion

Robert Baboian, Texas Instruments, Inc.; Steven L. Pohlman, Kennecott Corporation

---

Galvanic corrosion occurs when a metal or alloy is electrically coupled to another metal or conducting nonmetal in the same electrolyte. The three essential components are:

- Materials possessing different surface potential
- A common electrolyte
- A common electrical path

A mixed metal system in a common electrolyte that is electrically isolated will not experience galvanic corrosion, regardless of the proximity of the metals or their relative potential or size.

During galvanic coupling, corrosion of the less corrosion-resistant metal increases and the surface becomes anodic, while corrosion of the more corrosion-resistant metal decreases and the surface becomes anodic. The driving force for corrosion or current flow is the potential developed between the dissimilar metals. The extent of accelerated corrosion resulting from galvanic coupling is affected by the following factors:

- The potential difference between the metals or alloys
- The nature of the environment
- The polarization behavior of the metals or alloys
- The geometric relationship of the component metals or alloys

The differences in potential between dissimilar metals or alloys cause electron flow between them when they are electrically coupled in a conductive solution. The direction of flow, and therefore the galvanic behavior, depends on which metal or alloy is more active. Thus, the more active metal or alloy becomes anodic, and the more noble metal or alloy becomes cathodic in the couple. The driving force for galvanic corrosion is the difference in potential between the component metals or alloys.

Galvanic Series

A galvanic series of metals and alloys is useful for predicting galvanic relationships. Such a series is an arrangement of metals and alloys according to their potentials as measured in a specific electrolyte. The galvanic series allows one to determine which metal or alloy in a galvanic couple is more active. In some cases, the separation between the two metals or alloys in the galvanic series gives an indication of the probable magnitude of corrosive effect.

The potential of a metal or alloy is affected by environmental factors. Corrosion product films and other changes in surface composition can occur in some environments; therefore, no one value can be given for a particular metal or alloy. This requires a galvanic series to be measured in each environment of interest. Most commonly, however, the galvanic series has been constructed from measurements in seawater, as shown in Table 2. With certain exceptions, this series is broadly applicable in other natural waters and in uncontaminated atmospheres.

Protected end (cathodic, or most noble)

Because most engineering materials are alloys, the measurement of galvanic corrosion employing actual material is much more useful than predicting current flow from the electromotive force series. Therefore, tabulations such as Table 2 can be very useful.

Polarization

As stated above, electron flow occurs between metals or alloys in a galvanic couple. This current flow between the more active and more noble members causes shifts in potential due to polarization, because the potentials of the metals or alloys tend to approach each other.

The magnitude of the shift depends on the environment, as does the initial potential. If the more noble metal or alloy is more easily polarized, its potential is shifted more toward the more active metal or alloy potential. The shift in potential of the more active metal or alloy in the direction of the cathode is therefore minimized so that accelerated galvanic corrosion is not as great as would otherwise be expected. On the other hand, when the more noble metal or alloy is not readily polarized, the potential of the more active metal shifts further toward the cathode (that is, in the direction of anodic polarization) such that appreciable accelerated galvanic corrosion occurs. More detailed information on polarization can be found in the article "Kinetics of Aqueous Corrosion" in this Volume.

Area, Distance, and Geometric Effects

Factors such as area ratios, distance between electrically connected materials, and geometric shapes also affect galvanic-corrosion behavior.

Area effects in galvanic corrosion involve the ratio of the surface area of the more noble to the more active members(s). When the surface area of the more noble metal or alloy is large in comparison to the more active member, an unfavorable area ratio exists for the prevailing situation in which a couple is under cathodic control. The anodic current density on the more active metal or alloy is extremely large; therefore, the resulting polarization leads to more pronounced galvanic corrosion. The opposite area ratio--large active member surface, smaller noble member surface--produces only slightly accelerated galvanic effects because of the predominant polarization of the more noble material.

Effect of Distance. Dissimilar metals in a galvanic couple that are in close physical proximity usually suffer greater galvanic effects than those that are further apart. The distance effect is dependent on solution conductivity because the path of current flow is the primary consideration. Thus, if dissimilar pipes are butt welded with the electrolyte flowing through them, the most severe corrosion will occur adjacent to the weld on the anodic member.

Effect of Geometry. The geometry of the circuit also enters into the effect to the extent that current will not readily flow around corners. This is simply an extension of the principle described above, in which the current takes the path of least resistance.

Modes of Attack

Galvanic corrosion of the anodic member(s) of a couple may take the form of general or localized corrosion, depending on the configuration of the couple, the nature of the films induced, and the nature of the metals or alloys involved. Generally, there are five major categories.

Dissimilar Metals. The combination of dissimilar metals in engineering design by mechanical or other means is quite common--for example, in heating or cooling coils in vessels, heat exchangers, or machinery. Such combinations often lead to galvanic corrosion.

Nonmetallic Conductors. Less frequently recognized is the influence of nonmetallic conductors as cathodes in galvanic couples. Carbon brick in vessels is strongly cathodic to the common structural metals and alloys. Impervious graphite, especially in heat-exchanger applications, is cathodic to the less noble metals and alloys. Carbon-filled polymers can act as noble metals in a galvanic couple.

Another example is the behavior of conductive films, such as mill scale (magnetite, Fe_3O_4) or iron sulfides on steel, or of lead sulfate on lead. Such films can be cathodic to the base metal exposed at breaks or pores in the scale (Fig. 7) or even to such extraneous items as valves or pumps in a piping system.

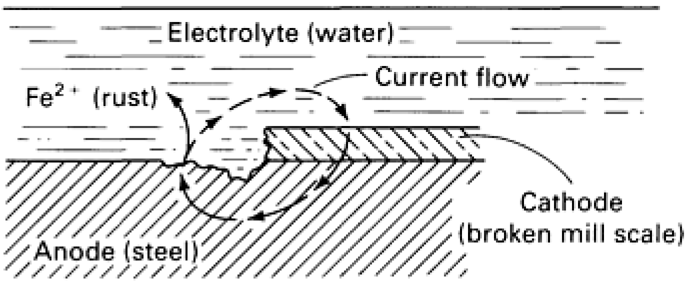

Fig. 7 Schematic showing how breaks in mill scale (Fe_3O_4) can lead to galvanic corrosion of steel

Metallic Coatings. Two types of metallic coatings are used in engineering design: noble metal coatings and sacrificial metal coatings. Noble metal coatings are used as barrier coatings over a more reactive metal. Galvanic corrosion of the substrate can occur at pores, damage sites, and edges in the noble metal coating. Sacrificial metal coatings provide cathodic protection of the more noble base metal, as in the case of galvanized steel or Alclad aluminum.

Cathodic Protection. Magnesium, zinc, and aluminum galvanic (sacrificial) anodes are used in a wide range of cathodic protection applications. The galvanic couple of the more active metal and a more noble structure (usually steel, but sometimes aluminum, as in underground piping) provides galvanic (cathodic) protection, while accelerated corrosion of the sacrificial metal (anode) occurs. The article "Cathodic Protection" in this Volume contains information on the principles and applications of this method of corrosion prevention and the selection of anode materials.

Metal Ion Deposition. Ions of a more noble metal may be reduced on the surface of a more active metal--for example, copper on aluminum or steel, silver on copper. This process is also known as cementation, especially with regard to aluminum alloys. The resulting metallic deposit provides cathodic sites for further galvanic corrosion of the more active metal.

Predicting Galvanic Corrosion

The most common method of predicting galvanic corrosion is by immersion testing of the galvanic couple in the environment of interest. Although very time consuming, this is the most desirable method of investigating galvanic corrosion. Initially, screening tests are conducted to eliminate as many candidate materials as possible. These screening tests consist of one or more of the following three electrochemical techniques: potential measurements, current measurements, and polarization measurements. Additional information can be found in the article "Evaluation of Galvanic Corrosion" in this Volume.

Potential measurements are made to construct a galvanic series of metals and alloys, as described above. As a first approximation, the galvanic series is a useful tool. However, it has serious shortcomings. Metals and alloys that form passive films will exhibit varying potentials with time and are therefore difficult to position in the series with certainty. Also, the galvanic series does not provide information on the polarization characteristics of the materials and so is not helpful in predicting the probable magnitude of galvanic effects.

Measurement of galvanic currents between coupled metals or alloys is based on the use of a zero-resistance milliammeter. Zero-resistance electrical continuity between the members of the galvanic couple is maintained electronically, while the resulting current is measured with the ammeter. Use of this technique should take into account certain limitations. First, when localized corrosion such as pitting or crevice corrosion is possible in the galvanic couple, long induction periods may be required before these effects are observed. Test periods must be of sufficient duration to take this effect into account. Also the measured galvanic current is not always a true measure of the actual corrosion current, because it is the algebraic sum of the currents due to anodic and cathodic reactions. When cathodic currents are appreciable at the mixed potential of the galvanic couple, the measured galvanic current will be significantly lower than

the true current. Therefore, large differences between the true corrosion rate calculated by weight loss and that obtained by galvanic current measurements have been observed.

Polarization measurements on the members of a galvanic couple can provide precise information concerning their behavior. The polarization curves and the mixed potential for the galvanically coupled metals in a particular environment can be used to determine the magnitude of the galvanic-corrosion effects as well as the type of corrosion.

An important application in the use of polarization measurements in galvanic corrosion is the prediction of localized corrosion. Polarization techniques and critical potentials are used to measure the susceptibility to pitting and crevice corrosion of metals and alloys coupled in chloride solutions. In addition, this technique is valuable in predicting galvanic corrosion among three or more coupled metals or alloys.

Performance of Alloy Groupings

Light Metals. Magnesium occupies an extremely active position in most galvanic series and is therefore highly susceptible to galvanic corrosion as described in the article "Corrosion of Magnesium and Magnesium Alloys" in this Volume. It is widely used as a sacrificial anode in cathodic protection.

Aluminum and its alloys also occupy active positions in the galvanic series and are subject to failure by galvanic attack (Fig. 8 and 9). In chloride-bearing solutions, aluminum alloys are susceptible to galvanically induced localized corrosion, especially in dissimilar-metal crevices. In this type of environment, severe galvanic effects are observed when aluminum alloys are coupled with more noble metals and alloys. Cementation effects are also observed in the presence of dissolved heavy-metal ions such as copper, mercury, or lead. Some aluminum alloys are used for sacrificial anodes in seawater. An active, anodic alloy is used to clad aluminum, protecting it against pitting in some applications.

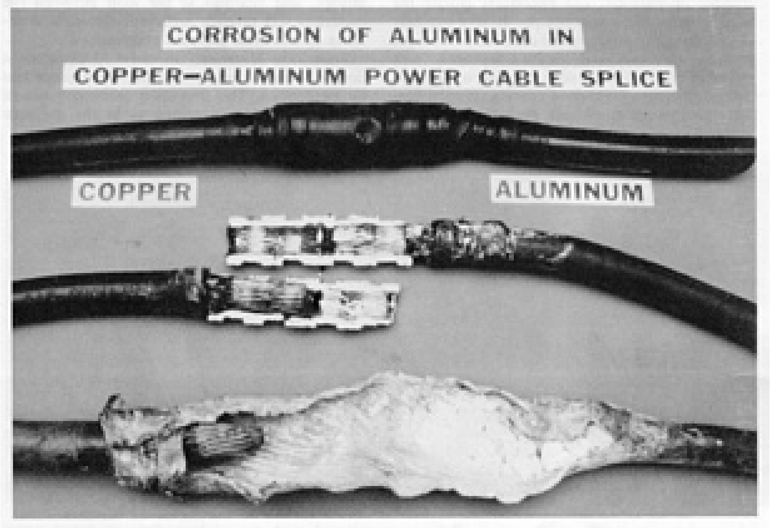

Fig. 9 Galvanic corrosion of aluminum in buried power cable splice (copper to aluminum). Courtesy of R. Baboian, Texas Instruments, Inc.

In the absence of chlorides or with low concentrations, as in potable water, aluminum and its alloys may be less active because of greater stability of the protective oxide film. Galvanic effects are not as severe under these conditions.

The galvanic-corrosion behavior of magnesium, aluminum, iron and steel, stainless steel, lead, tin, zinc, copper, nickel, cobalt, titanium, zirconium, tantalum, and noble metals are reviewed below. Detailed information on these metals and their alloys can be found in the Section "Specific Alloy Systems" in this Volume. Other articles of interest include "Cathodic Protection," which reviews metals and alloys used as sacrificial (galvanic) and impressed-current anodes; "Tarnish and Corrosion of Dental Alloys," which reviews corrosion-resistant materials used for inlays, implants, and other dental appliances; and "Corrosion of Metallic Implants and Prosthetic Devices," which reviews materials selection and corrosion behavior for orthopedic devices.

Iron and steel are fairly active materials and require protection against galvanic corrosion by the higher alloys. They are, however, more noble than aluminum and its alloys in chloride solutions. However, in low-chloride waters, a reversal of potential can occur that causes iron or steel to become more active than aluminum. A similar reversal can occur between iron and zinc in hot waters of a specific type of chemistry. Examples of galvanic corrosion of iron and steel are shown in Fig. 10, 11, 12, and 13.

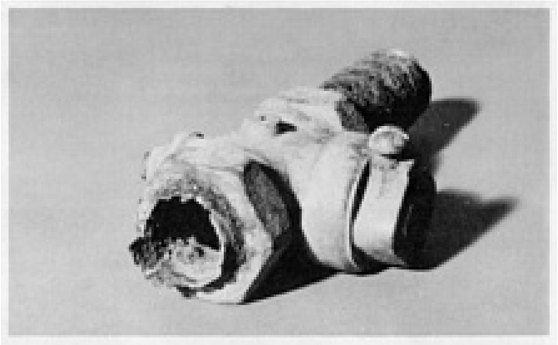

Fig. 13 Galvanic corrosion of steel pipe at brass fitting in humid marine atmosphere. Courtesy of R. Baboian, Texas Instruments, Inc.

Stainless Steels. Galvanic corrosion behavior of stainless steels is difficult to predict because of the influence of passivity. In the common galvanic series, a noble position is assumed by stainless steels in the passive state, while a more active position is assumed in the active state (Table 2). This dual position in galvanic series in chloride-bearing aqueous environments has been the cause of some serious design errors. More precise information on the galvanic behavior of stainless steels can be obtained by using polarization curves, critical potentials, and the mixed potential of the galvanic couple. In chloride-bearing environments, galvanically induced localized corrosion of many stainless steels occurs in couples with copper or nickel and their alloys and with other more noble materials. However, couples of stainless and copper alloys are often used with impunity in freshwater cooling systems. Iron and steel tend to protect stainless steel in aqueous environments when galvanically coupled. The passive behavior of stainless steels makes them easy to polarize; thus, galvanic effects on other metals or alloys tend to be minimized. However, galvanic corrosion of steel can be induced by stainless, particularly in aqueous environments and with adverse area ratios.

Lead, Tin, and Zinc. These three materials occupy similar positions in the galvanic series, although zinc is the most active. The oxide films formed on these materials can shift their potentials to more noble values. Thus, in some environments, they may occupy more noble positions than one might otherwise expect. For example, the tin coating in tin cans is anodic to steel under anaerobic conditions in the sealed container, but becomes cathodic when the can is opened and exposed to air. Zinc is an active metal. It is susceptible to galvanic corrosion and is widely used for galvanic anodes, in cathodic protection as a sacrificial coating (for example, galvanizing or electroplating) and as a pigment in certain types of coatings.

Copper Alloys. Copper and its alloys occupy an intermediate position in the galvanic series. They are not readily polarized in chloride-bearing aqueous solutions; therefore, they cause severe accelerated corrosion of more active metals, such as aluminum and its alloys and the ferrous metals. Somewhat similar to the nickel alloys, they lie between the active and passive positions for stainless steels (Table 2) and therefore induce localized corrosion of the active alloys.

Nickel Alloys. Nickel and its alloys are not readily polarized and will therefore cause accelerated corrosion of more active materials, such as aluminum and ferrous alloys. In chloride-bearing solutions, nickel is somewhat more noble than copper, and the cupronickels lie somewhere in between. Nickel and its alloys are similar to copper alloys in their effects on stainless steels. In some environments, the cast structure of a nickel weld may be anodic to the wrought parent metals.

The combination of a passive surface with the inherent resistance of nickel-chromium alloys, such as Inconel alloy 600 and Hastelloy alloy C-276, places them in more noble positions in the traditional galvanic series. In chloride-bearing solutions, Inconel alloy 600 is reported to occupy two positions because of existence of active and passive states in a manner similar to the stainless steels (Table 2). These alloys are readily polarized, and galvanic effects on other less noble metals and alloys therefore tend to be minimized.

Cobalt-base alloys, most of which are chromium bearing, are resistant to galvanic corrosion because of their noble position in the galvanic series. However, in environments in which their passive film is not stable, they occupy a more active position and can be adversely affected by more noble materials. The fact they they polarize readily tends to reduce their galvanic effects on less noble materials.

Reactive Metals. Titanium, zirconium, and tantalum are extremely noble because of their passive films. In general, these alloys are not susceptible to galvanic corrosion, and their ease of polarization tends to minimize adverse galvanic effects on other metals or alloys. Because of the ease with which they pick up hydrogen in the atomic state, they may themselves become embrittled in galvanic couples. Tantalum repair patches in glass-lined vessels have been destroyed by contact with cooling coils or agitators made of less noble alloys. Tantalum is susceptible to attack by alkalies, such as may form in the vicinity of a cathode in neutral solutions.

Noble metals. The term noble metal is applied to silver, gold, and platinum group metals. This designation in itself describes their position in the galvanic series and their corresponding resistance to galvanic corrosion. However, they do not polarize readily and can therefore have a marked effect in galvanic couples with other metals or alloys. This effect is observed with gold and silver coatings on copper, nickel, aluminum, and their alloys.

Methods of Control

Materials Selection. Combinations of metals or alloys widely separated in the relevant galvanic series should be avoided unless the more noble material is easily polarized. Metallic coatings can be used to reduce the separation in the galvanic 0series, as described below. Additional information is provided in the article "Materials Selection" in this Volume.

Environmental Control. In particular cases, it is possible to reduce or eliminate galvanic-corrosion effects between widely dissimilar metals or alloys in a particular environment. The use of corrosion inhibitors is effective in some cases. Elimination of cathodic depolarizers (deaeration of water by thermomechanical means plus oxygen scavengers such sodium sulfite or hydrazine) is every effective in some aqueous systems. Such methods are discussed in detail in the articles "Corrosion Inhibitors for Oil and Gas Production," "Corrosion Inhibitors for Crude Oil Refineries," and "Control of Environmental Variables in Water Recirculating Systems" in this Volume.

Barrier coatings of a metallic nature have already been discussed. Inert barrier coatings, organic or vitreous, can effectively isolate the metals from the environment. It is extremely dangerous to coat the anodic member of a couple because this may only reduce its area, with severely accelerated attack occurring at holidays in the otherwise protective coating. If inert barrier coatings are employed, both the anode and cathode must be protected--for example, the heads, tubesheets, and first 4 to 6 tube diameters on the tube side of a water-cooled heat exchanger.

Electrochemical techniques are comprised of three alternative methodologies: electrical isolation, use of transition materials, and cathodic protection.

Electrical Isolation. The joint between dissimilar metals can be isolated to break the electrical continuity. Use of nonmetallic inserts, washers, fittings, and coatings at the joint between the materials will provide sufficient electrical resistance to eliminate galvanic corrosion.

Transition Materials. In order to eliminate a dissimilar-metal junction, a transition piece can be introduced. The transition piece consists of the same metals or alloys as in the galvanic couple bonded together in a laminar structure. The

transition piece is inserted between the members of the couple such that the similar metals mate with one another. The dissimilar-metal junction then occurs at the bond interface, excluding the electrolyte.

Cathodic Protection. Sacrificial metals, such as magnesium or zinc, may be introduced into the galvanic assembly. The most active member will corrode while providing cathodic protection to the other members in the galvanic assembly (for example, zinc anodes in cast iron waterboxes of copper alloy water-cooled heat exchangers). Impressed-current systems can also provide the same effect. Both sacrificial anodes and impressed-current anodes are discussed in the article "Cathodic Protection" in this Volume.

Design. Unfavorable area ratios should be avoided. Metal combinations should be used in which the more active metal or alloy surface is relatively large. Rivets, bolts, and other fasteners should be of a more noble metal than the material to be fastened. Dissimilar-metal crevices, such as at threaded connections, are to be avoided. Crevices should be sealed, preferably by welding or brazing, although putties are sometimes used effectively. Replaceable sections of the more active member should be used at joints, or the corrosion allowance of this section should be increased, or both. Additional information is available in the article "Design Details to Minimize Corrosion" in this Volume.

Stray-Current Corrosion

Steven L. Pohlman, Kennecott Corporation

Stray-current corrosion, or stray-current electrolysis, is different from natural corrosion because it is caused by an externally induced electrical current and is basically independent of such environmental factors as oxygen concentration or pH. Environmental factors may enhance other corrosion mechanisms involved in the total corrosion process, but the stray-current corrosion portion of the mechanism is unaffected.

Stray currents are defined as those currents that follow paths other than their intended circuit. They leave their intended path because of poor electrical connections within the circuit or poor insulation around the intended conductive material. The escaped current then will pass through the soil, water, or any other suitable electrolyte to find a low-resistant path, such as a buried metal pipe or some other metal structure, and will flow to and from that structure, causing accelerated corrosion.

Sources of Stray Currents

The electric railways were the major source of stray direct current (dc), but since their demise, the problem has become less common. Other sources, such as cathodic protection systems, electrical welding machines, and grounded dc electric sources, create stray direct currents; therefore, stray-current corrosion does present problems occasionally. For example, stray-currents created by an electric welding machine on board ship with a grounded dc line located on shore will cause accelerated attack of the ship's hull as the stray currents generated at the welding electrodes pass out of the ship's hull through the water back to shore.

Stray currents cause accelerated corrosion to occur where they leave the metal structure and enter the surrounding electrolyte. At points where the current enters the structure, the site will become cathodic in nature because of changes in potential, while the area where the current leaves the metal will become anodic. These sites may be hundreds of yards apart. Houses in close proximity can experience dramatically different corrosion characteristics in their water lines. The pipes in one house may be protected, while those next door may be catastrophically failing.

Stray current flowing along a pipeline typically will not cause damage inside the pipe, because of the high conductivity of the metal compared to the fluid in the pipe. The damage occurring at the point where the current reenters the electrolyte will be localized and on the outside surface of the metal. In certain cases in which the pipe has insulated joints and the stray current enters the internal fluid, the corrosion will occur on the inside of the tube.

Damage caused by alternating current (ac) is less than that experienced by dc and decreases in severity as the frequency increases. Damage caused by alternating currents on active-passive metals, such as stainless steel and aluminum, is greater than damage to nonpassive metals, such as iron and zinc. The alternating reduction and oxidation of the surface layers caused by the ac may cause the passive layers to become porous and layered. A major source for ac stray currents is buried power lines.

Identifying Stray-Current Corrosion

Galvanic corrosion and stray-current corrosion are very similar in that they both show protected cathodic sites and preferentially corroded anodic sites. The major difference is that stray-current corrosion may vary over short periods of time, depending on the varying load of the power source, while galvanic corrosion proceeds at a constant rate because the electrochemical reaction is not dependent on an external current source.

Amphoteric metals such as aluminum and zinc can show signs of corrosion at the cathodic portion of the metal surface because of the build up of alkalies created by the cathodic electrochemical reactions. The extent of this type of corrosion is difficult to determine because it is dependent not only on the amount of current flow but also on the surrounding environment.

It is difficult to distinguish between ordinary corrosion and stray-current corrosion by visual inspection. In some cases, the attack is more localized, causing a concentration of pits that is not normally observed but under specific environmental conditions could occur even without the presence of stray currents. Some researchers have observed that stray-current corrosion tends to cause penetration along the grain boundaries--once again a phenomenon seen under many conditions. In the case of a gray cast iron, selective attack of the ferrite within the metal matrix has been observed. This type of attack can weaken the material and cause premature failure. The magnitude of stray currents is not easy to measure, but potential drops, potential differences, and the measurement of current flow along a buried structure are ways of determining the existence of stray currents.

Prevention of Stray-Current Corrosion

There are various ways to decrease the chances of stray-current corrosion from occurring. Basically, one should try to stop the leakage of the current from the intended circuit by maintaining good electrical connections and insulation. Therefore, a major factor in controlling stray-current corrosion is the testing for and controlling of the current before it enters the soil or surrounding electrolyte.

If current is escaping and nothing can be done to prevent it, the corrosion of the surrounding metal structures can be mitigated in several ways. One technique is called bonding, which consists of connecting the stray-current conductor with the source ground and thus eliminating the need for the current to leave the metal and enter the soil.

In addition, sacrificial anodes can also be placed in contact with the stray-current conductor to direct the corrosion to a preferred site. Also, dc power source can be placed on line to cause a flow of current in the opposite direction of the stray current and effectively protect the pipe by the impressed current.

Impeding the flow of the stray current along the metallic path by installing insulators is another way to protect an affected structure. Caution is required, however, because the current will flow around the insulators and cause corrosion damage at multiple sites if the source voltages are large. The insulator gaps must be numerous enough to make the current sufficiently small. Current densities passing through the circuit should be kept as low as possible.

Coating a pipe or structure is not an effective way to control the problem unless the coating is flawless. In fact, coatings that are cracked or contain pin holes will accelerate the attack at sites of imperfection.

General Biological Corrosion

Stephen C. Dexter, College of Marine Studies, University of Delaware

---

A number of metals, such as structural steel, copper alloys, magnesium alloys, and zinc, tend to corrode generally over the entire exposed surface in aqueous environments. This is particularly true in the absence of galvanic effects and crevices. The corrosion rates of these metals in aerated aqueous environments tend to be determined by the rate at which dissolved oxygen can be delivered to the metal surface. Thus, the corrosion rate will be affected by anything that changes the rate of oxygen transport. Biological organisms present in the environment have the potential to increase or decrease oxygen transport to the surface; consequently, they can either increase or decrease corrosion rates.

Although the focus of this section is on the influence of organisms on general corrosion rates, it should be noted that organisms are more likely to cause localized than general corrosion. More information on localized biological corrosion can be found in the article "Localized Corrosion" in this Volume.

Marine Environments

Effect of Macroorganisms. A heavy encrustation of biofouling organisms on structural steel immersed in seawater will often decrease the corrosion rate of the steel as long as the cover of organisms remains complete and relatively uniform. The heavy fouling layer acts as a barrier film in limiting the amount of dissolved oxygen reaching the metal surface. A layer of hard-shelled organisms, such as barnacles or mussels, on steel in the splash zone (just above the high tide level) also shields the metal from the damaging effect of wave action.

It should be emphasized that these beneficial effects on general corrosion occur under a complete fouling layer. If coverage is incomplete, as shown in Fig. 14, the fouling film is then more likely to cause the initiation of localized corrosion by creating oxygen concentration cells. The beneficial effects may also be lost if the fouling film leads to a high activity of sulfate-reducing bacteria at the metal surface. More information on this topic can be found in the Appendix "Biological Effects" to the article "Effects of Environmental Variables on Aqueous Corrosion" and in the section "Localized Biological Corrosion" in the article "Localized Corrosion" in this Volume, Additional information on both micro- and macrofouling in marine environments can also be found in the article "Marine Corrosion" (see the section "Seawater") and in Ref 2, 3, and 4.

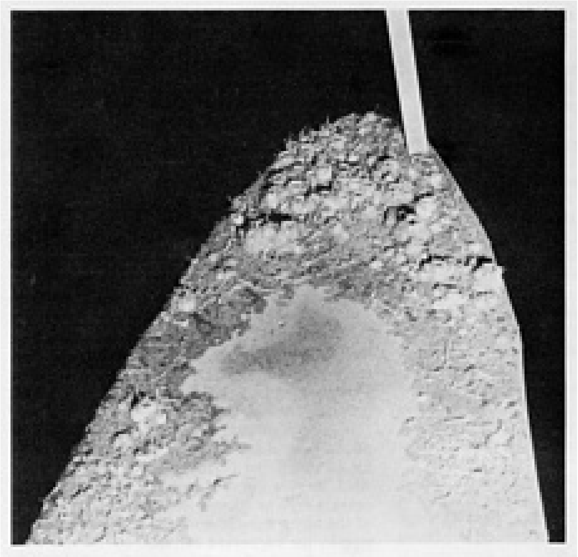

Fig. 14 Barnacles attached to the periphery of a high-strength steel rudder, which had originally been coated with an antifouling paint. During use, the paint around the edges had been removed by mechanical action, thus allowing the attachment of barnacles. Partial coverage of such macroorganisms can lead to localized corrosion. Complete coverage can sometimes provide a barrier film and limit corrosion. Courtesy of B. Little, Naval Ocean Research and Development Activity, Department of the Navy.

Effect of Microorganisms. A continuous film of bacteria, algae, and slime, as shown in Fig. 15, can have the same effect on oxygen transport and corrosion rates as that discussed above for the macroorganisms. It is rare, however, for a film of microorganisms in the marine environment to be continuous over large areas of exposed surface. Usually, microbial slime films are spotty. This is caused by a number of factors, including variability in the hydrodynamics of water flow over the surface and the natural tendency for the organisms to grow in discrete colonies rather than continuous films.

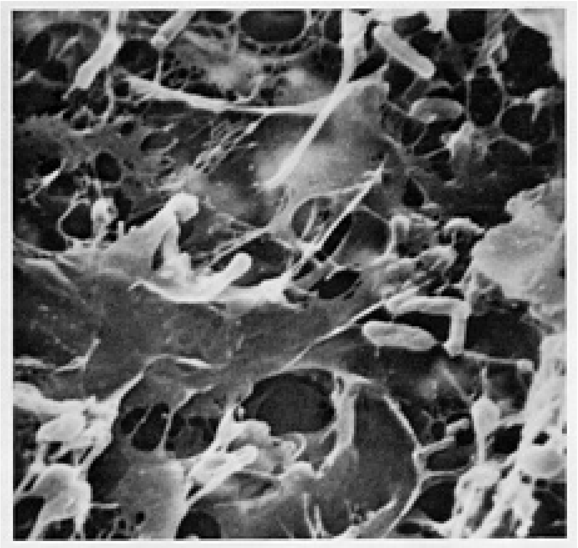

Fig. 15 Microbial film consisting of rod-shaped bacteria and slime. Courtesy of S.C. Dexter, University of Delaware

For these reasons, the influence of microbial films a marine environments is more likely to be a switch from general to localized corrosion than a change in the general corrosion rate. Microbial films are suspected of being capable of inducing pit initiation on stainless and copper alloys in marine environments. In addition, there are many references in the literature to the fact that natural seawater, with its full complement of organisms, is more corrosive than artificial seawater with fewer or different organisms. However, the effects are not yet well documented or understood. In general, microbial films do not seen to have the strong, well-documented effect on corrosion in marine environments that they do in freshwater and soil environments.

Freshwater Environments

As was the case in marine environments, microbial films will affect the general corrosion rate only if the film is uniformly distributed over the wetted surface. If microorganisms form in discrete deposits or colonies, the resulting corrosion is likely to be localized, rather than uniform. Again, the articles in this Volume that discuss biological corrosion should be consulted.

In some cases, a relatively uniform slime film does form. Examples are slime film formation on the piping of potable water handling systems and on the heat-transfer surfaces of low-temperature heat exchangers. In such cases, a small change in the general corrosion rate of the piping material is inconsequential, and the microbial slime film is of concern only if it leads to obstruction of flow, growth of organisms that would pose a health hazard, or localized corrosion.

Molten-Salt Corrosion

John W. Koger, Martin Marietta Energy Systems; Steven L. Pohlman, Kennecott Corporation

---

The corrosion of metal containers by molten, or fused, salts has been observed for an extended period of time, but over the last several decades, more effort has been directed toward understanding corrosion phenomena at higher temperatures. Annotated bibliographies of molten-salt corrosion for different media and metal combinations have been published and are cited in the selected references. Additional information on molten-salt corrosion can be found in the article "Fundamentals of High-Temperature Corrosion in Molten Salts" in this Volume.

Mechanisms of Molten-Salt Corrosion

Two general mechanisms of corrosion can exist in molten salts. One is the metal dissolution caused by the solubility of the metal in the melt. This dissolution is similar to that in molten metals, but is not common. The second and most common mechanisms is the oxidation of the metal to ions that is similar to aqueous corrosion. For this reason, molten-salt corrosion has been identified as an intermediate form of corrosion between molten metal and aqueous corrosion.

General, or uniform, metal oxidation and dissolution is a common form of molten-salt corrosion, but is not the only form of corrosion seen. Selective leaching is very common at higher temperatures, as are pitting and crevice corrosion at lower temperatures. All the forms of corrosion observed in aqueous systems, including stress-assisted corrosion, galvanic corrosion, erosion-corrosion, and fretting corrosion, have been seen in fused salts.

Electrochemically, the molten salt/metal surface interface is very similar to the aqueous solution/metal surface interface. Many of the principles that apply to aqueous corrosion also apply to molten-salt corrosion, such as anodic reactions leading to metal dissolution and cathodic reduction of an oxidant.

The concept of acid and base behavior of the melt is very similar to its aqueous counterpart. The corrosion process is mainly electrochemical in nature because of the excellent ionic conductivity of most molten salts. Some investigators feel that dissolved water enhances the electrochemical corrosion nature of the molten salts.

Even though the corrosion mechanism is similar, there are major differences between molten-salt and aqueous corrosion. The differences arise mainly from the fact that molten salts are partially electronic conductors as well as ionic conductors. This fact allows for reduction reactions to take place in the melt as well as the metal/melt interface. This behavior also allows increase in frequency of cathodic reactions and can therefore lead to a substantial increase in corrosion rate over a similar electrochemically controlled aqueous system, especially if the corrosion media contain very few oxidants. Because of property differences between water and molten salt, the rate-controlling step in most molten-metal systems is ion diffusion into the bulk solution, not the charge transfer reaction that is typical of aqueous systems. Molten-salt systems operate at higher temperatures than aqueous systems, which leads to different forms of corrosion attack.

In aqueous systems in which specific elements are removed from alloys, such as the dezincification of zinc from brass, whether the nobler element is oxidized at some stage in the process and is subsequently plated out or whether the element agglomerates by a surface diffusion mechanism is not clear. In both cases, bulk diffusion is unlikely to play a major role. In high-temperature molten-salt systems, dissolution of the less noble element is the most probable mechanism and will even occur when the element is present at low concentration. Unlike aqueous systems, the rate of dissolution is therefore related to the bulk diffusion of the selectively leached element.

Because molten-salt corrosion reactions are reduction/oxidation controlled, the relative nobilities of the salt melts and the metals are important. The corrosion potential of the melt is often controlled by impurities in the melt or gas phase, which increases the cathodic reaction rate or changes the acidic or basic nature of the melt. The aggressiveness of the salt melts is typically governed by its redox equilibria.

Thermal gradients in the melt can cause dissolution of metal at hot spots and metal deposition at cooler spots. The result is very similar to aqueous galvanic corrosion, and like aqueous galvanic corrosion, a continuous electrical path is necessary between the hot and cold areas. Crevice corrosion has been observed, and wash-line attack caused by oxygen concentration corrosion is not uncommon at the metal/molten salt/air interface.

High-temperature corrosion in molten salts often exhibits selective attack and internal oxidation. Chromium depletion in iron-chromium-nickel alloy systems can occur by the formation of a chromium compound at the surface and by the subsequent removal of chromium from the matrix, leaving a depleted zone. Thus, the selectively removed species move out, while vacancies move inward and eventually form voids. The voids tend to form at grain boundaries in most chromium-containing metals, but in some high-nickel alloys, the voids form in the grains. Specific examples of the types of corrosion expected for the different metal-fused salt systems will follow.

Types of Molten Salts

Molten Fluorides. Fluoride melts are important because of their consideration for nuclear reactor cooling systems. Corrosion in many fluoride molten-salt melts is accelerated because protective surface films are not formed. In fact, the fluoride salts act as excellent fluxes and dissolve the various corrosion products.

Typically, nickel-base alloys show better corrosion resistance than iron-base alloys. Studies have also shown that most nickel- and iron-base alloys that contain varying amounts of chromium show void formation to varying depths. In nonisothermal flow systems, the metallic material shows void formation in the hot section and deposits in the cold section. In most alloys that contain chromium, depletion of the chromium accompanies the void formation. Analysis of the attacked metal and salt clearly shows that selective removal and outward diffusion of chromium result from oxidation by the fluoride mixture.

Inconel alloy 600 and certain stainless steels become magnetic after exposure to molten fluoride salt. This magnetism is caused by the selective removal of the chromium and the formation of a magnetic iron-nickel alloy covering the surface. The conditions of the melt need to be controlled to minimize the selective removal of the alloying elements. This control can be done by maintaining the melt in a reducing condition. Addition of beryllium metal to the melt is one way to slow the corrosion rate. Examples of microstructures of nickel-base and stainless steels as a result of exposure to molten salts are shown in Fig. 16.

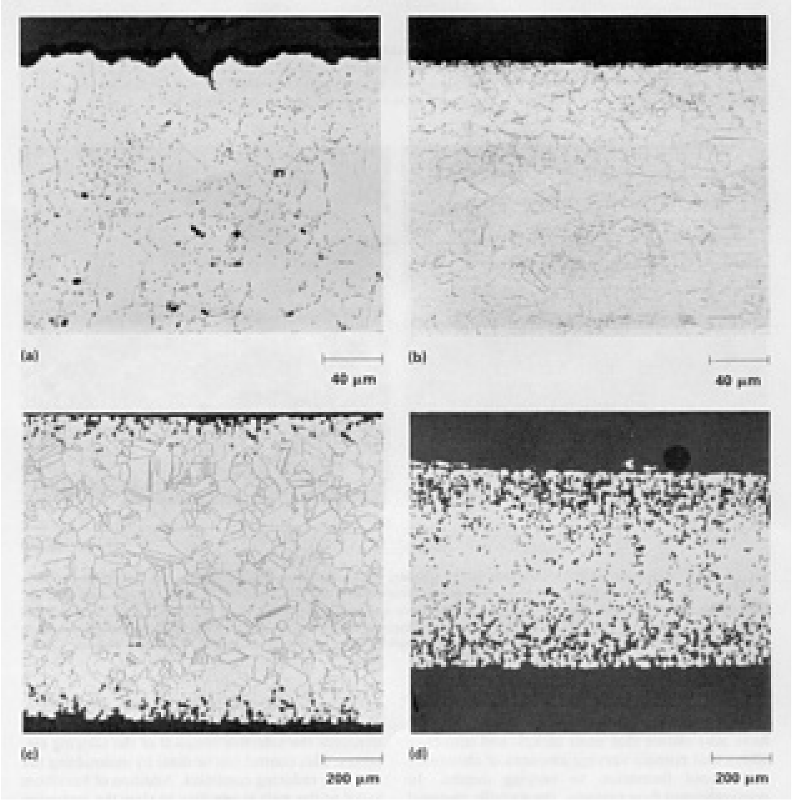

Fig. 16 Effect of molten-salt corrosion on nickel-base and stainless steel alloys. In all four examples, chromium depletion (dealloying) was the result of prolonged exposure. Accompanying chromium depletion was the formation of subsurface voids, which did not connect with the surface or with each other. As chromium was leached from the surface of the metal, a concentration (activity) gradient resulted and caused chromium atoms from the underlying region to diffuse toward the surface, leaving behind a zone enriched with vacancies. These vacancies would then agglomerate at suitable sites--primarily at grain boundaries and impurities. The vacancies became visible as voids, which tended to agglomerate and grow with increasing time and temperature. Koger, Martin Marietta Energy Systems

Chloride Salts. Molten salts consisting of chlorides are important, but because they have limited use, they have been studied less than fluoride systems. In general, chloride salts attack steels very rapidly with preferential attack of the carbides. Aluminum coatings on steels are not effective, while the addition of nickel to steel is beneficial. Nickel-base alloys decrease in resistance with increased oxygen partial pressure. In the chloride salts, no protective oxide scale is

formed on the nickel-base alloys. The attack of metal surfaces in pure sodium chloride has been observed at temperatures above 600 °C (1110 °F).

In most cases with iron-nickel-chromium alloys, the corrosion takes the form of intergranular attack. An increase of chromium in the alloy from 10 to 30% increases the corrosion rate by a factor of seven, while changes in nickel content have no effect. Thus, the intergranular attack is most likely selective with respect to chromium. The chromium removal begins at the grain boundary and continues with diffusion of the chromium from within the grain to the boundary layer, gradually enlarging the cavity in the metal. The gross corrosive attack is probably caused by the free chlorine, which is a highly oxidizing material, attacking the highly active structure-sensitive sites, such as dislocations and grain boundaries.

Selective attack of Inconel alloy 600 is observed in molten chloride melts. The resulting attacked region is a layer of porous spongelike material. The pores are not interconnected and are typically located at the grain boundaries.

Intergranular attack and rapid scales growth occur with zirconium alloys over 300 °C (570 °F). Platinum can be protected by the addition of oxide ions to the melt; this addition assists in the formation of a passive film.

Molten nitrates are commonly used for heat treatment baths; therefore, a great deal of material compatibility information exists. Plain carbon and low-alloy steels form protective iron oxide films that effectively protect the metal surface to approximately 500 °C (930 °F). Chromium additions increase the corrosion resistance of the steel, and hydroxide additions to the melt further increase the resistance of chromium containing steels. Aluminum and aluminum alloys should never be used to contain nitrate melts, because of the danger of explosion.

Molten Sulfates. High-temperature alloys containing chromium perform well in sulfate salts because they form a protective scale. If the chromium content is not sufficient, the alloy will suffer severe external corrosion and internal sulfidation. Non-film-forming metals, such as copper and silver, corrode very rapidly.

Hydroxide Melts. Stainless steels perform poorly in hydroxide melts because of selective oxidation of the chromium, which leads to pore formation in the metal. Nickel is more resistant than stainless steels or unalloyed steels.

The peroxide content of the melt controls the corrosion rate. An increase in water vapor and a decrease in oxygen pressure reduce the peroxide content and subsequently reduce the corrosion rate. An exception to this rule occurs with silver, which shows an increase in corrosion rate with increased water vapor. Most glass and silica are rapidly attacked by hydroxide melts, while alumina is more resistant.

Carbonate Melts. Austenitic stainless steels perform well in carbonate melts up to 500 °C (930 °F). If temperatures to 600 °C (1110 °F) are required, nickel-base alloys containing chromium are needed. For temperatures to 700 °C (1290 °F), high-chromium alloys containing at least 50% Cr are required. Above 700 °C (1290 °F), the passive films that form at lower temperatures will break down and preclude the use of metals. Aluminum coatings on steel structures perform well to 700 °C (1290 °F). For higher temperatures, alumina is required. Nickel does not provide adequate protection because of intergranular attack caused by the formation of nickel oxides.

Prevention of Molten-Salt Corrosion

There is a lack of reliable data for molten salts on structural material under industrial conditions, but several general rules should be observed. A material should be selected that will form a passive nonsoluble film in the melt if possible. Material selection is the key to successful containment. Minimizing the entry of oxidizing species such as oxygen and water into the melt is very important. The oxidizing power of the melt or its redox potential should be kept as low as possible, which can be accomplished by additives. The temperature of the bath should be kept as low as possible. The lower temperature not only decreases the diffusion rates of the ions into the melt but lowers the solubility of potentially passive surface films. Temperature gradients should be eliminated within the melts to decrease the selective dissolution and plating at hot and cold sites.

Corrosion in Liquid Metals

C. Bagnall, Westinghouse Electric Corporation, Advanced Energy Systems Division; W.F. Brehm, Westinghouse Hanford Company

---

This is a companion section to the article "Fundamentals of High-Temperature Corrosion in Liquid Metals" in this Volume. This section is intended to provide a pictorial account of the types of corrosion that may be found in a wide variety of liquid metal/containment/component combinations. The examples are not comprehensive, but will be informative and will provide a guide to appropriate literature sources for more specific information.

Liquid metals have long been considered for the improvement of efficiency in heat transfer systems. A recent example, from which many illustrations in this section are drawn (Fig. 17, 18, 19, 20, 21, 22), is the work that has been performed around the world on the sodium-cooled fast breeder reactor. This concept led to large-scale research and development programs that have continued through more than two decades. The result is a vast wealth of knowledge related to sodium corrosion behavior in all its varied aspects. The body of information greatly overshadows the corrosion data compiled for other liquid metals. This type of reactor is now in commercial operation in France and the Soviet Union for power generation. Development reactors are operating in the United Kingdom, West Germany, Japan, India, and the United States.

Liquid lithium systems have been designed for two widely different areas: space nuclear power and fusion reactors. These two applications draw on unique properties of this liquid metal and have led to studies with a wide range of containment materials and operating conditions. Space power reactors require low mass; this in turn demands high-temperature operation. Lithium, with its low melting point/high boiling point and high specific heat, is an ideal candidate heat transfer medium. Refractory metal alloy containment is essential for these reactors, which may have design operating temperatures as high as 1500 °C (2730 °F).

Liquid lithium in fusion reactor concepts is selected because here the neutronics allow tritium fuel to be bred from the lithium; this is essential in order to make the economics of the reactor viable. Containment temperatures are below 700 °C (1290 °F); therefore, iron-base alloys can be used for construction.

The effects of liquid lithium on stainless steel, nickel, and niobium containment materials are shown in Fig. 23, 24, 25, 26, 27, 28, 29, 30, 31, and 32.

Liquid mercury, potassium, and cesium have also been used for space and terrestrial applications. In some cases, these have involved two-phase systems in which the corrosion consideration became significantly altered. Lead, lead-bismuth, and lead-lithium alloys (Fig. 33) have received attention for topping cycle heat extraction systems, heat exchangers, reactor coolants, and, more recently, fusion reactor designs.

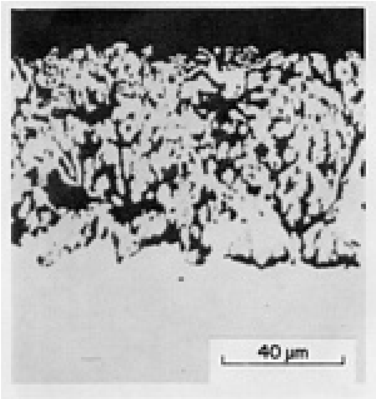

Fig. 33 Light micrograph of the polished cross section of a type 316 stainless steel exposed to thermally convective Pb-17at.% Li at 500 °C (930 °F) for 2472 h. Source: Ref 14

There are many other combinations of containment and liquid metals that have contributed to the knowledge of corrosion behavior; some have proved to be benign, while others have resulted in short-term catastrophic failures. In the discussion "Safety Considerations" in this section, some brief notes are given regarding safety precautions for handling liquid metals, operating circulating systems, dealing with fire and spillage, and cleaning contaminated components.

Forms of Liquid-Metal Corrosion

The forms in which liquid-metal corrosion are manifested can be divided into the following categories.

- Dissolution from a surface by (1) direct dissolution, (2) surface reaction, involving solid-metal atom(s), the liquid metal, and an impurity element present in the liquid metal, or (3) intergranular attack
- Impurity and interstitial reactions
- Alloying
- Compound reduction

All the variables present in the system play a part in the form and rate of corrosion that is established. There are ten key factors that have a major influence on the corrosion of metals and alloys by liquid-metal or liquid-vapor metal coolants. These are:

- Composition, impurity content, and stress conditionof the metal or alloy
- Exposure temperature and temperature range
- Impurity content of the liquid metal
- Circulating or static inventory
- Heating/cooling conditions
- Single or two-phase coolant
- Liquid-metal velocity
- Presence/control of corrosion inhibition elements
- Exposure time
- Monometallic or multialloy system components.

These factors have a varied influence, depending on the combination of containment material and liquid metal or liquid-metal alloy. In most cases, the initial period of exposure (of the order of 100 to 1000 h, depending on temperature and liquid metal involved), is a time of rapid corrosion that eventually reaches a much slower steady-state condition as factors related to solubility and activity differences in the system approach a dynamic equilibrium. In some systems, this

eventually leads to the development of a similar composition on all exposed corroding surfaces. High-nickel alloys and stainless steel exposed together in the high-temperature region of a sodium system will, for example, all move toward a composition that is more than 95% Fe.

Compatibility of a liquid metal and its containment varies widely, as is illustrated in Fig. 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, and 33. For a pure metal, surface attrition may proceed in an orderly, planar fashion, being controlled by either dissolution or a surface reaction. For a multicomponent alloy, selective loss of certain elements may lead to a phase transformation. For example, loss of nickel from austenitic stainless steel exposed to sodium may result in the formation of a ferritic surface layer (Fig. 17, 18a, 25, and 27). In high-nickel alloys, the planar nature of the corroding surface may be lost altogether, and a porous, spongelike layer may develop (Fig. 20 and 21). A more insidious situation can produce intergranular attack; liquid lithium, for example, will penetrate deep into refractory metals if precautions are not taken to ensure that the impurity element oxygen is in an oxide form more stable than Li_2O or LiO solutions, and is not left free in solid solution. Figure 31 illustrates intergranular attack in niobium.

Three factors--surface attrition, depth of depleted zone (for an alloy), and the presence of intergranular attack--should be evaluated collectively in any liquid-metal system. This evaluation will lead to an assessment of total damage, which may be presented either as a rate or as a cumulative allowance that must be made for the exposure of a given material over a given time. A large body of literature exists in which rate relationships for numerous liquid metal/containment combinations have been established. The more basic principles of liquid-metal corrosion are outlined in the article "Fundamentals of High-Temperature Corrosion in Liquid Metals" in this Volume and in the Selected References that follow this article.

One vitally important aspect of liquid-metal corrosion that is often overlooked is deposition. Corrosion itself is very often not a factor of major concern because surface recession rates in regions of maximum attack are often of the order of microns per year. The formation of compounds in the circulating liquid metal and the accumulation of deposits in localized regions where there is a drop in temperature, a change in flow rate or flow direction, or an induced change in surface roughness can, however, be very serious. If these deposits do not succeed in restricting flow channels completely, their nature is often such that they are only loosely adherent to deposition surfaces and may be dislodged by vibrations or thermal shock in the system, thus creating a major coolant flow restriction in a high-temperature region. Most deposits have a very low packing density; therefore, deposit growth can proceed at a rate that outstrips corrosion by several orders of magnitude. Examples of loosely adherent deposits are shown in Fig. 18(b), 22, 24, and 26. Figure 32 shows iron crystals that restricted flow in a pump channel of a lithium processing test loop.

Liquid-metal corrosion, as in other forms of corrosion, involves an appreciation for the source of corrosion in any system and an understanding of how potential sinks will operate on the corrosion burden, particularly if the liquid metal is not static but is circulated in a heat-transfer system either by pumping or by thermal convection.

Safety Considerations

The extensive work with the alkali and liquid metals has shown that such materials can be safely handled and used, provided certain precautions are needed. The requirements for the safe use of liquid metals are in essence those of good industrial or laboratory practice, involving protection from contamination, chemical reactions, exposure to toxic or irritating substances, and protection from high temperatures. More specific information and details on safe operation and handling are available in Ref 15 and 16 and in the Materials Safety Data sheets issued by the Manufacturing Chemists' Association.

Chemical Reactivity. All the liquid metals react with oxygen and moisture to some degree; with the alkali metals, the reaction is vigorous enough to be potentially hazardous, particularly with potassium, rubidium, and cesium. Use of inert gas covers and the exclusion of moisture are the best defenses. Even with the nonalkali metals where the reactions with water are slow, water, such as that found on equipment that is not completely dry, must not be brought in contact with liquid metals because of the danger of a steam explosion that can scatter liquid metal over a considerable area, damaging equipment and inflicting severe burns on unprotected workers. It goes without saying that workers in the vicinity of liquid-metal systems should wear appropriate protective clothing (Ref 15).

Potassium, rubidium, and cesium form higher oxides than the monoxide when exposed to air; these compounds are powerful oxidizing agents, often shock sensitive, and definitely hazardous in the proximity of organic materials. They will form at room temperature in contact with the solid metals. The practical application of this information is the need for extreme caution when handling the metals or compounds of the heavier alkali metals, particularly when they have been

stored for extended periods under less-than-ideal conditions, or when cleaning spills or fire residues. It is noted that the sodium-potassium eutectic alloy (NaK) will form potassium super-oxide when exposed to air or oxygen. Because NaK is liquid at normal room temperature, small leaks at low temperature do not necessarily freeze and self-seal.

Circulating Systems. It is usually convenient to provide a closed circulating system, or loop, in which to perform liquid-metal corrosion experiments. Reference 16 describes a simple system; the principles involved are the same for even very complex specialized devices. The loop will provide the means for circulation of the liquid metal; it will contain devices for on-line purification (if needed), while the inert cover gas will protect against chemical contamination. Insulation and an enclosure will protect against high temperatures and the spread of reaction products in case of a containment breach. Such systems provide a safe, convenient environment for handling liquid metals. Detailed operating procedures, involving common-sense principles such as maintaining the inert cover gas at all times and melting frozen metals by directionally heating away from a free surface, must be worked out for each system. The tens of millions of hours of safe operation of such systems, ranging from 1-L capacity test rigs to 4000-MW (thermal) nuclear reactors, validate the concept. References 17 and 18 describe many such test systems and the experiments performed in them.

Recovery From Spills and Accidents. It must be remembered that spills of the nonalkali metals, even though the chemical reactivity hazard may not be great, must be handled with care because of the toxic nature of many of the metals and their vapors. Leaks and spills of the alkali metals, particularly when some of the leaked material has burned, present a special hazard because the spilled material often contains finely divided unreacted metal mixed with combustion products. Such mixtures can react vigorously with moist air, water, and alcohol. The products of the heavier alkali metals are the most reactive in this respect, but mixtures containing sodium and lithium are certainly not immune to violent reactions if carelessly handled. Cleanup of these residues must be approached with extreme care.

Removal of Residual Metals From Corrosion Specimens. Nonalkali metals can often be removed from corrosion specimens by draining, forming an amalgam or solution with an alkali metal, and then removing the mixture by a technique discussed below. Alkali metals can be removed from specimens by reaction with water or alcohols; the most vigorous reaction is with water, and the rate decreases as one progresses to heavier weight alcohols. The reaction becomes more vigorous with increasing atomic weight of the alkali metals. Cesium/water reactions are definitely explosive. Use of ethanol and methanol is generally safe for sodium reaction, but one must remember the flammability hazard with alcohol vapors. The glycol ethers, such as butyl cellosolve, can also be used; they react more slowly than water, present less of a fire hazard than ethanol or methanol, but have toxic liquid and vapors. The water, alcohol, and glycol ether reactions all generate hydrogen; adequate ventilation must be provided to prevent the buildup of the hydrogen and the attendant danger of an explosion.

Anhydrous liquid ammonia forms a true solution with the alkali metals and can be used to remove adherent alkali metals from corrosion specimens. Precautions against the hazards of liquid ammonia must be taken; the alkali metal in solution with ammonia is then usually reacted with water or alcohol before the ammonia mixture is discarded. The conditions must be maintained truly anhydrous in order to avoid hydrogen generation and contamination of the samples. Hydrogen can become implanted in refractory metal samples and embrittle them even at subzero temperatures. If the proper equipment is available, evaporation of the residual metal from the surface can be done with excellent results.

Removal of alkali materials from pipework, if hydrogen generation is not a problem, can be accomplished with alcohol or gycol ether reaction, optionally followed by water rinsing to wash away the reaction products. It must be remembered that these reagents react very slowly, if at all, with oxides of the alkali metals. Another successful method in use is reaction with water vapor/inert gas (argon or nitrogen) mixtures, or water spray in an inert carrier gas, followed by water rinsing. Evaporation has also been successfully used and could be considered where hydrogen generation is not permitted. Ammonia-base systems have also been used for refractory metal pipework where hydrogen generation was prohibited. References 16, 17, and 18 contain more detailed information.

Fire Protection and First Aid. Firefighting and medical treatment should, of course, be left to the professionals. There are, however, several factors to keep in mind. An alkali metal fire does not expand, as does, for example, a petroleum fire. It does produce vast quantities of caustic smoke that react with moisture in or on the body, and this produces severe burns. The smoke must be avoided unless respiratory protection and protective clothing are worn.

Lithium presents a special hazard because of the toxic nature of some of its compounds and because it reacts with nitrogen. The combustion products of a lithium fire contain nitride and acetylide, which react with water to form ammonia and acetylene, respectively.

The only way to extinguish liquid-metal firs reliably is to smother them; various drying agents, such as sodium carbonate, sodium chloride, powdered dry graphite, or carbon microspheres, are effective. The sodium compounds should not be used on a lithium fire because of the chemical displacement reaction producing sodium metal that takes place. Instead, the graphite products should be used for extinguishment. It should be noted that few substances float on lithium; most tend to sink. Reference 19, however, describes the use of a ternary eutectic BaCl-NaCl-KCl salt for effective lithium fire extinguishment.

Inert gas blanketing is also effective for extinguishing fires; argon is preferred to nitrogen because of its higher density. Very effective fire suppression can be achieved by using inert gas blanketing in combination with a catch pan having a perforated floor to let the escaping liquid metal run to a second argon-blanketed chamber underneath the first. Of course, the hazards of oxygen-deficient atmospheres must be recognized and controlled when using inert gas flooding as fire suppression. Reference 20 provides more information about fire suppression in the alkali metals.

Emergency first aid treatment should concentrate on removing the victim from danger (for example, out of the smoke generated by a fire) and then removing the metal or compounds from skin and eyes. Running water is the most effective treatment because the cooling and flushing effect overcomes any hazard from reaction of a small amount of metal on the skin or clothing. Safety showers and eyewash fountains should be readily available to workers involved with liquid metals; they should not be eliminated because of the presence of the alkali metals. More than one person has been spared serious injury because a safety shower was available to wash away a sodium spill.

High-Temperature Corrosion

Ian G. Wright, Battelle Columbus Division

When metal is exposed to an oxidizing gas at elevated temperature, corrosion can occur by direct reaction with the gas, without the need for the presence of a liquid electrolyte. This type of corrosion is referred to as tarnishing, high-temperature oxidation, or scaling. The rate of attack increases substantially with temperature. The surface film typically thickens as a result of reaction at the scale/gas or metal/scale interface due to cation or anion transport through the scale, which behaves as a solid electrolyte. For continuous, nonporous scales, ionic transport through the scale is the rate-controlling process. The thermodynamic stability, the ionic defect structure, and certain morphological features of the scale formed are key factors in determining the resistance of an alloy to a specific environment.

Initial film growth is usually very rapid. If the scale is a nonporous solid and completely covers the metal surface, the reaction rate will decrease when the thickness reaches a few thousand angstroms as the transport of reactive species through the film becomes rate controlling. The subsequent corrosion rate depends on the details of this transport mechanism, which may be due to electrical potential or concentration gradients or to migration along preferential paths, and so may correspond to any of several rate laws, as shown in Fig. 34. Where a diffusion process is rate controlling, the kinetics usually follow a parabolic rate law, in which the rate progressively decreases with time. Figure 35(a) illustrates the compact, continuous protective scale of essentially chromium oxide (Cr_2O_3) formed on Alloy 800. If the scale is porous (or is formed as a vapor species) or does not completely cover the metal surface, a linear rate is usually experienced.

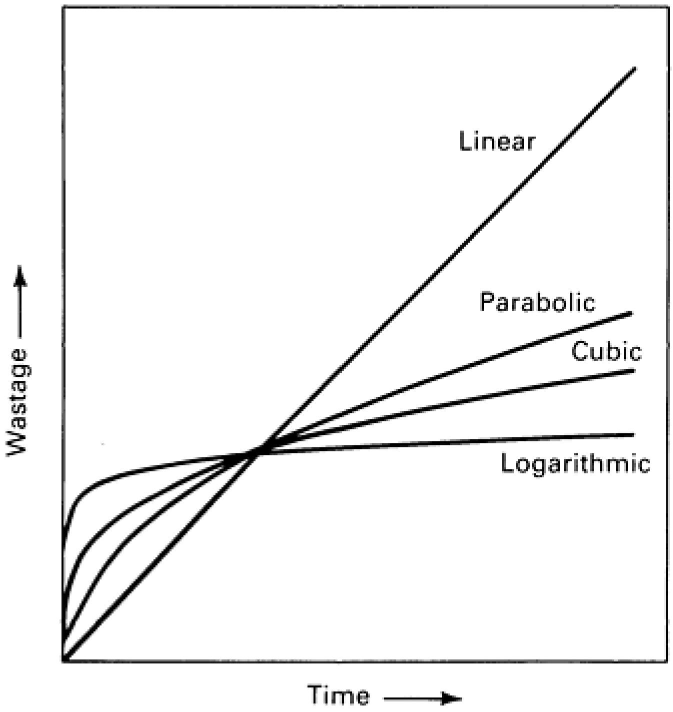

Fig. 34 Forms of kinetic curves that represent various thermal degradation process

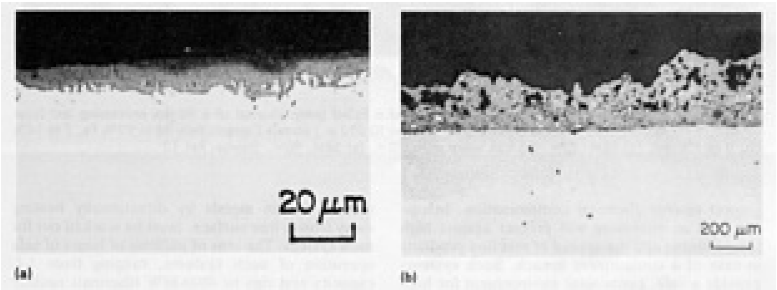

Fig. 35 Protective and nonprotective scales formed on Alloy 800. (a) Cr_2O_3-base protective oxide scale formed in sulfur-free oxidizing gas. (b) Sulfide-oxide scale formed in reducing conditions containing hydrogen sulfide. Courtesy of I.G. Wright, Battelle Columbus Division

The latter circumstance can be assessed from the Pilling-Bedworth ratio, which is the ratio of the volumes of oxide produced to the metal consumed by oxidation; values of 1.0 or greater result in complete surface coverage by oxide and, usually, protective behavior. This is not a complete nor foolproof measure for assessing the likelihood of protective scaling behavior. At high temperatures, the growth of nominally protective oxides may be sufficiently rapid that the compressive stresses resulting from a Pilling-Bedworth ratio greater than 1 become sufficiently great that the scale (or alloy) deforms and possibly spalls as a relief mechanism; in some cases, the protection offered by such scales may be low at this point, as shown in Fig. 36.

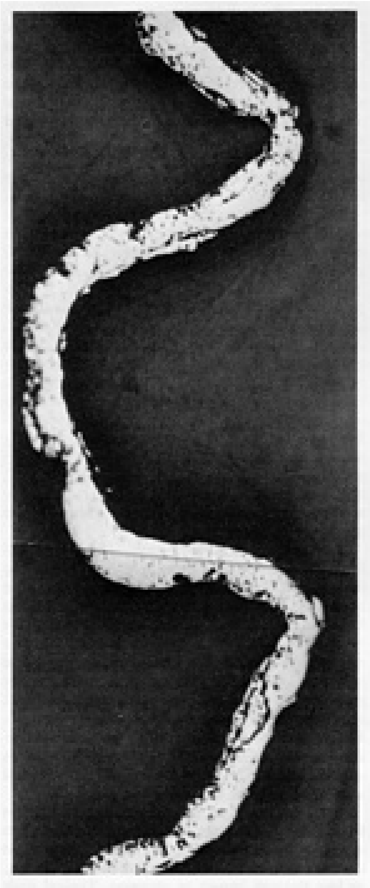

Fig. 36 Cr_2O_3 scale formed on pure chromium at 1100 °C (2012 °F). A Pilling-Bedworth ratio of 2.0 results in high compressive stress in the scale, which is relieved by buckling and spalling. Courtesy of I.G. Wright, Battelle Columbus Division.

The desired characteristics for a protective oxide scale include the following:

- High thermodynamic stability (highly negative Gibbs free energy of formation) so that it forms preferentially to other possible reaction products
- Low vapor pressure so that the oxide forms as a solid and does not evaporate into the atmosphere
- Pilling-Bedworth ratio greater than 1.0 so that the oxide completely covers the metal surface
- Low coefficient of diffusion of reactant species (metal cations, and corrodent anions) so that the scale has a slow growth rate
- High melting temperature
- Good adherence to the metal substrate, which usually involves a coefficient of thermal expansion close to that of the metal, and sufficient high-temperature plasticity to resist fracture from differential thermal expansion stresses

High-temperature scales are usually thought of as oxides, but may also be sulfides, possibly carbides, or mixtures of these species. Oxides and sulfides are nonstoichiometric compounds and semiconductors. There are essentially two types of semiconductors: *p*-type (or positive carrier)--which may have vacancies in its metal lattice, or an excess of anions contained interstitially--and *n*-type (or negative carrier)--which may have an excess of metal ions contained interstitially, or vacant anion lattice sites. For diffusion-controlled scaling, the rate of scale growth can be altered by modification of the concentration of the particular defects involved. For example, *p*-type oxides exhibit increased cationic transport rates (increased oxidation rates) at increased oxygen pressures, while transport in *n*-type oxides is essentially independent of oxygen pressure. Both types of oxide can be doped by the addition of specific ions to the oxide lattice. For *p*-type metal deficit oxides, for example, the addition of cations of higher valence than the native cations results in an increase in the number of cation vacancies and therefore an increase in the oxidation rate, while lower-valence cation additions have the opposite effect.

Sulfides typically exhibit an intrinsically greater rate of transport of anions and cations than the oxides of the same metal and so provide scales that are significantly less protective than oxides. Detailed information on the kinetics of high-temperature corrosion in gases and the thermodynamic stability of oxide/sulfide scales can be found in the article "Fundamentals of Corrosion in Gases" in this Volume.

High-Temperature Oxidation

Alloys intended for high-temperature applications are designed to have the capability of forming protective oxide scales. Alternatively, where the alloy has ultrahigh-temperature strength capabilities (which is usually synonymous with reduced levels of protective scale forming elements), it must be protected by a specially designed coating. Oxides that effectively meet the criteria for protective scales listed above and can be formed on practical alloys are limited to Cr_2O_3, alumina (Al_2O_3), and possibly silicon dioxide (SiO_2). In the pure state, Al_2O_3 exhibits the slowest transport rates for metal and oxygen ions and so should provide the best oxidation resistance.

Alloying requirements for the production of specific oxide scales have been translated into minimum levels of the scale-forming elements, or combinations of elements, depending on the base alloy composition and the intended service temperature. Figure 37 schematically represents the oxidation rate of iron-chromium alloys (1000 °C, or 1832 °F, in 0.13 atm oxygen) and depicts the types of oxide scale associated with various alloy types. Figure 38 illustrates the morphology of a semiprotective scale formed on a cobalt-chromium alloy. Alloys based on these minimum specifications will form the desired protective oxide upon initial exposure, but because of the accompanying deletion of the scale forming element, they will probably be unable to re-form the protective layer in the event of loss or failure of the initial scale.

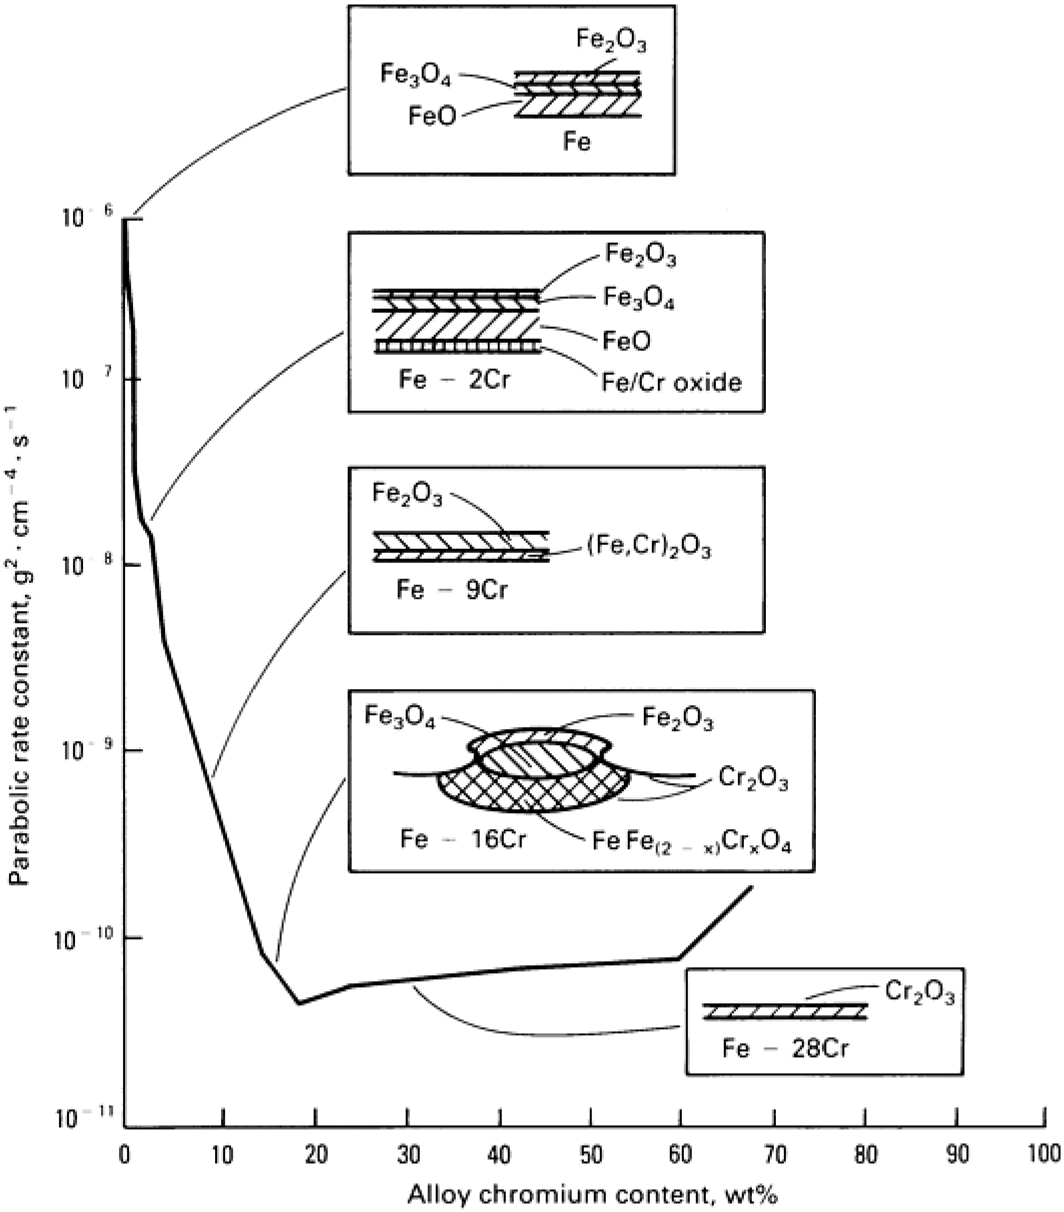

Fig. 37 Schematic of the variation with alloy chromium content of the oxidation rate and oxide scale structure (based on isothermal studies at 1000 °C, or 1832 °F, in 0.13 atm oxygen)

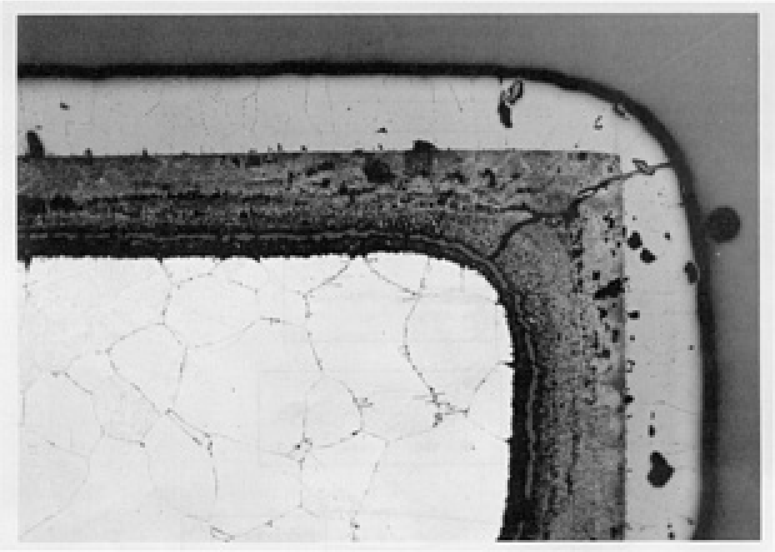

Fig. 38 Multilayer oxide scale formed on Co-10Cr alloy at 1100 °C (2012 °F). Outer layer is CoO; inner (mottled gray) layer is CoO containing dissolved chromium and particles of Co-Cr spinel. The chromium level in this alloy is insufficient to form a fully protective Cr_2O_3 scale. Courtesy of I.G. Wright, Battelle Columbus Division

A useful concept in assessing the potential high-temperature oxidation behavior of an alloy is that of the reservoir of scale-forming element contained by the alloy in excess of the minimum level (around 20 wt% for iron-chromium alloy at 1000 °C, or 1832 °F, according to Fig. 37). The more likely the service conditions are to cause repeated loss of the protective oxide scale, the greater the reservoir of scale-forming element required in the alloy for continued protection. Extreme cases of this concept result in chromizing or aluminizing to enrich the surface regions of the alloy or in the provision of an external coating rich in the scale-forming elements.

The breakdown of protective scales based on Cr_2O_3 or Al_2O_3 appears, in the majority of cases, to originate through mechanical means. The most common is spallation as a result of thermal cycling, or loss through impact or abrasion. Typical scale structures on an Fe-18Cr alloy after thermal cycling are shown in Fig. 39. Cases in which the scales have been destroyed chemically are usually related to reactions occurring beneath deposits, especially where these consist of molten species. An additional mode of degradation of protective Cr_2O_3 scale is through oxidation to the volatile chromium trioxide (CrO_3), which becomes prevalent above about 1010 °C (1850 °F) and is greatly accelerated by high gas flow rates.

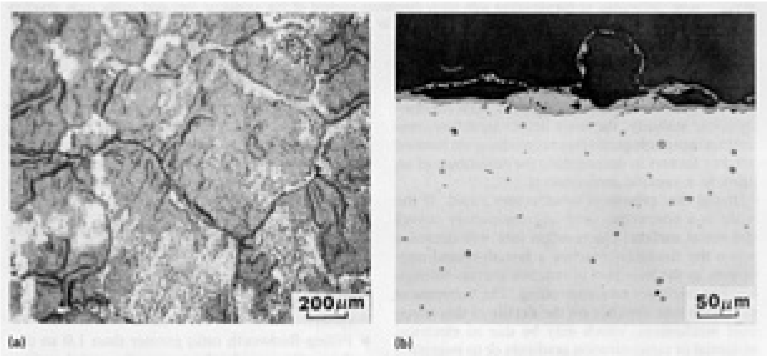

Fig. 39 Topography (a) and cross section (b) of oxide scale formed on Fe-18Cr alloy at 1100 °C (2012 °F). The bright areas on the alloy surface (a) are areas from which scale has spalled. The buckled scale and locally thickened areas (b) are iron-rich oxide. The thin scale layer adjacent to the alloy is Cr_2O_3, which controls the oxidation rate. Courtesy of I.G. Wright, Battelle Columbus Division

Because these protective oxide scales will form wherever the alloy surface is exposed to the ambient environment, they will form at all surface discontinuities; therefore, the possibility exists that notches of oxide will form at occluded angles in the surface, which may eventually serve to initiate or propagate cracks under thermal cycling conditions. The ramifications of stress-assisted oxidation (and of oxidation assisting the applied stress) in the production of failure conditions are not very well understood, but constitute important considerations in practical failure analysis.

Sulfidation

When the sulfur activity (partial pressure, concentration) of the gaseous environment is sufficiently high, sulfide phases, instead of oxide phases, can be formed. The mechanisms of sulfide formation in gaseous environments and beneath molten-salt deposits have been determined in recent years. In the majority of environments encountered in practice by oxidation-resistant alloys, Al_2O_3 or Cr_2O_3 should form in preference to any sulfides, and destructive sulfidation attack occurs mainly at sites where the protective oxide has broken down. The role of sulfur, once it has entered the alloy, appears to be to tie up the chromium and aluminum as sulfides, effectively redistributing the protective scale-forming elements near the alloy surface and thus interfering with the process of formation or re-formation of the protective scale. If sufficient sulfur enters the alloy so that all immediately available chromium or aluminum is converted to sulfides, then the less stable sulfides of the base metal may form because of morphological and kinetic reasons. It is these base metal sulfides that are often responsible for the observed accelerated attack, because they grow much faster than the oxides or sulfides of chromium or aluminum; in addition, they have relatively low melting points, so that molten slag phases are often possible. Fig. 35 compares a protective (oxide) scale and a nonprotective (sulfide) scale formed on Alloy 800.

Sulfur can transport across continuous protective scales of Al_2O_3 and Cr_2O_3 under certain conditions, with the result that discrete sulfide precipitates can be observed immediately beneath the scales on alloys that are behaving in a protective manner. For reasons indicated above, as long as the amount of sulfur present as sulfides is small, there is little danger of accelerated attack. However, once sulfides have formed in the alloy, there is a tendency for the sulfide phases to be preferentially oxidized by the encroaching reaction front and for the sulfur to be displaced inward, forming new sulfides deeper in the alloy, often in grain boundaries or at the sites of other chromium- or aluminum-rich phases, such as carbides. In this way, finger-like protrusions of oxide/sulfide can be formed from the alloy surface inward, which may act to localize stress or otherwise reduce the load-bearing section. Such attack of an austenitic stainless steel experienced in a coal gasifier product gas is shown in Fig. 40. The sulfidation behavior of Alloy 800 at temperatures and oxygen and sulfur potentials representative of coal gasification processes is illustrated in Fig. 41, 42, and 43.

Carburization

As in the case of sulfide penetration, carburization of high-temperature alloys is thermodynamically unlikely except at very low oxygen partial pressures, because the protective oxides of chromium and aluminum are generally more likely to form than the carbides. However, carburization can occur kinetically in many carbon-containing environments. Carbon transport across continuous nonporous scales of Al_2O_3 or Cr_2O_3 is very slow, and alloy pretreatments likely to promote such scales, such as initially smooth surfaces or preoxidation, have generally been found to be effective in decreasing carburization attack. In practice, the scales formed on high-temperature alloys often consist of multiple layers of oxides resulting from localized bursts of oxide formation in areas where the original scale was broken or lost. The protection is derived from the innermost layer, which is usually richest in chromium or aluminum. Concentration of gaseous species such as carbon monoxide in the outer porous oxide layers appears to be one means by which sufficiently high carbon activities can be generated at the alloy surface for carburization to occur in otherwise oxidizing environments. The creation of localized microenvironments is also possible under deposits that create stagnant conditions not permeable by the ambient gas.

Once inside the alloy, the detrimental effects of the carbon depend on the location, composition, and morphology of the carbide formed. Austenitic steels should carburize more readily than ferritic steels because of the high solubility of carbon in austenite. Iron-chromium alloys containing less than about 13% Cr contain various amounts of austenite, depending on temperature, and should be susceptible to carburization, while alloys with 13 to 20% Cr will form austenite as a result of absorption of small amounts of carbon. Iron-chromium alloys containing more than ~20% Cr can absorb considerable amounts of carbon before austenite forms, becoming principally $(CrFe)_{23}C_6$ and ferrite. An example of rapid high-temperature carburization attack of an austenitic stainless steel is shown in Fig. 44.

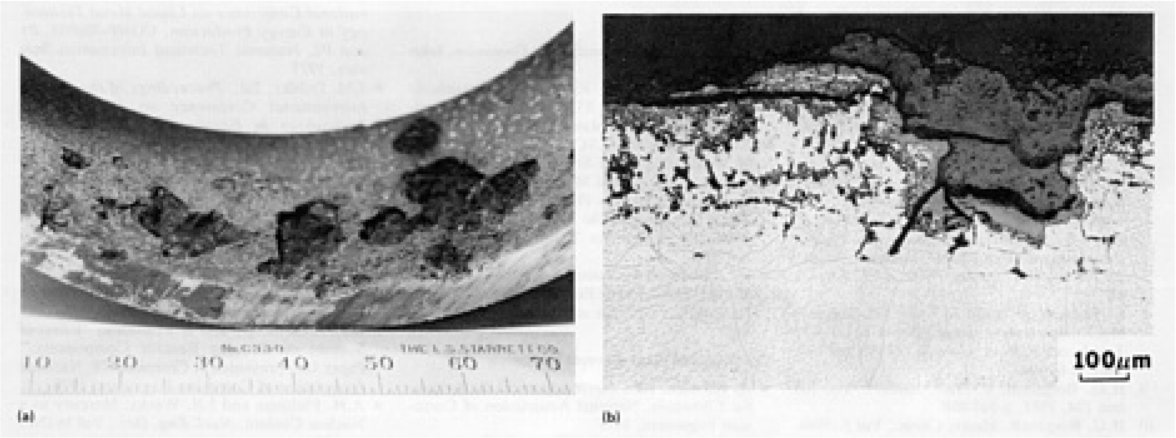

Fig. 44 Example of high-temperature carburization attack pitting in type 310 reactor wall after ~4000-h exposure to coal gasification product gas. The pits were formed during operation under conditions of high carbon activity in the gas. (a) Overall view of pitting. (b) Section through a pit. Courtesy of I.G. Wright, Battelle Columbus Division

Minor alloying elements can exert an influence on the susceptibility to carburization of various alloys. In particular, silicon, niobium, tungsten, titanium, and the rare earths have been noted as promoting resistance to carburization. Experience with aluminum and manganese has been varied, while lead, molybdenum, cobalt, zirconium, and boron are considered detrimental.

Other Forms of High-Temperature Corrosion

Hydrogen Effects. In hydrogen at elevated temperatures and pressures, there is increasing availability of atomic hydrogen that can easily penetrate metal structures and react internally with reducible species. An example is the attack experienced by carbon steel, in which atomic hydrogen reacts with iron carbide to form methane, which then leads to fissuring of the steel. Alloy steels with stable carbides, such as chromium carbides, are less susceptible to this form of attack. For example, 2.25 Cr-1Mo suffers some decarburization in high-temperature high-pressure hydrogen, but is less likely to fissure than carbon steel. The susceptibility of steels to attack by hydrogen can be judged from the Nelson Curves, which indicate the regions of temperature and pressure in which a variety of steels will suffer attack. Nelson curves and examples of high-temperature hydrogen attack of carbon and alloy steels are illustrated and discussed in the article "Corrosion in Petroleum Refining and Petrochemical Operations" in this Volume.

A further example of hydrogen attack is copper containing small amounts of cuprous oxide. This oxide reacts to form steam within the alloy, resulting in significant void formation.

Hot Corrosion. The term hot corrosion is generally used to describe a form of accelerated attack experienced by the hot gas path components of gas turbine engines. Two forms of hot corrosion can be distinguished; most of the corrosion encountered in turbines burning liquid fuels can be described as Type I hot corrosion, which occurs primarily in the metal temperature range of 850 to 950 °C (1550 to 1750 °F). This is a sulfidation-based attack on the hot gas path parts involving the formation of condensed salts, which are often molten at the turbine operating temperature. The major components of such salts are sodium sulfate (Na_2SO_4) and/or potassium sulfate (K_2SO_4), apparently formed in the combustion process from sulfur from the fuel and sodium from the fuel or the ingested air. Because potassium salts act very similarly to sodium salts, alkali specifications for fuel or air are usually taken to the sum total of sodium plus potassium. An example of the corrosion morphology typical of Type I hot corrosion is shown in Fig. 45.

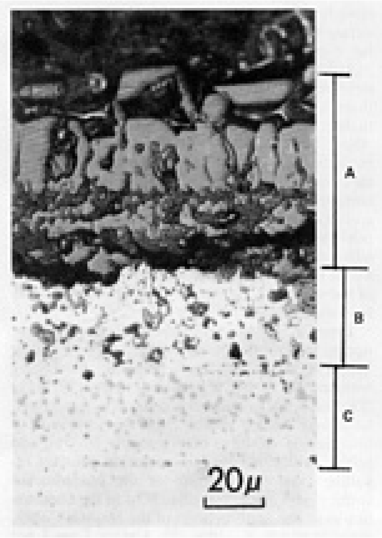

Fig. 45 Ni-20Cr-2ThO$_2$ after simulated Type I hot corrosion exposure (coated with Na$_2$SO$_4$ and oxidized in air at 1000 °C, or 1832 °F). A, nickel-rich scale; B, Cr$_2$O$_3$ subscale; C, chromium sulfides. Courtesy of I.G. Wright, Battelle Columbus Division

Very small amounts of sulfur and sodium or potassium in the fuel and air can produce sufficient Na_2SO_4 in the turbine to cause extensive corrosion problems because of the concentrating effect of turbine pressure ratio. For example, a threshold level has been suggested for sodium in air of 0.008 ppm by weight below which hot corrosion will not occur. Type I hot corrosion, therefore, is possible even when premium fuels are used. Other fuel (or air) impurities, such as vanadium, phosphorous, lead, and chlorides, may combine with Na_2SO_4 to form mixed salts having reduced melting temperature and thus broaden the range of conditions over which this form of attack can occur. Also, agents such as unburned carbon can promote deleterious interactions in the salt deposits.

Research over the past 15 years has led to greater definition of the relationships among temperature, pressure, salt concentration, and salt vapor-liquid equilibria so that the location and rate of salt deposition in an engine can be predicted. Additionally, it has been demonstrated that a high chromium content is required in an alloy for good resistance to Type I hot corrosion. The trend to lower chromium levels with increasing alloy strength has therefore rendered most superalloys inherently susceptible to this type of corrosion. The effects of other alloying additions, such as tungsten, molybdenum, and tantalum, have been documented, and their effects on rendering an alloy more or less susceptible to Type I hot corrosion are known and mostly understood.

Although various attempts have been made to develop figures of merit to compare superalloys, these have not been universally accepted. Nonetheless, the near standardization of such alloys as Alloy 738 and Alloy 939 for first-stage blades/buckets, and FSX-414 for first stage vanes/nozzles, implies that these are the accepted best compromises between high-temperature strength and hot corrosion resistance. It has also been possible to devise coatings with alloying levels adjusted to resist this form of hot corrosion. The use of such coatings is essential for the protection of most modern superalloys intended for duty as first-stage blades or buckets.

Type II, or low-temperature hot corrosion, occurs in the metal temperature range of 650 to 700 °C (1200 to 1400 °F), well below the melting temperature of Na_2SO_4, which is 884 °C (1623 °F). This form of corrosion produces characteristic pitting, which results from the formation of low-melting mixtures of essentially Na_2SO_4 and cobalt sulfate ($CoSO_4$), a corrosion product resulting from the reaction of the blade/bucket surface with sulfur trioxide (SO_3) in the combustion gas. The melting point of the Na_2SO_4-$CoSO_4$ eutectic is 540 °C (1004 °F). Unlike Type I hot corrosion, a partial pressure of SO_3 in the gas is critical for the reactions to occur. Knowledge of the SO_3 partial pressure-temperature relationships inside a turbine allows some prediction of where Type II hot corrosion can occur. Cobalt-free nickel-base alloys (and coatings) may be more resistant to Type II hot corrosion than cobalt-base alloys; it has also been observed that resistance to Type II hot corrosion increases with the chromium content of the alloy or coating.

Localized Corrosion

Chairman: Stephen C. Dexter, College of Marine Studies, University of Delaware

Introduction

THE FORMS OF CORROSION described in this article--filiform, crevice, pitting, and biological corrosion--all have the common feature that the corrosion damage produced is localized rather than spread uniformly over the exposed metal surface. This makes these forms of attack more difficult to deal with than those producing a generalized attack (see the article "General Corrosion" in this Volume). Instead of dealing with a slow, relatively uniform loss of metal thickness, the engineer is now faced with high rates of metal penetration at specific sites (or localized deterioration under a coating system in the case of filiform corrosion), while the remainder of the metal (or coating) goes largely unaffected. The attack can also be harder to detect because much of the damage may be subsurface, with only a small opening visible to the eye at the metal surface. Moreover, these forms of attack are economically important and dangerous because they can lead to premature failure of a structure by rapid penetration with little overall weight loss.

The purpose of this article is to provide the engineer with enough information to identify which form of corrosion is taking place on an existing structure or which form of corrosion is likely to occur on a new structure. Therefore, most of this article is devoted to illustrating the appearance of these localized forms of corrosion and to describing the classes of metals and alloys susceptible to them and the environmental conditions under which they occur. Some information is also given on the mechanisms of the attack and measures that can be used to prevent it. More information on these latter two topics can be found in the references given in this article as well as the Sections "Specific Alloy Systems" and "Fundamentals of Corrosion" in this Volume.

Filiform Corrosion

Christopher Hahin, Materials Protection Associates

Filiform corrosion occurs on metallic surfaces coated with a thin organic film that is typically 0.1 mm (4 mils) thick. The pattern of attack is characterized by the appearance of fine filaments emanating from one or more sources in semirandom directions. The source of initiation is usually a defect or mechanical scratch in the coating. The filaments are fine tunnels composed of corrosion products underneath the bulged and cracked coating. Filiforms are visible at an arm's length as small blemishes. Upon closer examination, they appear as fine striations shaped like tentacles or cobweb-like traces (Fig. 1). A filiform has an active head, and a filamentous tail (Fig. 2). A close-up of the head/tail interface is shown in Fig. 3.

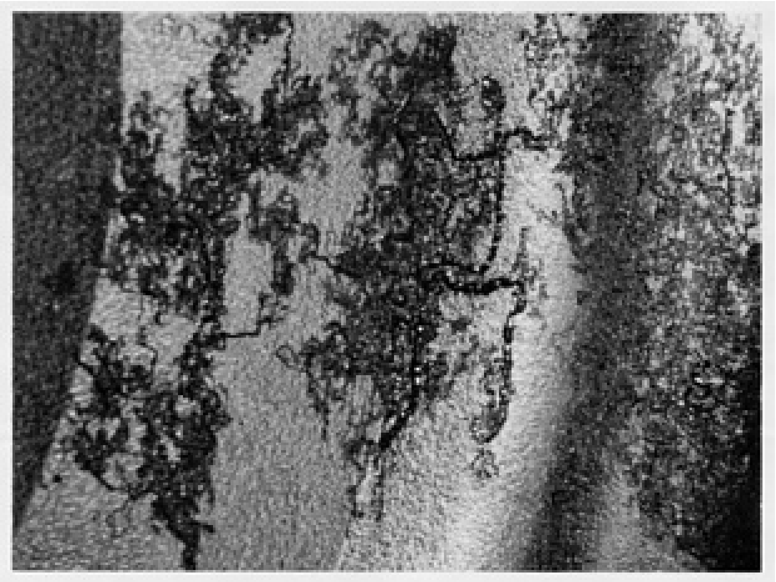

Fig. 1 A lacquered steel can lid exhibiting filiform corrosion showing both large and small filaments partially oriented in the rolling direction of the steel sheet. Without this 10× magnification by a light microscope, the filiforms look like fine striations or minute tentacles.

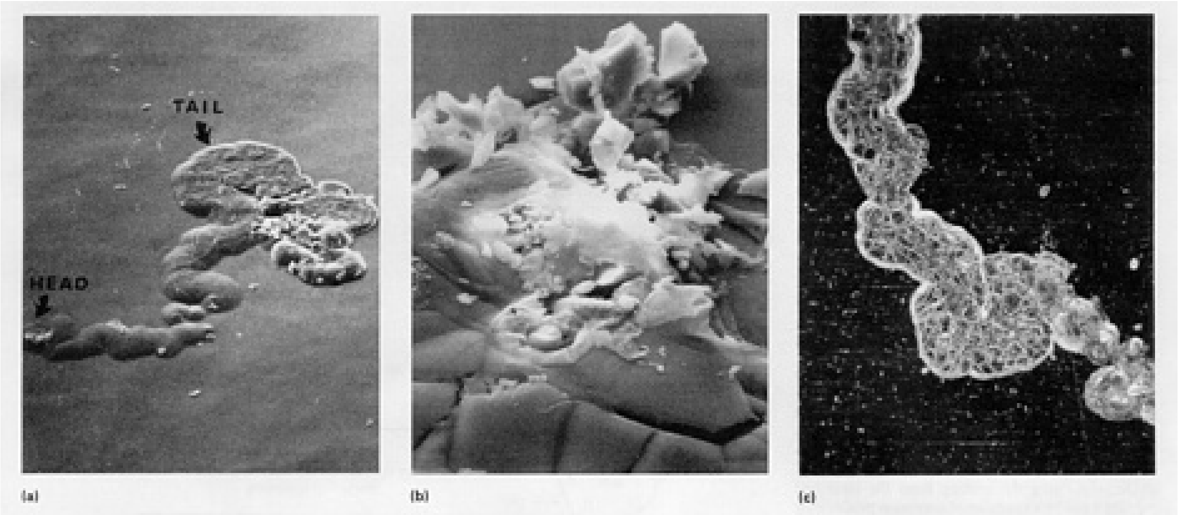

Fig. 2 Filiform corrosion on PVC-coated aluminum foil. (a) Advancing head and cracked tail section of a filiform cell. SEM. 80×. (b) The gelatinous corrosion products of aluminum oozing out of the porous end tail section of a filiform cell. SEM. 830×. (c) Tail region of a filiform cell. Tail appears iridescent due to internal reflection. Light microscopy. 60×

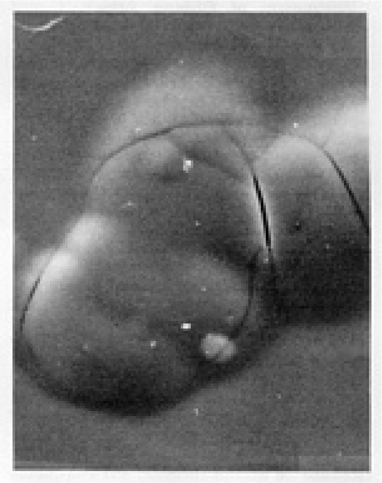

Fig. 3 Close-up of the advancing head shown in Fig. 2(a). Minute cracks can be seen at the head/tail interface of a filiform corrosion cell. These cracks are entry points for water and air to provide a source of hydroxyl ions and an electrolyte. Intermediate corrosion products are just beginning to form in the head, and they undergo further reaction to form an expanded tail. The tail region is a progressive reaction zone that ultimately forms spent corrosion products. Between the head and porous end, ions gradually react with water and oxygen and are slowly transported in the direction of the tail to form final corrosion products. SEM. 760×

Filiform corrosion is often mistaken as having biological origins because of its wormlike appearance. Filiform corrosion routinely occurs on coated steel cans, aluminum foil laminated packaging, painted aluminum, and other lacquered metallic items placed in areas subjected to high humidity. Filiform corrosion has been observed on many organically coated metals and alloys, including steels, tin-plated steel, aluminum, and magnesium. The susceptibility of a metal to filiform corrosion can be determined by placing several coated and scratched panels in a salt fog chamber as described in ASTM D 2803 (Ref 1). If susceptible, filiform filaments will gradually grow out perpendicularly from the scratch. Many of these filaments will later orient themselves in the rolling direction of the panel.

Filiform attack occurs when the relative humidity is typically between 65 to 90% for most cases. The lowest reported relative humidity was 58% for nitrocellulose lacquer on steel, and even lower relative humidities were reported for aluminum in very corrosive environments (Ref 2). The average width of a filament varies between 0.05 to 3 mm (2 to 120 mils). Filament width depends on the coating, the ambient relative humidity, and the corrosive environment. Typical filament height is about 20 μm (0.8 mil). The filament growth rate can also vary widely, with rates observed as low as 0.01 mm/d (0.4 mil/d) and up to a maximum rate of 0.85 mm/d (35 mils/d). The depth of attack in the filiform tunnels can be as deep as 15 μm (0.6 mil). The fluid in the leading head of a filiform is typically acidic, with a pH from 1 to 4. In all cases, oxygen or air and water were needed to sustain filiform corrosion. This indicates that filiform corrosion is a specialized differential aeration cell (see the "Glossary of Terms" in this Volume for a definition of differential aeration cell).

Filiform Corrosion of Coated Steels

Characteristics of Coated Steels. Steel and tin-plated steel are routinely coated to provide resistance to atmospheric corrosion, to isolate foodstuffs from their containers, and to provide an adherent surface for ink and paint. Transparent organic coatings can also be lightly tinted with various dyes to impart a brass, bronze, or bluish cast to improve the appearance of the steel. Tin plating on steel is very thin--of the order of 1.5 μm (0.06 mil) thick--and is a porous barrier (see the article "Corrosion of Tin and Tin Alloys" in this Volume). In some environments, tin is often cathodic to steel. In aggressive environments, tin plate provides little corrosion protection for the steel substrate. The corrosion rate of steel is fairly slow in alkaline environments, but increases markedly in acidic environments when the pH is less than 3. Steel is subject to pitting in concentrated chloride environments. Tin is amphoteric (it corrodes in alkaline and acidic media), but it is not rapidly attacked in certain deaerated acids. However, steel and tin are both readily corroded by aerated acids. Such conditions of low pH, aeration, and high chloride concentrations are often found to exist in the active heads of filiform corrosion cells in steel.

To prevent general rusting, many coatings are applied to steel to shield it from moist or humid environments. Filiform corrosion has been observed on steels coated with lacquers, varnish, polyurethane, boiled linseed oil, and various alkyd, urea, and epoxy paints. The coatings are applied by spraying, by direct contact with rubber rolls, by dipping, or by electrostatic methods. Cured and dried coatings are uneven in thickness, with numerous hills and valleys. Lacquers can contain entrapped solvents if they are insufficiently cured.

In general, organic coatings are flexible, and they tend to soften at higher temperatures. Coatings can separate from the steel substrate because of physical abrasion. The ease of separation depends on how well the surface was prepared before it was coated. Organic coatings can be semipermeable to water and can have numerous flaws caused by improper application of the coating, poor curing, or solvent entrapment. Coated articles may sustain some minor mechanical abrasions during their curing or storage. Coatings often crack when blistered by corrosion product expansion, gas evolution, or water retention. Coatings, therefore, have many potential defect sources at which filiform corrosion can begin. Heads of filiform cells will continue to remain active as long as the coating keeps expanding and cracking and if moisture and oxygen are available.

Conditions Leading to Filiform Attack. Filiform corrosion generally occurs in coated steels when the relative humidity is between 60 to 95% in a temperature range of 20 to 35 °C (70 to 95 °F). The surrounding atmosphere must contain air or oxygen. Attack usually begins at cuts, knicks, pores, or other disruptions in the coating. Carbon dioxide can also stimulate filiform corrosion by dissolving in water to create carbonic acid. If the condensing atmospheres contain concentrations of chlorides, sulfates, sulfides, or carbon dioxide, the likelihood of filiform corrosion is substantially increased because these constituents help to acidify the filiform head. The rate of advancing growth generally increases with greater condensed salt concentration and higher acidity in the head. Filiform corrosion has been observed on steels coated with various lacquers and other slower-drying resins. Table 1 lists filiform growth rates for steel at 23 to 25 °C (73 to 77 °F), the physical dimensions of filaments, and the active range of relative humidity for different coating systems.

Table 1 Filiform corrosion growth rates on various coated metals

Coating	Initiating environment	Typical rate		Relative humidity, %	Filament width	
		mm/d	**mils/d**		**mm**	**mils**
Steels						
Varnish	NaCl	0.33-0.53	13-21	65-85	0.1-0.3	4-12

Epoxy	HCl vapor	0.3	12	75	. . .	. . .

General Appearance. Filiform cells on coated steels consist of an active head, which is blue, blue-green, or grayish in color, and a brownish, rusty filament-shaped tail. Filament growth tends to be more random when the steel surface has no burnished texture or pronounced rolling direction. Typical filament growth rates are about 0.2 to 0.4 mm/d (8 to 16 mils/d), with an average filament width of 0.2 mm (8 mils). Filament heights vary with the type of coating and the

corrosive environment. A moist environment of 80% relative humidity is typically needed at room temperature to initiate filiform attack. Warmer temperatures generally exacerbate the situation.

The solution in the advancing head of a filiform is usually acidic, with moisture and oxygen entering primarily through the long tail. The typical acidity in the filiform head is pH 1 to 4. Anions such as chloride, sulfide, or sulfate may enter the head from a corrosive atmosphere or by direct deposition on the surface and combine with the condensed water vapor that percolates through the cracked coating. Atmospheric corrosives may be supplemented by continual leaching of solvents or unreacted constituents of the coating that combine with water. The head is filled with ferrous ions and the tail with ferric hydroxides and hydrated ion oxides, depending on the longitudinal position in the tail and the age of the filaments. The advancing head of one filament is deflected or halted when it contacts a tail of another filiform, because a filiform tail is generally alkaline and filled with spent corrosion products. The head literally tunnels through the substrate, separating the coating from the steel and bulging it out by expansion of corrosion products or by hydrogen gas evolution if the head is very acidic (Ref 3). The constant forward motion of a filament will cease if the tail is not continually aerated and supplied with water vapor condensate.

Mechanism of Filiform Attack. Coated steels have numerous defects on their surfaces where air and water vapor condensate can penetrate through to the steel substrate. If the condensing atmosphere contains significant concentrations of salts, the condensate is more electrolytically conductive, and iron can more readily dissolve into solution. The activity of the head is initiated when its oxygen concentration or pH is considerably less than in the tail. Dissolved salts in the head solution can further decrease the solubility of oxygen. High salt concentrations can also lead to further acidification of the filiform head. In contrast, the tail is better aerated and receives a greater amount of freshly condensed water vapor. Voltage measurements between the head and tail regions normally indicate a potential difference of 0.1 to 0.2 V. The head advances as iron goes into solution; this undercuts the bond between the coating and the steel substrate.

The mechanism of coating expansion in the head region is not yet fully understood. Corrosion product expansion and the undercutting of the coating/steel interface in the head are major contributors to filament head bulging (Ref 4). Head and tail solution chemistry and temperature also affect the film strength of the coating and its bonding to the steel substrate. The head is a moving pool of acidic electrolyte. The trailing tail is a progressive zone of corrosion products and reactants that are gradually being converted to spent corrosion products. The end of the tail is where corrosion products have been completely reacted and fully expanded. The alkalinity of the tail region also stimulates coating cracking and debonding by softening and weakening the paint film.

If the filiform head solution is particularly acidic (pH 1 to 2), blistering can occur because of hydrogen evolution as a cathodic reaction:

$$2H^+ + 2e = H_2$$

The head or tail may bulge or blister considerably. If the bulged coating ruptures completely, a new initiation site is created, and this permits the formation of new filament heads.

The size of a filament is apparently governed by the original defect size and the flexibility of the film. The texture of the rolled surface and the nature of the coating also shape the geometry and the spread rate of filiform attack. The ferrous ions formed in the head are transported toward the tail and further oxidized in the first section of the tail by forming ferric hydroxide.

Water and oxygen can enter the cell at cracks in the coating in the tail region or at the head/tail interface. Water is either consumed by the head electrolyte or can be involved in cathodic reactions. Hydroxyl ions are provided by the oxygen reduction reaction, which takes place in the tail:

$$O_2 + 2H_2O + 4e = 4OH^-$$

There is a general transport of iron ions toward the tail region, where they combine with hydroxyl ions to form ferric hydroxides in the tail. Toward the end of the tail, ferric hydroxide decomposes to ferric oxide and water. Other iron hydrates may also form. Because the corrosion products of iron expand considerably, the coating bulges or splits. As the coating further cracks or splits, more oxygen and water can enter the tail, further stimulating the corrosion reactions. In some brittle coatings, the head may be very small, and cracks may form rapidly. A general diagram illustrating the mechanism of filiform corrosion in iron and steel is shown in Fig. 4(a).

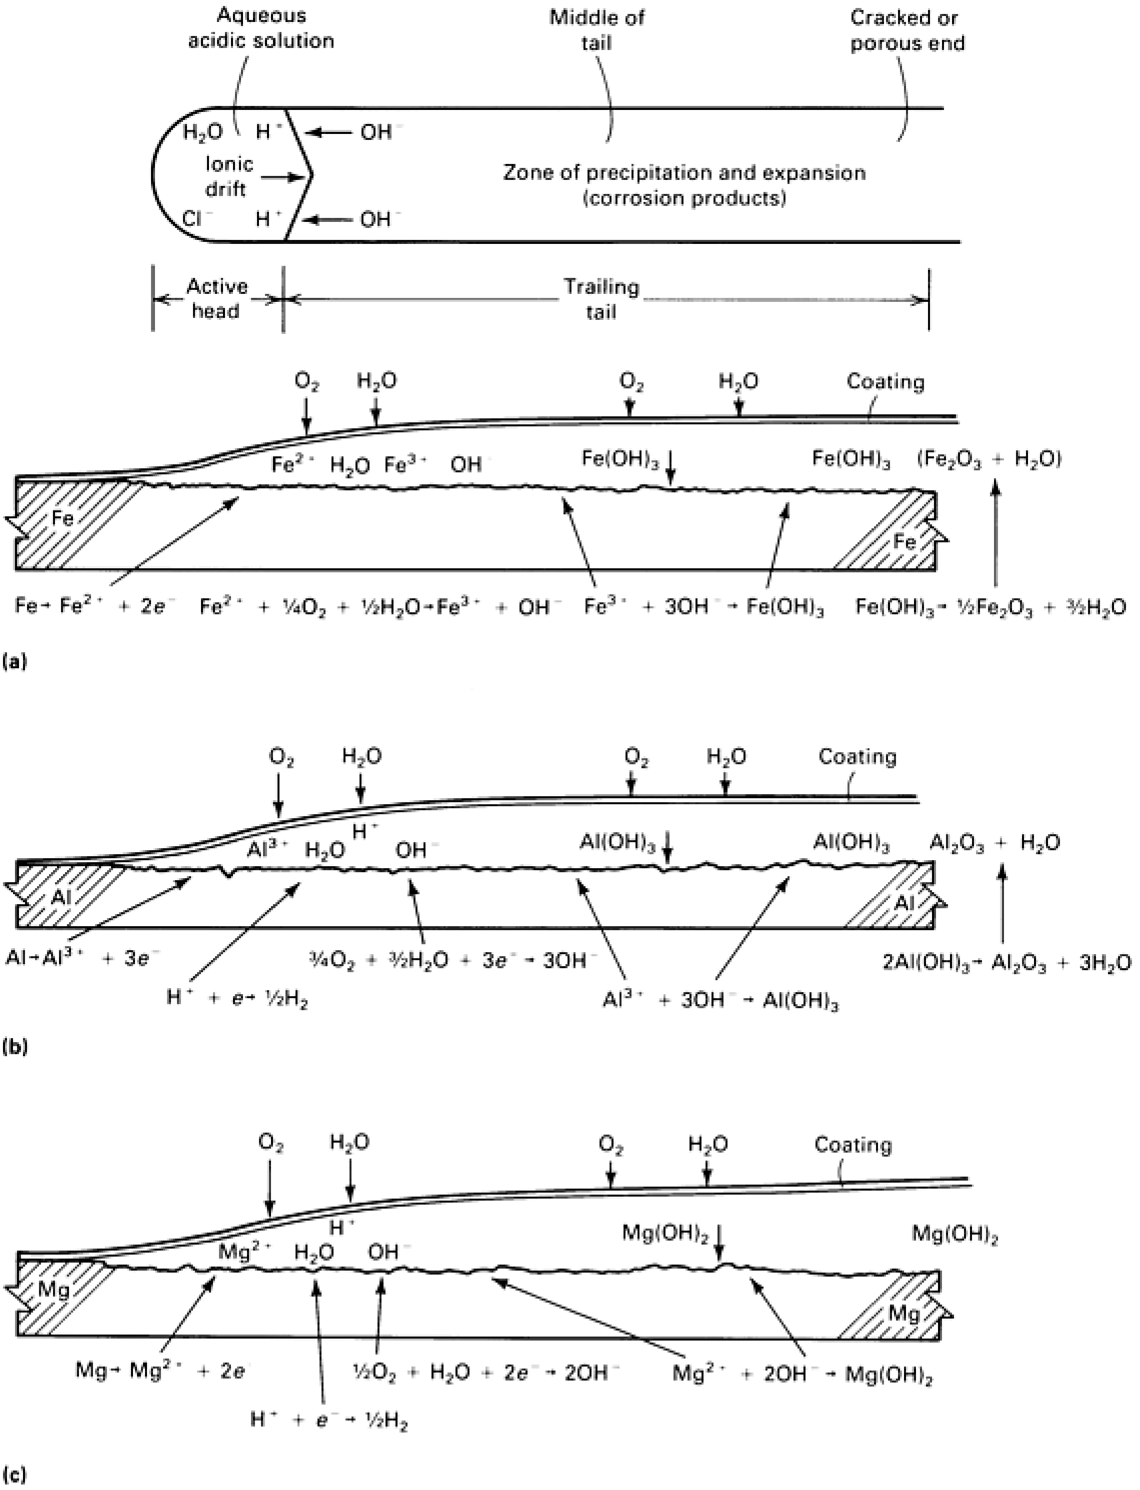

Fig. 4 Diagrams of the filiform corrosion cell in steel (a), aluminum (b), and magnesium (c). Corrosion products and predominant reactions are labeled. Filiform corrosion is a differential aeration cell driven by differences in oxygen concentration in the head versus the tail section. Potential differences between the head and tail are of the order of 0.1 to 0.2 V.

Water is required to form an electrolyte and to stimulate hydroxyl production. Water is necessary for the formation of new heads from a central defect source. The corrosivity of the head electrolyte is increased when salts are present on the surface or in the condensed water vapor. High salt concentrations in the head electrolyte decrease oxygen solubility and may further acidify the head solution. Several studies have shown that sealing the cracked tail halts filiform corrosion (Ref 4, 5, 6). By sealing the porous tail with epoxy, oxygen was prevented from entering. Similar effects were achieved

by replacing oxygen with nitrogen gas. The driving force of the reaction--differential aeration--was stopped, and the filiform heads ceased to advance.

Filiform Corrosion of Coated Aluminum and Magnesium

Filiform corrosion is commonly observed on coated aluminum sheet, plate and foil, and magnesium sheet and plate. The appearance of filiform corrosion in aluminum and magnesium is similar to that of iron and steel, except that the corrosion products are gelatinous and milky in color. When dry, their filaments may take on an iridescent or clear appearance because of internal light reflection. Filament growth rates for aluminum are similar to those of coated steels. Magnesium has somewhat higher growth rates than aluminum. Filiform attack in both aluminum and magnesium is particularly severe in warm coastal and tropical regions that experience salt fall or in heavily polluted industrial areas.

Aluminum is susceptible to filiform corrosion in a relative humidity range of 75 to 95%, with temperatures between 20 to 40 °C (70 to 105 °F). Relative humidities as low as 30% in hydrochloric acid (HCl) vapors have been reported (Ref 6). Filiforms grow most rapidly at 85% relative humidity in aluminum. Typical filament growth rates average about 0.1 mm/d (4 mils/d). Filament width varies with increasing relative humidity--from 0.3 to 3 mm (12 to 140 mils). The depth of penetration in aluminum can be as deep as 15 μm (0.6 mil). Numerous coating systems used on aluminum are susceptible to filiform corrosion, including epoxy, polyurethane, alkyd, phenoxy, and vinyls. Condensates containing the chloride, bromide, sulfate, carbonate, and nitrate ions have stimulated filiform growth in coated aluminum alloys. Growth rates for filiform corrosion on aluminum and magnesium coated with lacquers and various slower drying resins are summarized in Table 1.

Mechanism of Filiform Attack. Filiform corrosion on aluminum and magnesium, as in iron and steel, is also a corrosion cell driven by differential aeration. The filiform cell consists of an active head and a tail that receives oxygen and condensed water vapor through cracks and splits in the applied coating. In aluminum, the head is filled with flowing flocs of opalescent alumina gel moving toward the tail. Gas bubbles may be present if the head is very acidic. In magnesium, the head appears blackish because of the etching of the magnesium, but the corrosive fluid is clear when the head is broken. Filiform tails in aluminum and magnesium filiforms are whitish in appearance. The corrosion products are hydroxides and oxides of aluminum and magnesium. Anodic reactions produce Al^{3+} or Mg^{2+} ions, which react to form insoluble precipitates with the hydroxyl ions produced in the oxygen reduction reaction occurring predominately in the tail.

The mechanism of initiation and activation in aluminum and magnesium are the same as for coated iron and steel, as shown in Fig. 4(b) and 4(c). The acidified head is a moving pool of electrolyte, but the tail is a region in which aluminum ion transport and gradual reaction with hydroxyl ions take place. The final corrosion products are partially hydrated and fully expanded in the porous tail. The head and middle sections of the tail are corresponding locations for the various initial reactant ions and the intermediate products of corroding aluminum in aqueous media.

However, in contrast to steel, aluminum and magnesium have shown a greater tendency to form blisters in acidic media, with hydrogen gas evolved in cathodic reactions in the head region. The corrosion products in the tail are either aluminum trihydroxide ($Al(OH)_3$), a whitish gelatinous precipitate, or magnesium hydroxide ($Mg(OH)_2$), a whitish precipitate.

Filiform Corrosion in Aircraft. Aircraft are routinely painted for corrosion protection, decreased drag resistance, and identification. Aircraft operating in warm, saline regions sustain considerable corrosion damage. In recent years, filiform corrosion was observed on 2024- and 7000-series aluminum alloys coated with polyurethane and other coatings (Ref 7, 8). Filiform corrosion increased in severity when chloride concentrations on the metal were high, particularly when the aircraft were frequently flying over ocean waters or based in coastal airfields and hangars. Prepainted surface treatment quality and the choice of primers were also influential. Two-coat polyurethane paint systems experienced far fewer incidences of filiform corrosion than single-coat systems did. Filiform corrosion rarely occurred when bare aluminum was chromic acid anodized or primed with chromate or chromate-phosphate conversion coatings. Rougher surfaces also experienced a greater severity of filiform attack. If left unchecked, filiform corrosion may lead to more serious structural damage caused by other forms of corrosion.

Filiform Corrosion in Packaging. Aluminum is widely used for cans and other types of packaging. Aluminum foil is routinely laminated to paperboard to form a moisture or vapor barrier. If the aluminum foil is consumed by filiform corrosion, the product may be contaminated, lost, or dried out because of breaks in the vapor barrier. Typical coatings on aluminum foil are nitrocellulose and polyvinylchloride (PVC), which provide a good intermediate layer for colorful printing inks.

Degradation of the foil-laminated paperboard may occur during its production or its subsequent storage in a moist or humid environment (Fig. 5). During the production of foil-laminated paperboard, moisture from the paperboard is released after heating in a continuous-curing oven. Heat curing dries the lacquer on the foil. Filiform corrosion can result as the heated laminate is cut into sheets and stacked on skids, while the board is still releasing stored moisture. As shown in Fig. 6, the hygroscopic paperboard is a good storage area for moisture. Packages later exposed to humidities above 75% in warm areas can also experience filiform attack. Coatings with water-reactive solvents, such as polyvinyl acetate, should not be used. Any solvents entrapped in the coating can weaken the coating, induce pores, or provide an acidic media for further filament propagation. Harsh curing environments can also result in the formation of flaws in the coating due to uneven shrinkage or rapid volatilization of the solvent. Rough handling can induce mechanical rips and tears.

Fig. 5 Penetration of the aluminum foil vapor barrier on laminated packaging. The interior of the package is back illuminated, showing the loss of aluminum foil to filiform attack. Light microscopy. 10×

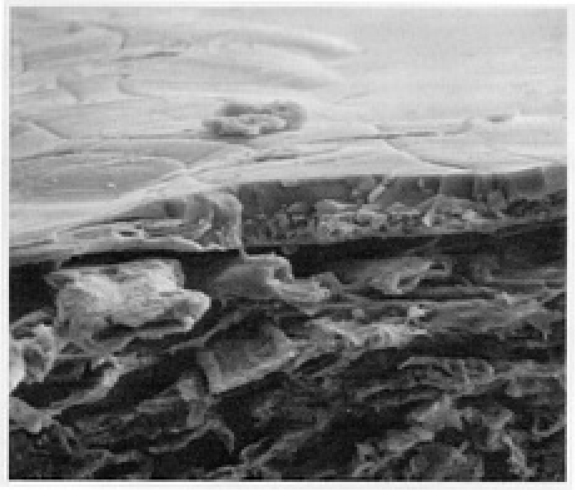

Fig. 6 Cross section of aluminum foil laminated on paperboard showing the expansion of the PVC coating by the corrosion products of filiform corrosion. Note the void spaces between the paperboard fibers that can entrap water. SEM. 650×

Figure 7 shows typical flaws in PVC coating applied by a chromium-plated gravure. The tendency to follow flaws in the coated foil, such as hills and valleys or mechanical gouges in the coating, is demonstrated in the filiforms on foilcoated paperboard observed by light microscopy (Fig. 8).

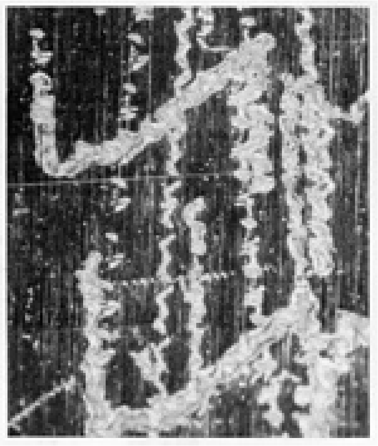

Fig. 8 Filiform in a nitrocellulose-coated aluminum foil laminated to paperboard showing a tendency to follow both the gravure imprint and the rolling direction of the sheet. Light microscopy. 75×

Prevention of Filiform Corrosion

Reduction in Relative Humidity Below 60%. Although the most direct method, reducing relative humidity is not practical if the metal is exposed to the elements or is in motion, as is the case for aircraft and automobiles. For articles in longer-term storage, controlled environments are beneficial--for example, the use of drying fans and humidistats or the addition of desiccants to plastic packaging or to small, confined areas. Structural designs can prevent moisture entrapment by better drainage or by attempting to exclude moisture entry. Reducing the ambient temperature can also be beneficial because it results in a decrease in the amount of moisture the air can hold.

Use of Zinc and Zinc Primers on Steel. Filiform corrosion is reduced when the steel substrate is galvanized. Zinc chromate primers, chromic acid anodizing, and chromate or chromate-phosphate conversion coatings have provided some relief from filiform corrosion in aluminum alloys.

Multiple-Coat Paint Systems. Multiple coats on metal surfaces have fewer penetration and defect sites than single-coat paint systems. Multiple-coat systems resist penetration by mechanical abrasion and have fewer hills and valleys. Thicker coatings achieved by layer buildup have demonstrated substantially better resistance to filiform corrosion by decreasing oxygen and moisture penetration, decreased solvent entrapment, and fewer initiation sites. Smooth, well-prepared primed metal surfaces generally have better resistance than rougher surfaces.

Use of Less Active Metal Substrates. Steel, aluminum, and magnesium are all chemically active. The substitution of more resistant materials exposed to the initiating environment, such as copper, austenitic stainless steel, or titanium, may be necessary. Unless a coating is mandatory, a material substitution may eliminate the central part of the problem. Economics and structural considerations, however, will usually dictate whether a material substitution is a practical solution.

Crevice Corrosion

R.M. Kain, LaQue Center for Corrosion Technology, Inc.

The presence of narrow openings or spaces (gaps) between metal-to-metal or nonmetal-to-metal components may give rise to localized corrosion at these sites. Similarly, unintentional crevices such as cracks, seams, and other metallurgical defects could serve as sites for corrosion initiation. Resistance to crevice corrosion can vary from one alloy-environment system to another. Passive alloys, particularly those in the stainless steel group, are more prone to crevice corrosion than materials that exhibit more active behavior. Figure 9, for example, shows crevice corrosion of a type 304 stainless steel fastener removed from a seawater jetty after 8 years. Although the washer shows severe deterioration, the function of the fastener was not diminished. On the other hand, Fig. 10 shows crevice corrosion beneath the water box gasket of an alloy 825 (44Ni-22Cr-3Mo-2Cu) seawater heat exchanger that allowed sufficient leakage to warrant shutdown and replacement after only 6 months.

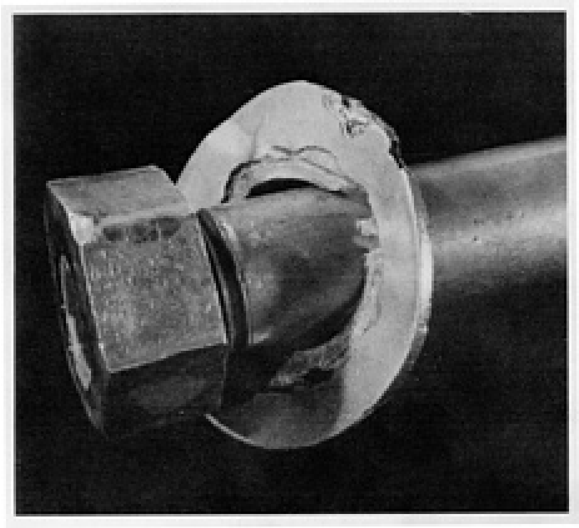

Fig. 9 Crevice corrosion at a metal-to-metal crevice site formed between components of type 304 stainless steel fastener in seawater

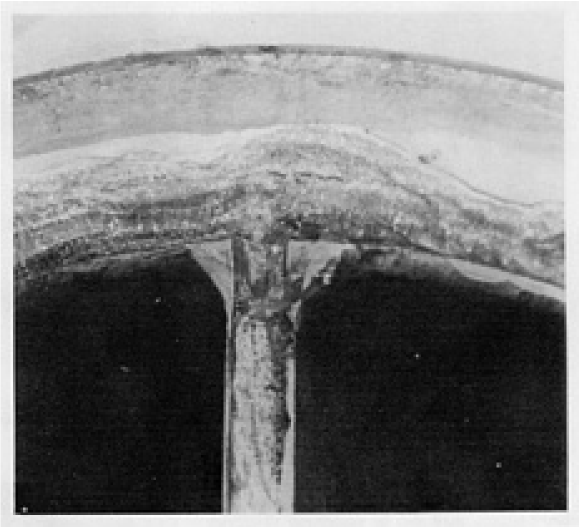

Fig. 10 Crevice corrosion at nonmetal gasket site on an alloy 825 seawater heat exchanger

In cases in which the bulk environment is particularly aggressive, general corrosion may preclude localized corrosion at a crevice site. Figure 11 compares the behavior of type 304 and type 316 stainless steels exposed in different zones of a model sulfur dioxide (SO_2) scrubber. In the aggressive acid condensate zone, type 304 incurred severe general corrosion of the exposed surfaces, while the more resistant type 316 suffered attack beneath a polytetrafluoroethylene (PTFE) insulating spacer. In the higher pH environment of the limestone slurry zone, type 304 was resistant to general corrosion, but was susceptible to crevice corrosion. Other alloy systems, such as aluminum and titanium, may also be susceptible to crevice corrosion (Ref 10). For aluminum, the occurrence of crevice corrosion would depend on the passivity of the particular alloy. In most cases, general corrosion would likely preclude crevice corrosion. Titanium alloys are typically quite resistant, but may be susceptible to crevice corrosion in elevated-temperature chloride-containing acidic environments.

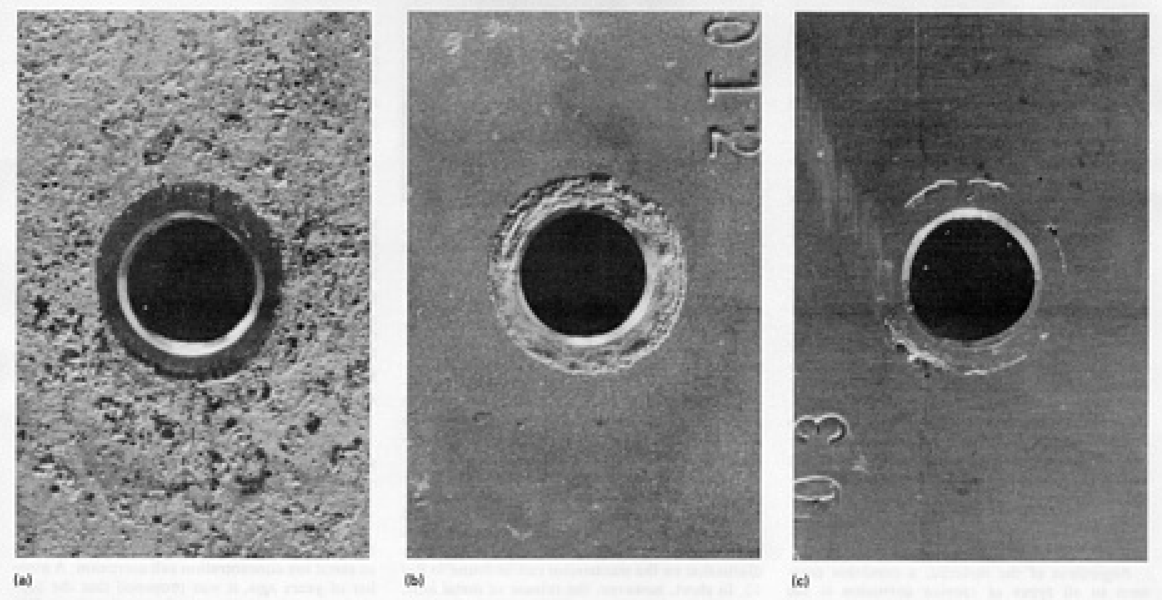

Fig. 11 Variation in stainless steel corrosion resistance in model SO_2 scrubber environments. (a) Type 304 in acid condensate. (b) Type 316 in acid condensate. (c) Type 304 in limestone slurry zone. Source: Ref 9

In seawater, localized corrosion of copper and its alloys at crevices is different from that of stainless-type materials because the attack occurs outside of the crevice rather than within. In general, the degree of crevice-related attack increases as the resistance to general corrosion increases. Figure 12 compares the crevice corrosion behavior for several different materials exposed to ambient-temperature seawater for various periods. In each case, a nonmetallic washer created the crevice. The more classical form of crevice corrosion (that is, beneath the crevice former) is shown for type 904L stainless steel (20Cr-25Ni-4.5Mo-1.5Cu) after only 30 days of exposure (Fig. 12a). For 70Cu-30Ni, corrosion occurred just outside of the crevice mouth and was found to be quite shallow after 6 months (Fig. 12b). In contrast, crevice-related corrosion of alloy 400 (70Ni-30Cu) was more severe after only 45 days (Fig. 12c). In some cases, corrosion may occur within as well as outside of the crevice.

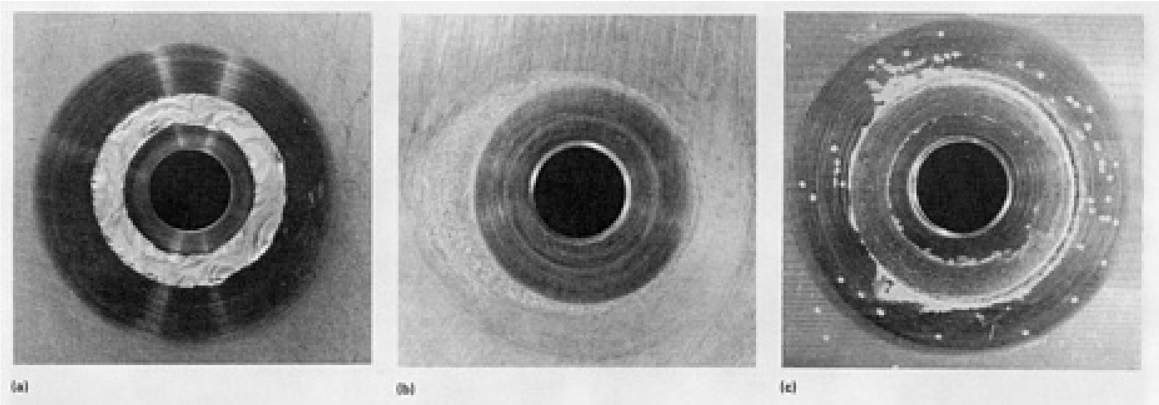

Fig. 12 Crevice-related corrosion for different alloys in natural seawater. (a) Alloy 904L (20Cr-25Ni-4.5Mo-1.5Cu) after 30 days. (b) 70Cu-30Ni after 180 days. (c) Alloy 400 (70Ni-30Cu) after 45 days

Mechanisms

Regardless of the material, a condition common to all types of crevice corrosion is the development of localized environments that may differ greatly from the bulk environment. In perhaps its simplest form, crevice corrosion may result from the establishment of oxygen differential cells. This can occur when oxygen within the crevice electrolyte is consumed, while the boldly exposed surface has ready access to oxygen and becomes cathodic relative to the crevice area. Crevice corrosion, for example, can be encountered by stainless-type alloys in some concentrations of sulfuric acid. Although the passivity of the exposed surfaces is maintained by dissolved oxygen in the acid, the presence of a crevice (for example, a gasket or O-ring seal) excludes oxygen and corrosion ensues in the active state.

Crevice corrosion in neutral chloride containing environments, such as natural waters and acid-chloride media, is more complex than the preceding example given for acid. It does, however, begin with the deoxygenation stage.

For stainless steels, numerous interrelated metallurgical, geometrical, and environmental factors affect both crevice corrosion initiation and propagation (Ref 11). A number of these factors are indicated in Table 2, and a more thorough discussion on the mechanism can be found in Ref 12. In short, however, the release of metal ions, particularly chromium, in the crevice produces an acidic condition as a result of a series of hydrolysis reactions. To effect charge neutrality with excess H^+ ions, Cl^- ions migrate and concentrate from the bulk environment. If the concentration of acid and chloride in the crevice solution becomes sufficiently aggressive to cause breakdown of the passive film, crevice corrosion initiation occurs. Although natural seawater, for example, is typically pH 8 and contains about 0.5 *M* Cl^-, crevice solutions may attain a pH of 1 or less and contain 5 to 6 *M* Cl^- (saturated) (Ref 12).

Table 2 Factors that can affect the crevice corrosion resistance of stainless steels

Geometrical
Type of crevice: metal to metal nonmetal to metal Crevice gap (tightness) Crevice depth Exterior to interior surface area ratio
Environmental
Bulk solution: O_2 content pH chloride level temperature agitation Mass transport, migration Diffusion and convection Crevice solution: hydrolysis equilibria Biological influences
Electrochemical reactions
Metal dissolution O_2 reduction H_2 evolution
Metallurgical
Alloy composition: major elements minor elements impurities Passive film characteristics

Crevice corrosion of the copper-containing alloys, as shown in Fig. 12, is frequently identified as metal ion concentration cell corrosion. A number of years ago, it was proposed that the concentration of metal ions in the crevice electrolyte rendered the crevice area cathodic to the area immediately outside the mouth of the crevice (Ref 13, 14). Corrosion outside of the crevice (anode) progressed because the bulk environment contained a much lower concentration of metal ions. In some cases, this has been supported by the observation of plated-out copper within the crevice. Other researchers have refuted this premise, suggesting that the mode of attack is merely a variation on the oxygen differential cell mechanism (Ref 15). In any event, the morphology of crevice-related attack for copper alloys is distinctly different from that for stainless steels and can be recognized accordingly.

Types of Crevices

Crevices fall into two categories: man-made and naturally occurring. The former may be unavoidable and may serve a particular design purpose, such as the fastener and gasket examples shown in Fig. 9 and 10. Other man-made crevices may result during fabrication or assembly. Some of these may be avoidable after consideration of the consequences of crevice corrosion. For example, Fig. 13 shows crevice corrosion at a stainless steel tube and tubesheet test assembly after only 3 months of exposure to seawater. In an actual service situation, this occurrence could be prevented by weld sealing

the joints and/or by applying cathodic protection. Sealants, coatings, and greases can also promote localized corrosion by forming sites at the interface with some susceptible materials (Ref 16).

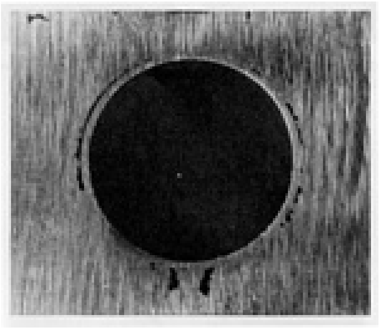

Fig. 13 Crevice corrosion at tube/tubesheet interface after 3 months of exposure in a natural seawater test

Naturally occurring crevices, such as those formed by debris, sand, and, in the case of marine applications, the attachment of barnacles or other biofouling organisms, may be a problem for some materials. It is well documented, for example, that type 304 and type 316 may incur crevice corrosion beneath barnacles (Ref 17). This may be a limiting factor in the use of these and other stainless alloys for condenser tube service if the surfaces are not kept free of fouling. Even higher-alloyed material may incur this attack. In a 1-year tidal zone test, nickel-base alloys 600 (15Cr-8Fe) and 690 (29Cr-8Fe), which have excellent resistance to chloride stress-corrosion cracking, incurred shallow crevice penetrations beneath barnacles (Ref 18). Figure 14 compares the resistance of these molybdenum-free alloys with the high molybdenum containing nickel-base alloy 625 (22Cr-4.5Fe-9Mo), which was totally resistant. Stainless steels with over 4 to 5% Mo may also be resistant to barnacle-related crevice corrosion.

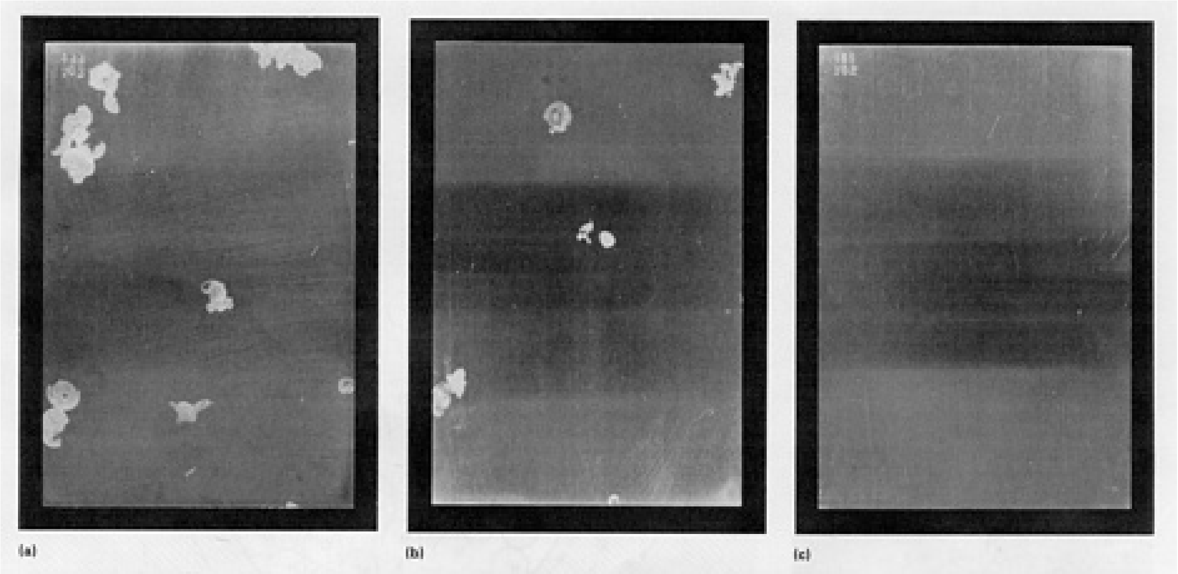

Fig. 14 Incidence of barnacle-related crevice corrosion for three nickel-base alloys after 1-year tidal zone exposures. Susceptible materials, alloy 600 (a) and alloy 690 (b), do not contain molybdenum. Resistant material, alloy 625 (c), contains about 9% Mo. Source: Ref 18

Crevice Geometry

To gain a greater appreciation of crevice corrosion, one must recognize the importance of crevice geometry because it is frequently the controlling factor governing resistance to corrosion in a particular situation. The occurrence or absence of

crevice corrosion for a given alloy-environment system may or may not be indicative of performance under other conditions in which more severe crevices exist.

Crevices can be defined by the dimension of the gap (degree of tightness) and by the depth (distance from the mouth). For stainless steels in chloride-containing environments, tighter crevices reduce the volume of crevice electrolyte that must be deoxygenated and acidified and will generally cause more rapid initiation of attack. Typically, tighter crevices can be achieved between nonmetal and metal components than between two metal components. However, if gaps of equal dimension can be produced with metal-to-metal components, corrosion initiation can be more rapid because of metal ion production from both surfaces. This is illustrated in Fig. 15, which contains micrographs of the actual gap for crevices assembled under laboratory conditions. Dimensions of the order shown may or may not reflect those attainable in actual service. Variations in crevice geometry from one application to another can frequently account for variability in alloy performance.

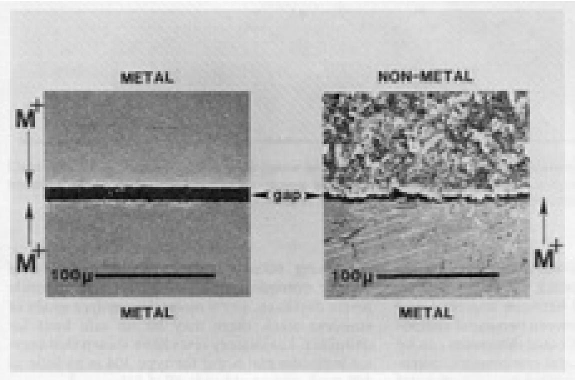

Fig. 15 Examples of crevice gaps attainable for metal-to-metal and nonmetal-to-metal crevices

Increasing the crevice tightness, depth, bulk environment chloride levels, and acidity increases the chances for crevice initiation (Ref 19, 20). In some cases, however, deep crevices may restrict propagation because of a voltage drop through the crevice solution (Ref 11). The use of higher-alloy stainless-type material offers the advantage of providing resistance over a broader range of conditions.

Other Environments

In addition to seawater, stainless steels may be susceptible to crevice corrosion in other chloride-containing natural waters. The occurrence of crevice corrosion is less likely as bulk chloride levels decrease. For a molybdenum-free grade of stainless steel, there may be no safe limit for chlorides. Laboratory tests have shown that crevice initiation can occur for type 304 in as little as 100 mg/L (ppm) chloride (Ref 21).

Crevice corrosion may also occur in severe marine atmospheres. In contrast to seawater immersion, however, the extent of attack is quite minimal. Figure 16 shows very shallow penetration found at lap joints of test rack fabricated of type 316 stainless steel after a 10-years exposure in the 25-m (80-ft) test site at Kure Beach, NC. In coastal architectural applications, rust staining from crevices may detract from the appearance of stainless steel if it is not periodically cleaned.

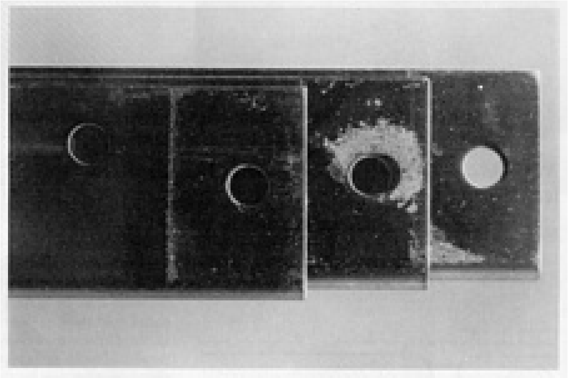

Fig. 16 Example of shallow crevice corrosion incurred by type 316 stainless steel at lap joints after a 10-year exposure in aggressive marine atmosphere. Source: Ref 22

Prevention of Crevice Corrosion

Many of the factors noted in Table 2 must be considered if crevice corrosion is to be eliminated or minimized (Ref 23). Wherever possible, crevices should be eliminated at the design stage. When unavoidable, they should be kept as open and shallow as possible to allow continued entry of the bulk environment. Cleanliness is an important factor, particularly when conditions promote deposition on metal surfaces.

In critical areas, weld overlays with more corrosion-resistant alloys have proved to be effective measures in some cases (Ref 24). Similarly, the use of cathodic protection can be beneficial (Ref 25). The consequences of overprotection, however, should be recognized for those alloys that may be susceptible to hydriding and embrittlement (Ref 16).

Pitting Corrosion

A.I. Asphahani and W.L. Silence, Haynes International, Inc.

Pitting corrosion represents an important limitation to the safe and reliable use of many alloys in various industries. Pitting is a very serious type of corrosion damage because of the rapidity with which metallic sections might be perforated. The unanticipated occurrence of pitting and its unpredictable propagation rate make it difficult to take it into consideration in practical engineering designs.

Deterioration by pitting is one of the most dangerous and most common types of localized corrosion encountered in aqueous environments (Ref 26, 27). In the chemical-processing industries, localized corrosion is a major cause of repeated service failures (Ref 28, 29) and is estimated to account for at least 90% of metal damage by corrosion (Ref 30).

Pitting corrosion is defined as an extremely localized corrosive attack. Simply stated, pitting is the type of localized corrosion that produces pits, that is, sites of corrosive attack that are relatively small compared to the overall exposed surface. If appreciable attack is confined to a relatively small fixed area of metal acting as an anode, the resultant pits are described as deep (Fig. 17a). If the area of attack is relatively larger and not so deep, the pits are called shallow (Fig. 17b). Depth of pitting is sometimes expressed by the term pitting factor (Ref 31). This is the ratio of deepest metal penetration to average metal penetration as determined by the weight loss of the specimen (Fig. 18). A pitting factor of unity represents uniform, or general, corrosion.

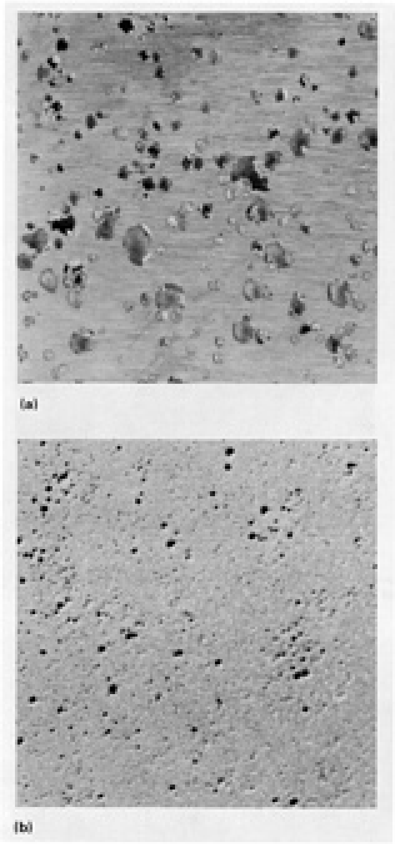

Fig. 17 Examples of deep pits (a) and shallow pits (b)

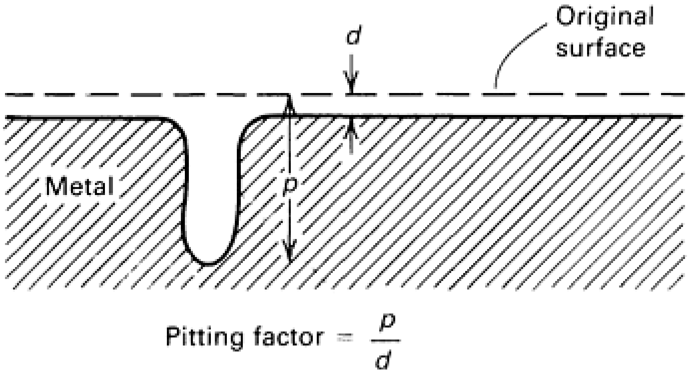

Fig. 18 Schematic illustrating the pitting factor *p/d*

Mechanisms and Theories

It is stated that pits begin by the breakdown of passivity at favored nuclei on the metal surface (Ref 32). The breakdown is followed by the formation of an electrolytic cell. The anode of this cell is a minute area of active metal, and the cathode is a considerable area of passive metal. The large potential difference characteristic of this passive-active cell (for example, approximately 0.5 V for 300-series stainless steel) accounts for considerable flow of current with rapid corrosion at the small anode. The corrosion-resistant passive metal surrounding the anode and the activating property of the corrosion products within the pit account for the tendency of corrosion to penetrate the metal rather than spread along the surface.

Once pits are initiated, they may continue to grow by a self-sustaining, or autocatalytic, process; that is, the corrosion processes within a pit produce conditions that are both stimulating and necessary for the continuing activity of the pit (Ref

33). This process is illustrated schematically in Fig. 19. Pit growth is controlled by rate of depolarization at the cathode areas. In seawater, control is exercised by the amount and availability of dissolved oxygen. Ferric chloride, a more effective depolarizer than dissolved oxygen, cause greater numbers of pits and more rapid penetration in various industrial services.

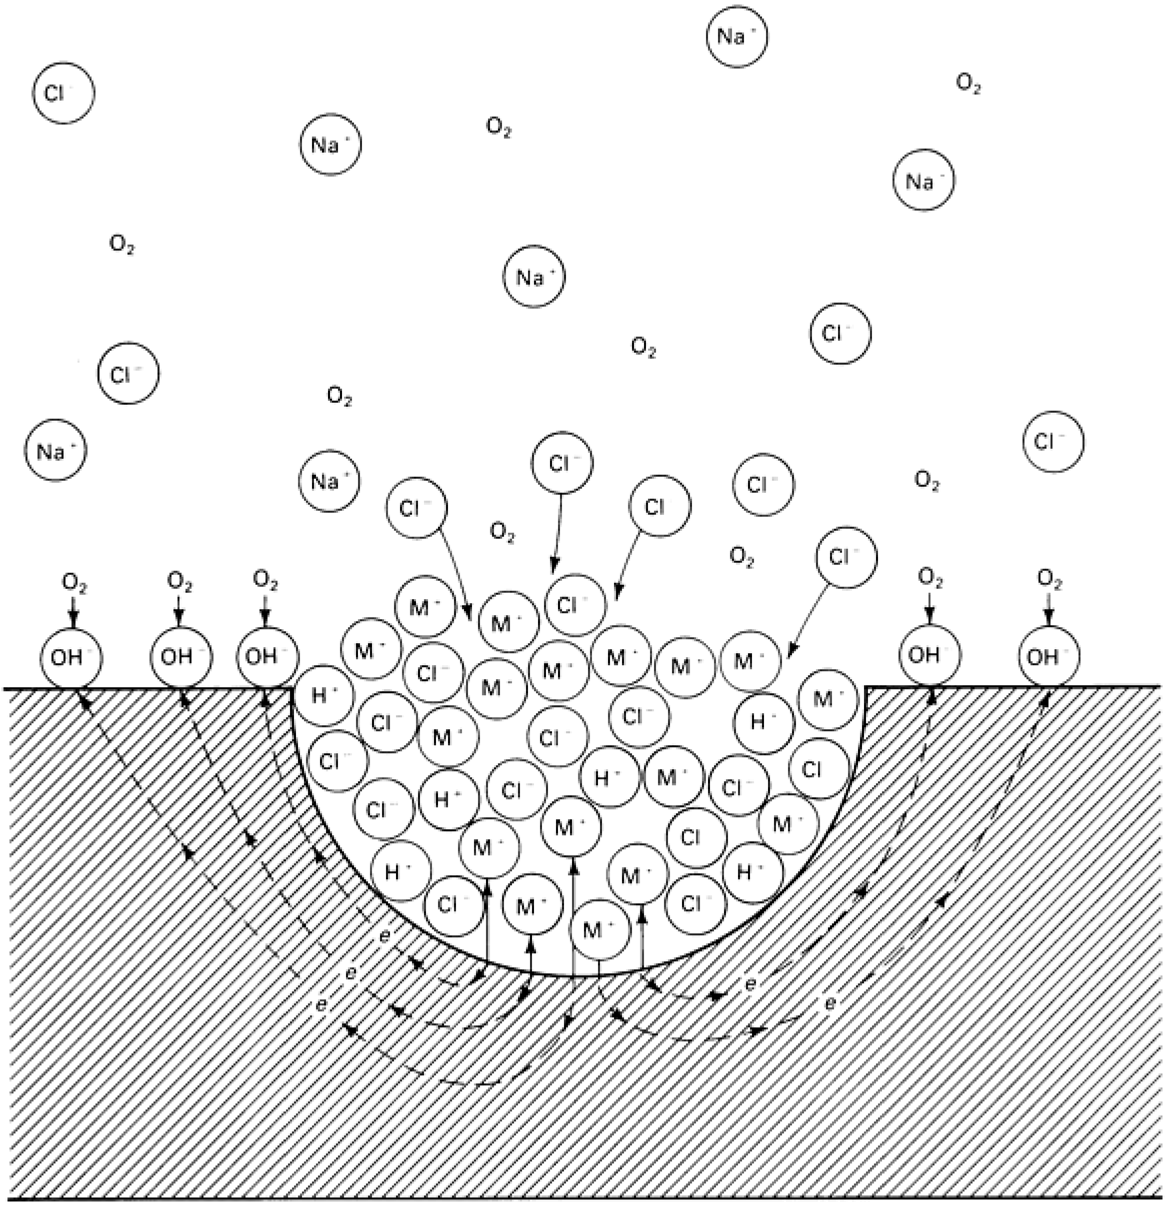

Fig. 19 Autocatalytic processes occurring in a corrosion pit. The metal, M, is being pitted by an aerated NaCl solution. Rapid dissolution occurs within the pit, while oxygen reduction takes place on the adjacent surfaces. A more detailed explanation of this self-sustaining process is given in Ref 34.

The propagation of pits is thought to involve the dissolution of metal and the maintenance of a high degree of acidity at the bottom of the pit by the hydrolysis of the dissolved metal ions. The anodic metal dissolution reaction at the bottom of the pit ($M \rightarrow M^{n+} + ne$) is balanced by the cathodic reaction on the adjacent surface ($O_2 + 2H_2O + 4e \rightarrow 4OH^-$). The increased concentration of M^{n+} within the pit results in the migration of chloride ions (Cl^-) to maintain neutrality. The metal chloride formed, M^+Cl-, is hydrolyzed by water to the hydroxide and free acid ($M^+Cl^- + H_2O \rightarrow MOH + H^+Cl^-$). The generation of this acid lowers the pH values at the bottom of the pit (pH approximately 1.5 to 1.0), while the pH of the bulk solution remains neutral.

Most of the research focuses on understanding the factors that control pit initiation. Various theories have been proposed that attempt to explain the pitting phenomenon (Ref 35). These include kinetic theories, which explain the breakdown of passivity in terms of the competitive absorption between chloride ions and oxygen, and thermodynamic theories, which consider the pitting potential as that potential at which the chloride ion is in equilibrium with the oxide film.

Occurrence and Testing

Pitting corrosion occurs in most commonly used metals and alloys. Iron buried in the soil corrodes with the formation of shallow pits, but stainless steels immersed in seawater characteristically corrode with the formation of deep pits. Aluminum tends to pit in waters containing Cl^- (for example, at stagnant areas), and aluminum brasses are subject to pitting attack in polluted waters.

In environments containing appreciable concentrations of Cl^- or Br^-, most stainless materials (for example, iron-base, nickel-base, cobalt-base, and titanium alloys) tend to corrode at specific areas and tend to form deep pits. Figure 20 shows deep pits that formed in a type 316 stainless steel centrifuge head from a calcium chloride ($CaCl_2$) solution. Ions such as thiosulfate ($S_2O_3^{2-}$) may also induce pitting of stainless steels. In the absence of passivity, such as in deaerated alkali-metal chlorides and nonoxidizing metal chlorides (for example, stannous chloride, $SnCl_2$, or nickel chloride $NiCl_2$), pitting does not occur, although general, or uniform, corrosion may be appreciable in such environments.

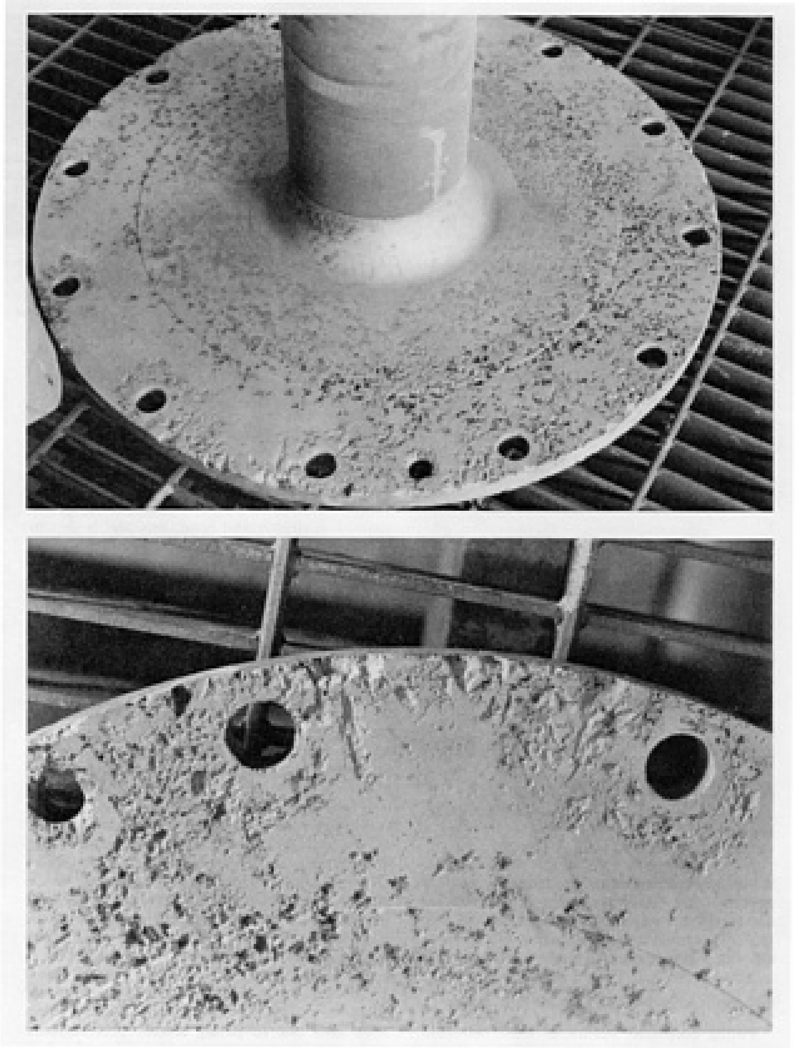

Fig. 20 Two views of deep pits in a type 316 stainless steel centrifuge head due to exposure to $CaCl_2$ solution. Courtesy of N.W. Sachs, Allied Corporation

The selection of materials for resistance to pitting corrosion in specific industrial services is better made when based on field testing and actual service performance. However, such empirical information is often generated under ill defined environmental conditions and is dependent on many uncontrollable factors that do not allow a precise comparison among the potential candidate alloys or metals. Accelerated laboratory tests might be useful in this respect. Such tests include the classic immersion tests (freely corroding conditions) and the advanced electrochemical techniques.

The immersion tests are very practical in providing decisive, direct comparison among various alloys, and these tests correlate very well with service experience. Figure 21 clearly distinguishes the improved pitting resistance of alloys G (Ni-20Fe-22Cr-6Mo), 625 (Ni-22Cr-9Mo), and C-276 (Ni-16Cr-16Mo-4W) from that of alloy 825 (Ni-30Fe-21Cr-3Mo) and type 316 stainless steel. Also, immersion tests allow emphasis on the effect of temperature on pitting resistance (Fig. 22) and allow establishment of the critical pitting temperature, that is, the temperature above which pitting occurs in a specific environment (Fig. 23). The higher the critical pitting temperature is (for example >120 °C, or 250 °F, for alloy C-22), the more resistant the alloy is to pitting corrosion.

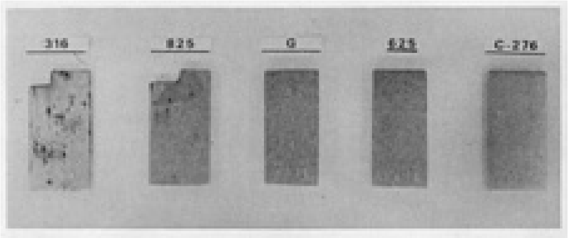

Fig. 21 Results of a 24-h test on five different alloys in 7 vol% H_2SO_4 + 3 vol% HCl + 1% $FeCl_3$ + 1% $CuCl_2$ solution at 25 °C (77 °F)

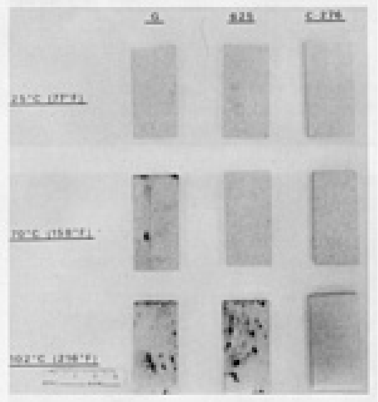

Fig. 22 Effect of temperature on pitting resistance of three different alloys. 24-h test in 7 vol% H_2SO_4 + 3 vol% HCl + 1% $FeCl_2$ + 1% $CuCl_2$ solution

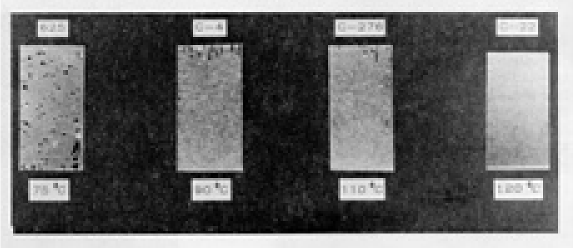

Fig. 23 Critical temperature above which pitting is observed for four different alloys. 24-h test in 7 vol% H_2SO_4 + 3 vol% HCl + 1% $FeCl_3$ + 1% $CuCl_2$ solution. Alloy C-4: Ni-16Cr-16Mo. Alloy C-22: Ni-22Cr-13Mo-3W.

Remaining alloy compositions are given in text.

The electrochemical techniques used to investigate pitting corrosion include the simple monitoring of corrosion potential and its fluctuation with time due to pitting attack, potentiostatic tests, potentiodynamic tests (at relatively slow scan rates of a few millivolts per minute), rapid scan potentiodynamic techniques, potentiostatic induction time studies, potentiostatic scratch techniques, galvanostatic polarization techniques (or anodic pitting tests), constant potential techniques (or potentiostatic point-to-point methods), and cyclic polarization (or anodic hysteresis loop techniques). Reliable, comparative data can be generated with the electrochemical testing techniques to assess the effects of potential, temperature, pH, chloride ion concentration, heat treatment, and alloying elements (Ref 36). The potentiostatic polarization method is judged the most practical in generating data relevant to actual service performance (Ref 36, 37). More detailed information on testing and evaluation of pitting corrosion can be found in the articles "Laboratory Testing" and "Evaluation of Pitting Corrosion" in this Volume.

Prevention of Pitting Corrosion

Typical approaches to alleviating or minimizing pitting corrosion find their roots in the following major principles:

- Reduce the aggressivity of the environment--for example, chloride ions concentration, temperature, acidity, and oxidizing agents
- Upgrade the materials of construction--for example, addition of molybdenum/tungsten, overalloying of welds, and lining with high alloy
- Modify the design of the system--for example, avoid crevices, circulate/stir to eliminate stagnant solutions, and ensure proper drainage

In addition, based on the concept of critical potential to induce pitting corrosion, cathodic protection would be a good solution if design allows (Ref 38). Also, addition of extraneous ions (for example, OH^- or NO_3^-) would augment resistance to pit formation.

The applicability of any of the above mentioned remedial measures, among others, is dependent on the specific situation. A review and analysis of successful case histories of various remedial measures are recommended.

Most of the documented cases in which biological organisms are the sole cause of, or an accelerating factor in, corrosion involve localized forms of attack. One reason for this is that organisms often do not form in a continuous film on the metal surface.

The large fouling organisms in marine environments settle as individuals, and it is often a period of months or even years before a complete cover is built up. A scatter of individual barnacles on a stainless steel surface will create oxygen concentration cells. The portion of the metal surface covered by the barnacle shell is shielded from dissolved oxygen in the water and thus becomes the anode through mechanisms described in the Section "Fundamentals of Corrosion" in this Volume. The result is crevice corrosion under the base of the barnacles, as shown in Fig. 24. A similar effect can take place on aluminum and, to a lesser extent, on structural steel.

Fig. 24 Corrosion under a scatter of individual barnacles on a stainless steel surface

Microscopic organisms also tend to settle on metal surfaces in the form of discrete colonies or at least spotty, rather than continuous, films. Those few cases in which continuous films do form have been dealt with in the preceding article "General Corrosion" in this Volume. In the remainder of this section, the localized forms of attack influenced by microorganisms, as shown schematically in Fig. 25, will be discussed.

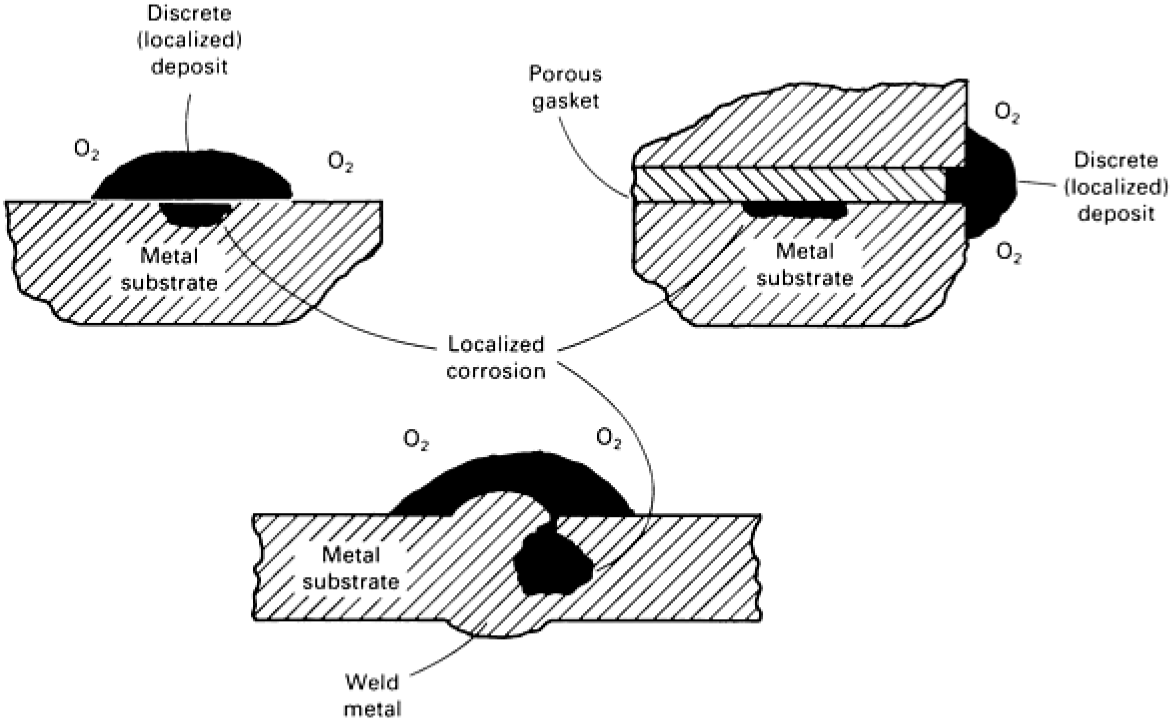

Fig. 25 The three most common forms of microbial corrosion. Source: Ref 39

This section will catalog the industries most often reported as being affected by microbiological corrosion and the organisms usually implicated in the attack, and will illustrate the types of attack that have most commonly been documented by representing generalized case histories for different classes of alloys. Cases that are still in the research stage or cases in which evidence for a primary role of the biofilm is not convincing will not be covered.

Further information on the mechanisms of localized biological corrosion can be found in the article "Effects of Environmental Variables on Aqueous Corrosion" (see the Appendix "Biological Effects") in this Volume. Additional information on the detection and control of biological corrosion can be found in the articles "Evaluation of Microbiological Corrosion" and "Control of Environmental Variables in Water Recirculating Systems," respectively, in this Volume.

Industries and Organisms Involved

The various industries that have been affected by microbiological corrosion problems are listed in Table 3. References to problems in the chemical-processing, nuclear power, oil field (both onshore and offshore), and underground pipeline industries are most common in the published literature (see also the articles on these industries in the Section "Specific Industries and Environments" in this Volume). This does not necessarily mean that these industries are more prone to problems of this type than other industries, but it does mean that these industries have been quick to recognize the biological causes of some of their corrosion problems, to take steps to solve these problems, and to make the results public.

Table 3 Industries known to be affected by microbiological corrosion

Industry	Problem areas
Chemical-processing industries	Stainless steel tanks, pipelines and flanged joints, particularly in welded areas after hydrotesting with natural river or well waters
Nuclear power generation	Carbon and stainless steel piping and tanks; copper-nickel, stainless, brass and aluminum bronze cooling water pipes and tubes, especially during construction, hydrotest, and outage periods
Onshore and offshore oil and gas industries	Mothballed and waterflood systems; oil and gas handling systems, particularly in those environments soured by sulfate reducing bacteria (SRB)-produced sulfides
Underground pipeline industry	Water-saturated clay-type soils of near-neutral pH with decaying organic matter and a source of SRB
Water treatment industry	Heat exchangers and piping
Sewage handling and treatment industry	Concrete and reinforced concrete structures
Highway maintenance industry	Culvert piping
Aviation industry	Aluminum integral wing tanks and fuel storage tanks
Metal working industry	Increased wear from breakdown of machining oils and emulsions

The frequency of literature reports of microbiological corrosion problems in these industries also does not mean that corrosion is accelerated everywhere microorganisms are present in these industries. Many bacteria existing in natural and man-made environments do not cause or accelerate corrosion. Bacteria may exist at the corrosion site only because the electrochemistry of corrosion creates a favorable environment for their growth.

A select number of organisms, however, are repeatedly cited as causing corrosion in environments in which there would be none without them, or as accelerating corrosion, or as changing a relatively slow rate of general corrosion into one with rapid localized penetration of the metal. These organisms are listed in Table 4.

Table 4 Microorganisms most commonly implicated in biological corrosion

Genus or species	pH range	Temperature range °C	Oxygen requirement	Metals affected	Action
Bacteria					
Desulfovibrio **Best known:** ***D, desulfuricans***	4-8	10-40	Anaerobic	Iron and steel, stainless steels, aluminum, zinc, copper alloys	Utilize hydrogen in reducing SO_4^{2-} to S^{2-} and H_2S; promote formation of sulfide films
Desulfotomaculum **Best known:** ***D. nigrificans*** **(also known as** ***Clostridium*****)**	6-8	10-40 (some 45-75)	Anaerobic	Iron and steel, stainless steels	Reduce SO_4^{2-} to S^{2-} and H_2S, (spore formers)
Desulfomonas	. . .	10-40	Anaerobic	Iron and steel	Reduce SO_4^{2-} to S_{2-} and H_2S
Thiobacillus thiooxidans	0.5-8	10-40	Aerobic	Iron and steel, copper alloys, concrete	Oxidizes sulfur and sulfides to form H_2SO_4; damages protective coatings
Thiobacillus ferrooxidans	1-7	10-40	Aerobic	Iron and steel	Oxidizes ferrous (Fe^{2+}) to ferric (Fe^{3+})
Gallionella	7-10	20-40	Aerobic	Iron and steel, stainless steels	Oxidizes ferrous (and manganous) to ferric (and manganic); promotes tubercule formation
Sphaerotilus	7-10	20-40	Aerobic	Iron and steel, stainless steels	Oxidizes ferrous (and manganous) to ferric (and manganic); promotes tubercule formation
S. natans	. . .	. . .	. . .	Aluminum alloys	
Pseudomonas	4-9	20-40	Aerobic	Iron and steel, stainless steels	Some strains can reduce Fe^{3+} to Fe^{2+}
P. aeruginosa	4-8	20-40	Aerobic	Aluminum alloys	

Fungi					
Cladosporium resinae	3-7	10-45 (best at 30-35)	. . .	Aluminum alloys	Produces organic acids in metabolizing certain fuel constituents

Biological Corrosion of Iron and Steel

A large number of case histories involving the microbial acceleration of the localized corrosion of iron and steel have been presented in the literature. These are far too numerous to list in this article. An excellent introduction to the literature can be gained by referring to Ref 40, 41, 42, 43, 44, 45, and 46.

Anaerobic Corrosion. The corrosive action of the sulfate-reducing bacteria (SRB) from the genera *Desulfovibrio, Desulfotomaculum,* and *Desulfomonas* in anaerobic environments is well known. The morphology of attack is almost always localized and often looks much like the pitting shown for cast iron in Fig. 26. A general review of the mechanism and the fundamentals of biological corrosion in aqueous environments is given in the article "Effects of Environmental Variables on Aqueous Corrosion" (see the Appendix "Biological Effects") in this Volume.

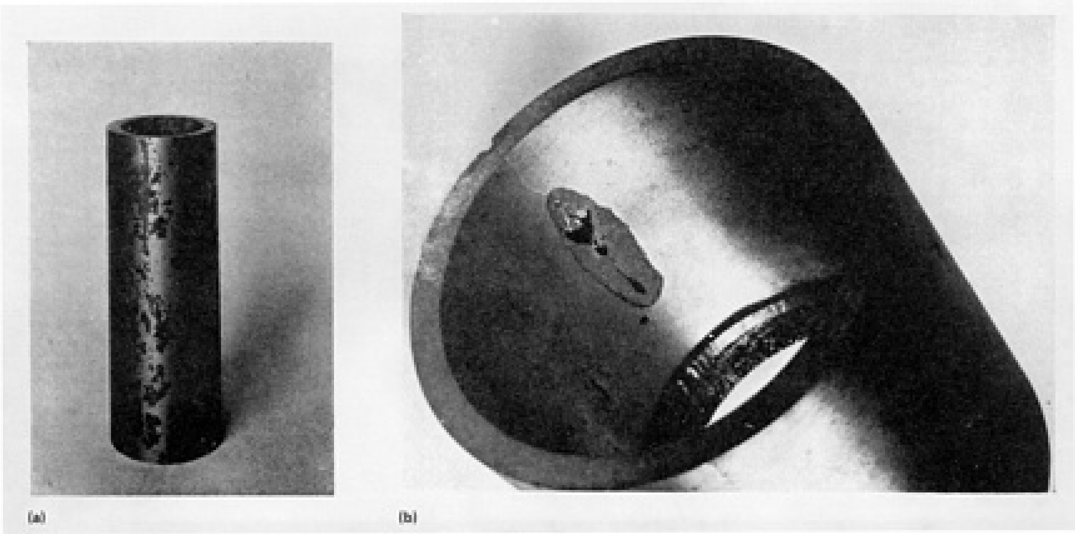

Fig. 26 Anaerobic biological corrosion of cast iron. (a) Cast iron pipe section exhibiting external pitting caused by bacteria. (b) Cast iron pipe showing penetration by bacteria-induced pitting corrosion. Source: Ref 42

In the early decades of this century, it was generally believed that the SRB could influence the corrosion of steel only in totally anaerobic environments such as deaerated soils and marine sediments. Recently, it has been recognized that anaerobic corrosion by SRB can take place in nominally aerated environments. In these latter cases, anaerobic microenvironments can exist under biodeposits of aerobic organisms, in crevices built into the structure, and at flaws in various types of coating systems. The most corrosive environments are often those in which alternate aerobic-anaerobic conditions exist because of the action of variable flow hydrodynamics or periodic mechanical action.

The anaerobic corrosion of iron and steel has been identified in such diverse environments as waterlogged soils of near-neutral pH; bottom muds of rivers, lakes, marshes, and estuaries (especially when these contain decaying organic material as a source of sulfates for the SRB); under marine fouling deposits and in various other offshore industrial environments (Ref 47); under nodules or tubercules in natural freshwaters and recirculating cooling waters; and under disbonded areas of pipeline coatings.

A considerable amount of work has been done to assess the relative aggressiveness of various soils and sediments. The work in soils prior to 1970 is reviewed in Ref 48. Factors such as the presence of absence of SRB, soil resistivity, and water content were considered. It was discovered that SRB activity correlated well with soil redox potential, E_h, on the normal hydrogen scale, a variable that is much easier to measure than numbers of SRB. Aggressive soils tended to have

mean resistivities of less than 2000 $\Omega \cdot$ cm and a mean redox potential more negative than 400 mV on the normal hydrogen scale corrected to pH 7. Soils that were borderline based on these two tests tended to be aggressive if their water content was over 20%. With regard to redox potential alone, soil corrosivity varied as follows (Ref 48);

Soil E_h	Corrosivity
< 100 mV	Severe
100-200 mV	Moderate
200-400 mV	Slight
> 400 mV	Noncorrosive

Other attempts to assess the risk of corrosion by SRB have been sporadic. One investigation attempted to assess the severity of the SRB hazard on the inside of submarine pipelines carrying North Sea crude oil by measuring both the numbers of SRB present in the oil and the activity (or vigor of growth) of the organisms (Ref 49). The risk was assessed as extreme if both the numbers of organisms and their activity were rated high, and the risk was considered to be minimal if both were rated low.

Efforts to solve the anaerobic iron and steel corrosion problem as outlined in Ref 48 include:

- Replacing the iron or steel with noncorrodible materials, such as fiberglass, PVC, polyethylene, and concrete
- Creating a nonaggressive environment around the steel by backfilling with gravel or clay-free sand to encourage good drainage (that is, oxygenating to suppress SRB), making the environment alkaline, or using biocides (in closed industrial systems)
- Using cathodic protection, although potentials of -0.95 V versus $Cu/CuSO_4$ (or even more negative) are often required; at these potentials, the risk of hydrogen cracking or blistering should be assessed
- Using various barrier coatings, some with corrosion inhibitors and/or biocides

Aerobic Corrosion. Corrosion of iron and steel under oxygenated conditions generally involves the formation of acidic metabolites. The aerobic sulfur-oxidizing bacteria *Thiobacillus* can create an environment of up to about 10% H_2SO_4, thus encouraging rapid corrosion. Other organisms produce organic acids with similar results. This corrosion can be localized or general, depending on the distribution of organisms and metabolic products. If all the bacterial activity is concentrated at a break or delamination in a coating material, the corrosion is likely to be highly localized. If, on the other hand, the metabolic products are spread over the surface, the corrosion may be general, as has been reported for carbon steel tendon wires used to prestress a concrete vessel in a nuclear power plant (Ref 46). In this case, the wires were coated with a hygroscopic grease prior to installation. A study to determine the cause of corrosion concluded that the wires, shown in Fig. 27, were corroded by formic and acetic acids excreted by bacteria in breaking down the grease.

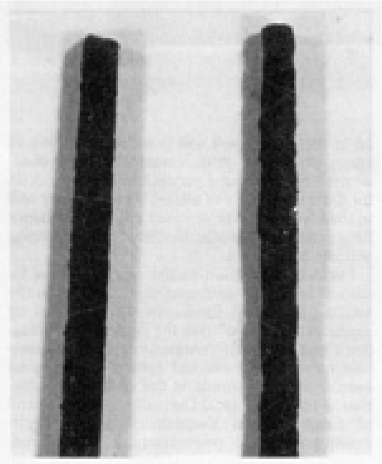

Fig. 27 Carbon steel wires from a prestressing tendon of a nuclear power plant showing the damage resulting from the formation of organic acids in the tendon due to the breakdown of grease by the bacteria present in the tendon. Source: Ref 46

Other cases of aerobic corrosion of iron and steel begin with the creation of oxygen concentration cells by deposits of slime-forming bacteria. Such corrosion is often accelerated by the iron-oxidizing bacteria in the formation of tubercules. This topic is addressed in the discussion "Tuberculation" in this section.

Biological Corrosion of Stainless Steel

There are two general sets of conditions under which localized biological corrosion of austenitic stainless steel occurs (Fig. 25). These will be illustrated by two generalized case histories. Typical examples of microbiologically induced localized corrosion of stainless steel are shown in Fig. 28.

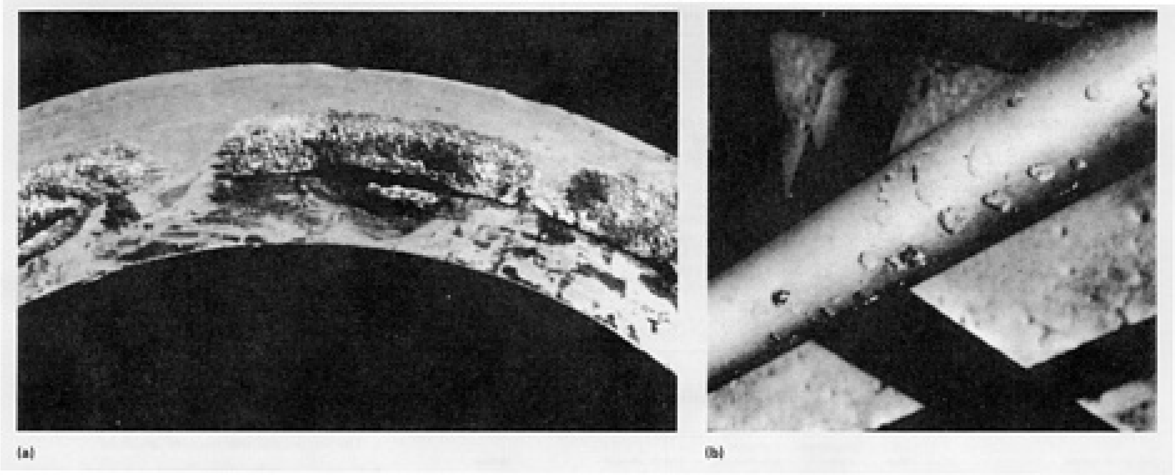

Fig. 28 Localized biological corrosion of austenitic stainless steel. (a) Crevice corrosion of type 304 stainless steel flange from a cooling water system. Staining shows evidence of adjacent biomounds. The corrosion attack reached a depth of 6 mm ($\frac{1}{4}$ in.). Courtesy of W.K. Link and R.E. Tatnall, E.I. Du Pont de Nemours & Co., Inc. (b) Pits on the underside of type 304 stainless steel piping used in a waste treatment tank (after sandblasting to remove biomounds). Courtesy of G. Kobrin and R.E. Tatnall, E.I. Du Pont de Nemours & Co., Inc.

Hydrotest or Outage Conditions. As originally reported in Ref 50, a new production facility required type 304L and 316L austenitic stainless steels for resistance to nitric and organic acids. All of the piping and flat-bottomed storage tanks

were field erected and hydrostatically tested. The hydrotest water was plant well water containing 20 ppm chlorides and was sodium softened.

The pipelines were not drained after testing. The tanks were drained, but were then refilled for ballast because of a hurricane threat. Two to four months after hydrotesting, water was found dripping from butt welds in the nominally 3-mm ($\frac{1}{8}$-in.) wall piping. Internal inspection revealed numerous pits in and adjacent to welds under reddish-brown deposits in both piping and tanks. Upon cleaning off the deposit, the researchers found a large stained area with a pit opening. Metallographic sectioning showed a large subsurface cavity with only a small opening to the surface. Photographs of the weld corrosion deposits and the resulting pitting corrosion are shown in Fig. 26 to 35 in the article "Corrosion of Weldments" in this Volume (see the discussion "Microbiologically Induced Corrosion"). Pitted welds in a type 316L tank showed some evidence of preferential attack of the δ-ferrite stringers, as shown in Fig. 29. It is not yet known why such attack often concentrates at the weld line.

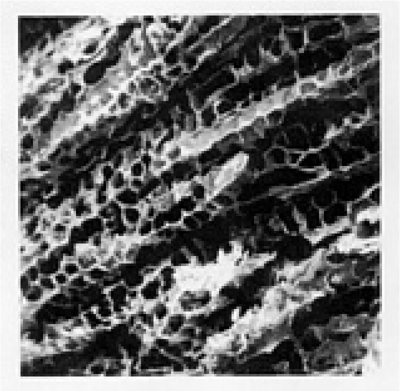

Fig. 29 SEM micrograph showing matrix remaining after preferential corrosion of the δ-ferrite phase in a type 316 stainless steel. 300×. Courtesy of J.G. Stoecker, Monsanto Company

Well water and deposits both showed high counts of the iron bacteria, *Gallionella*, and the iron/manganese bacteria, *Siderocapsa.* Deposits also contained thousands of parts per million of iron, manganese, and chlorides. Sulfate-reducing and sulfur-oxidizing bacteria were not present in either water or deposits. The proposed mechanism for the attack involves:

- Original colonization by the iron and manganese bacteria at the weld seams to create an oxygen concentration cell
- Dissolution of ferrous and manganous ions under the deposits
- Attraction of chloride ions as the most abundant anion to maintain charge neutrality
- Oxidation of the ferrous and manganous ions to ferric and manganic by the bacteria to form a highly corrosive acidic chloride solution in the developing pit

Many failures of this type have been reported in the chemical-processing industries in new equipment after hydrotesting but prior to commissioning in service. Similar failures have been reported in older equipment in both the chemical-processing and nuclear power industries when untreated well or river water was allowed to remain stagnant in the equipment during outage periods. Occasionally, the pitting will be accompanied by what appear to be chloride stress-corrosion cracks under the deposits (Ref 45, 46). Examples of transgranular cracks in a type 304 stainless steel tank are shown in Fig. 30.

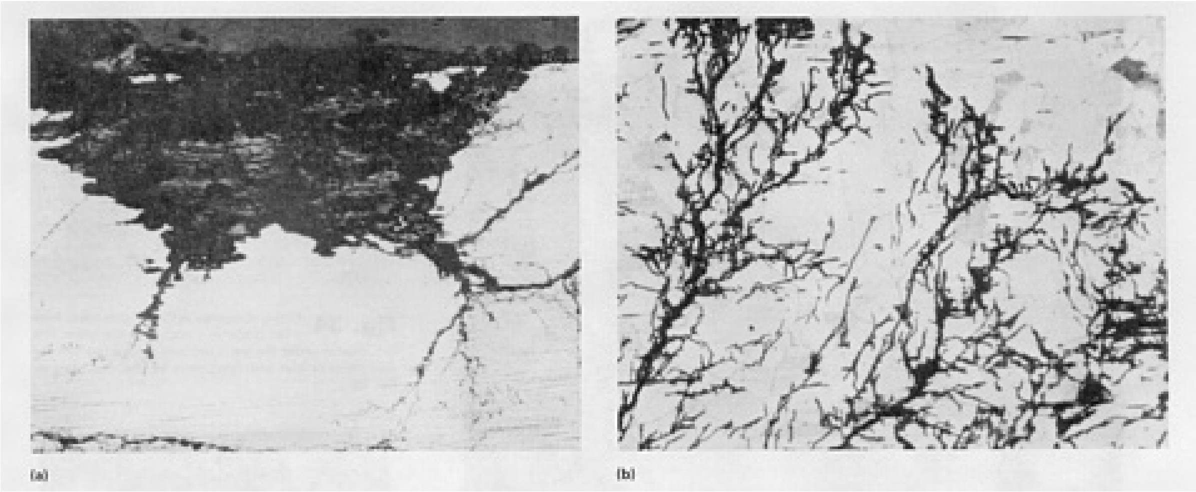

Fig. 30 Cracks emanating from pits in a type 304 stainless tank that was placed in hot demineralized water service with an operating temperature that fluctuated from 75 to 90 °C (165 to 195 °F). These branched transgranular cracks are typical of chloride stress-corrosion cracking of austenitic stainless steel. 250×. 10% oxalic acid etch. Source: Ref 51

Crevice or Gasket Conditions. A different set of conditions has lead to the localized corrosion of asbestos-gasketed flanged joints in a type 304 stainless steel piping system (Ref 52). Inspection of the system after about 3 years of service in river water revealed severe crevice corrosion in and near the flanged and gasketed joints. The corrosion sites were covered by voluminous tan-to-brown, slimy biodeposits, as shown in Fig. 31(a). Under the deposits were broad, open pits with bright, active surfaces (Fig. 31(b)). The surfaces under the gasket material and adjacent to the corroded areas were covered with black deposits, which emitted H_2S gas when treated with HCl.

Fig. 31(a) Single remaining biodeposit adjacent to resulting corrosion on a type 304 stainless steel flange. Numerous other similar deposits were dislodged in opening the joint. This flange was covered by a type 304 blind flange and was sealed with a bonded asbestos gasket. Source: Ref 52

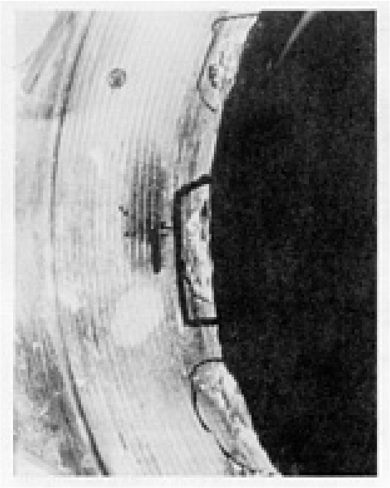

Fig. 31(b) Close-up of gouging-type corrosion under deposits shown in Fig. 31(a) after cleaning to remove black corrosion products. Source: Ref 52

The biodeposits were high in iron, silt- and slime-forming bacteria, and iron bacteria, but not chloride, manganese, and sulfur compounds. Sulfate-reducing bacteria were found only in the black deposits. These bacteria had survived continuous chlorination (0.5 to 1.0 ppm residual), caustic adjustment of pH to 6.5 to 7.5, and continuous additions of a polyacrylate dispersant and a nonoxidizing biocide (quarternary amine plus tris tributyl tin oxide) (Ref 52).

The suspected mechanism involves:

- Colonization by slime-forming bacteria at low-velocity sites near gasketed joints
- Trapping of suspended solids rich in iron by the growing biodeposit, thus creating an environment conducive to growth of the filamentous iron bacteria.
- Rapid depletion of oxygen in the crevice area by a combination of biological and electrochemical mechanisms (Ref 53), creating an environment for the SRB
- Breakdown of passivity by a combination of oxygen depletion and SRB activity, causing localized corrosion

Standard approved methods for controlling the biological corrosion of stainless alloys are currently being developed. Some general guidelines for avoiding problems in hydrotesting, however, are given in Ref 50. These guidelines are summarized as follows. First, demineralized water or high-purity steam condensate is used for the test water. The equipment should be drained and dried as soon as possible after testing. Second, if a natural freshwater must be used, it should be filtered and chlorinated, and the equipment should be blown or mopped dry within 3 to 5 days after testing.

Biological Corrosion of Aluminum

Pitting corrosion of integral wing aluminum fuel tanks in aircraft that use kerosene-base fuels has been a problem since the 1950s (Ref 54). The fuel becomes contaminated with water by vapor condensation during variable-temperature flight conditions. Attack occurs under microbial deposits in the water phase and at the fuel/water interface. The organisms grow either in continuous mats or sludges, as shown in Fig. 32, or in volcanolike tubercules with gas bubbling from the center, as shown schematically in Fig. 33.

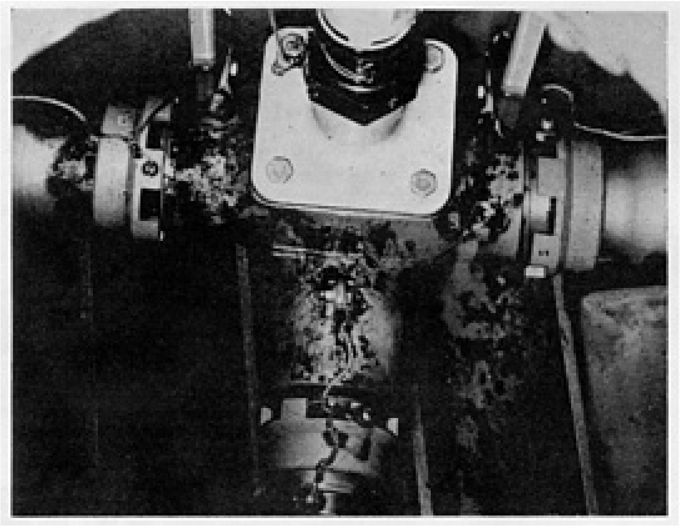

Fig. 32 Microbial growth in the integral fuel tanks of jet aircraft. Source: Ref 42

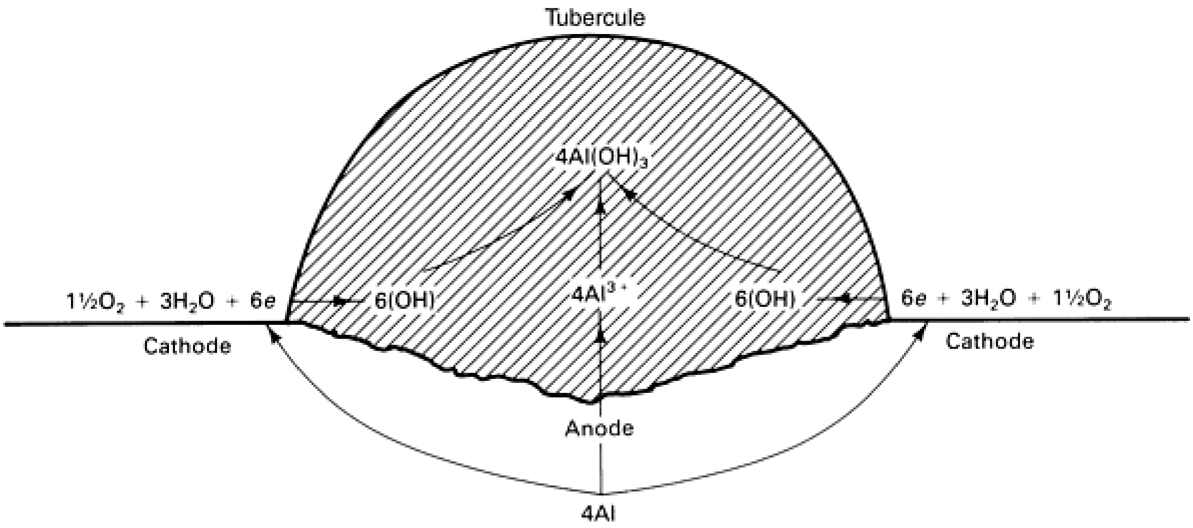

Fig. 33 Schematic of tubercule formed by bacteria on an aluminum alloy surface. Source: The Electrochemical Society

The organisms commonly held responsible are *Pseudomonas*, *Cladosporium*, and *Desulfovibrio.* These are often suspected of working together in causing the attack. *Cladosporium resinae* is usually the principal organisms involved; it produces a variety of organic acids (pH 3 to 4 or lower) and metabolizes certain fuel constituents. These organisms may also act in concert with the slime-forming *Pseudomonads* to produce oxygen concentration cells under the deposit. Active SRB have sometimes been identified at the base of such deposits.

Control of this type of attack has usually focused on a combination of reducing the water content of fuel tanks; coating, inspecting, and cleaning fuel tank interiors; and using biocides and fuel additives. More information can be found in Ref 44 and 54.

Biological Corrosion of Copper Alloys

Far less is known about the influence of micro-organisms on the corrosion of copper and copper alloys than was the case for iron and steel. The well-known toxicity of cuprous ions toward living organisms does not mean that the copper-base alloys are immune to biological effects in corrosion. It does mean, however, that only those organisms having a high

tolerance for copper are likely to have a substantial effect. *Thiobacillus thiooxidans,* for example, can withstand copper concentrations as high as 2%. Most of the reported cases of microbial corrosion of copper alloys are caused by the production of such corrosive substances as CO_2, H_2S, NH_3, and organic or inorganic acids.

Copper-nickel tubes from the fan coolers in a nuclear power plant were found to have pitting corrosion under bacterial deposits (Fig. 34). Slime-forming bacteria acting in concert with iron- and manganese-oxiding bacteria were responsible for the deposits.

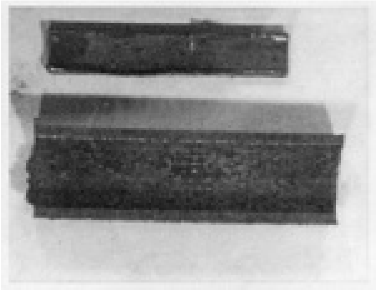

Fig. 34 Pitting corrosion in 90Cu-10Ni tubes from a fan cooler in a nuclear power plant. Pits are located under the small deposits associated with the deposition of iron and manganese by bacteria. Source: Ref 46

In another case, Monel heat-exchanger tubes were found to have severe pitting corrosion (Fig. 35) under discrete deposits rich in iron, copper, manganese, and silicon, with some nickel. Associated with the deposit were slime-forming bacteria, along with iron- and manganese-oxidizing bacteria. Several million SRB were found within each pit under the deposit. It was thought that the deposit-forming organisms created an environment conducive to growth of SRB, which then accelerated corrosion by the production of H_2S.

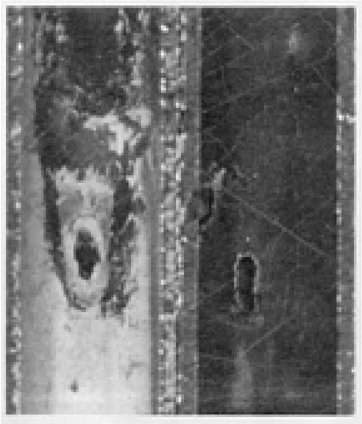

Fig. 35 Pitting corrosion in Monel tubes from a heat exchanger. Each pit was originally covered by a discrete deposit containing large numbers of SRB. Source: Ref 46

It is quite common to have bacterial slime films on the interior of copper alloy heat exchanger and condenser tubing. Usually, these films are a problem only with heat transfer as long as the organisms are living. When they die, however, organic decomposition produces sulfides, which are notoriously corrosive to copper alloys. Occasionally, NH_3-induced stress-corrosion cracking has been directly attributed to microbial NH_3 production.

Tuberculation

The formation of tubercules by biological organisms acting in conjunction with electrochemical corrosion occurs in many environments and on many alloys. An example of tuberculation in a steel economizer tube in sulfuric acid service is

shown in Fig. 36. This example shows that it is possible for tubercules to form without the presence of any microorganisms; the phenomenon usually takes place in biologically active aqueous systems.

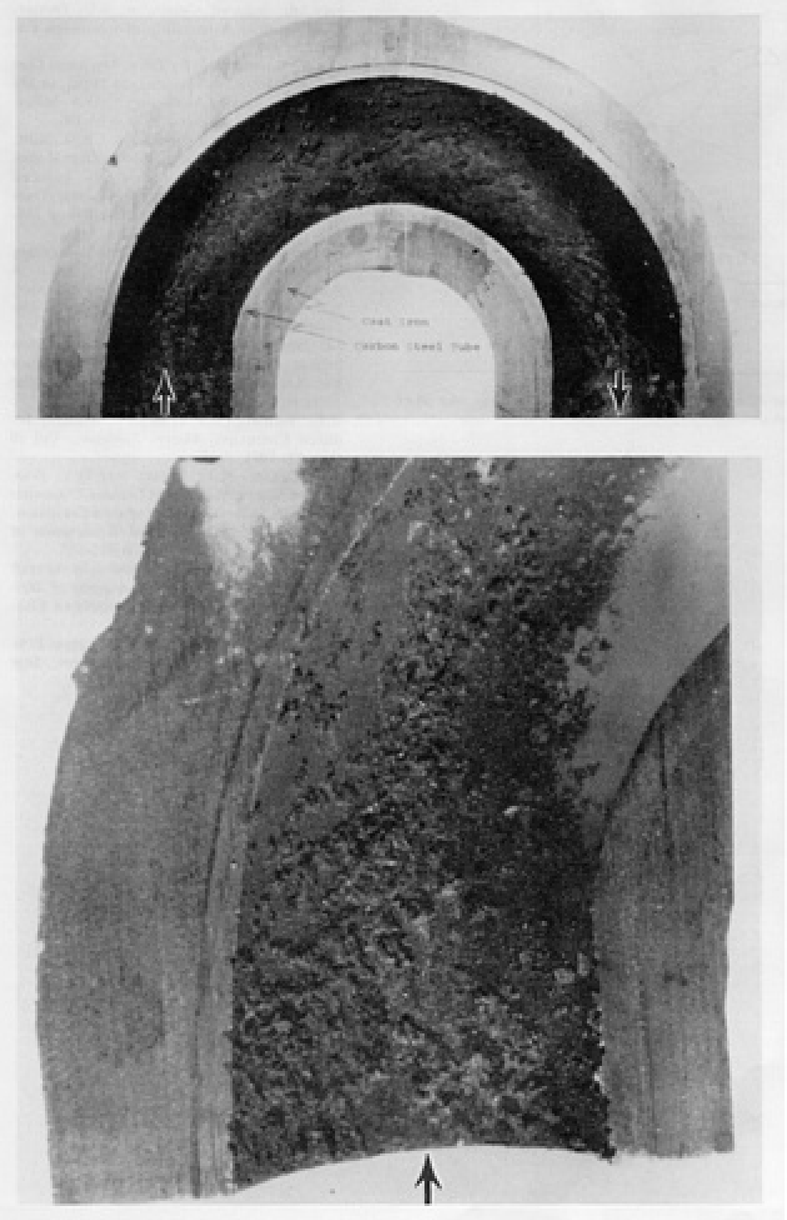

Fig. 36 Steel hairpin bend tube used in the economizer of a sulfuric acid waste heat boiler. The tube exhibits tuberculation associated with oxygen attack. The bottom photograph shows the tubercules in greater detail. Source: Ref 55

The process of tubercule formation is a complex one. A number of the reactions that can take place are illustrated for a ferrous alloy in Fig. 37. The volcanolike structure often starts with a deposit of slime-forming and iron-oxidizing bacteria at a point of low flow velocity. This creates an oxygen concentration cell, thus promoting dissolution of iron as Fe^{2+} under the deposit. As the Fe^{2+} ions move outward, they are oxidized to Fe^{3+}; this occurs electrochemically as they encounter higher oxygen concentrations and/or by the action of iron bacteria. The resulting corrosion product, $Fe(OH)_3$, mingles with the biodeposit to form the wall of the growing tubercule. When bacteria are present, the tubercule structure is usually less brittle and less easily removed from the metal surface than when they are absent. The outside of the tubercule becomes cathodic, while the metal surface inside becomes highly anodic.

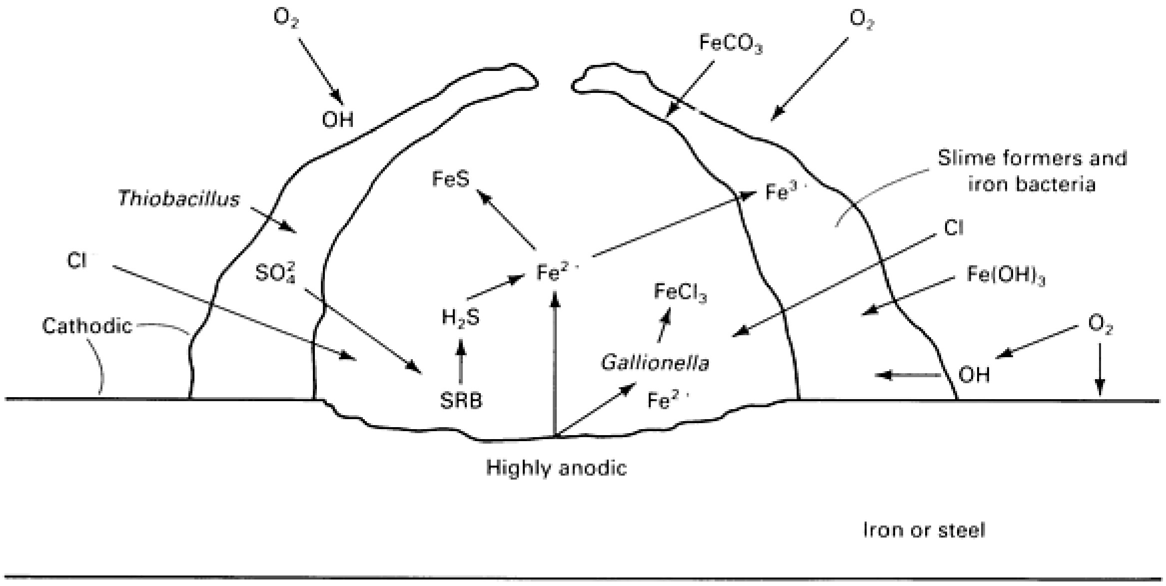

Fig. 37 Schematic diagram of electrochemical and microbial processes involved in tuberculation. Not all of these processes may be active in any given situation.

As the tubercule matures, some of the biomass may start to decompose, providing a source of sulfates for SRB to use in producing H_2S in the anaerobic interior solution. In some cases, the sulfur-oxidizing bacteria may assist in the formation of the sulfates. Depending on the ions available in the water, the tubercule structure may contain some $FeCo_3$ and, when SRB are present, some FeS. Finally, if there is a source of chlorides and if the iron-oxidizing bacteria *Gallionella* are present, a highly acidic, ferric chloride solution may form inside the tubercule.

Generally, not all of the above reactions will take place in any single environment. As the individual tubercules on a surface grow under the influence of any combination of reactions, they will eventually combine to form a mass that severely limits flow (or even closes it off altogether), leaving a severely pitted surface underneath.

Metallurgically Influenced Corrosion

Robert Steigerwald, Bechtel National, Inc.

Introduction

THE PURPOSE of this article is to discuss corrosion as affected by metallurgical factors. These factors include alloy chemistry and heat treatment. Mechanical factors such as stress will not be covered. The metallurgical influences considered are the relative stability of the components of an alloy, metallic phases, metalloid phases such as carbides, and local variations in composition in a single phase. One example is given of the ways in which nonmetallic inclusions, such as oxides and sulfides, may influence corrosion.

Dealloying, selective leaching, and parting are terms used to describe that form of corrosion in which an element is selectively removed from an alloy. This phenomenon is discussed in a separate section of this article.

Stress corrosion and hydrogen embrittlement will not be discussed. However, they will be mentioned when they are influenced by one of the mechanisms under discussion.

The most common form of metallurgically influenced corrosion is intergranular corrosion. It occurs when corrosion is localized at grain boundaries. Often, this localized corrosion leads to the dislodgement of individual grains and a roughening, or sugaring, of the affected surface. It is typified by an apparent increase in the corrosion rate with time.

Mechanisms of Intergranular Corrosion

Intergranular corrosion takes place when the corrosion rate of the grain-boundary areas of an alloy exceeds that of the grain interiors. This difference in corrosion rate is generally the result of differences in composition between the grain boundary and the interior.

The differences in corrosion rate may be caused by a number of reactions. A phase may precipitate at a grain boundary and deplete the matrix of an element that affects its corrosion resistance. A grain-boundary phase may be more reactive than the matrix. Various solute atoms may segregate to the grain boundaries and locally accelerate corrosion. The metallurgical changes that lead to intergranular corrosion are not always observable in the microstructure; therefore, corrosion tests may sometimes be the most sensitive indication of metallurgical changes (see, for example, the article "Evaluation of Intergranular Corrosion" in this Volume).

Figure 1 illustrates the electrochemistry of intergranular corrosion. Polarization curves are shown for the grain-boundary and matrix areas. The system chosen is one that exhibits active-passive behavior, for example, a chromium-nickel-iron stainless steel in sulfuric acid (H_2SO_4). Several points must be noted. The difference in corrosion rate varies with potential. The rates are close or the same in the active and transpassive ranges and vary considerably with potential in the passive range.

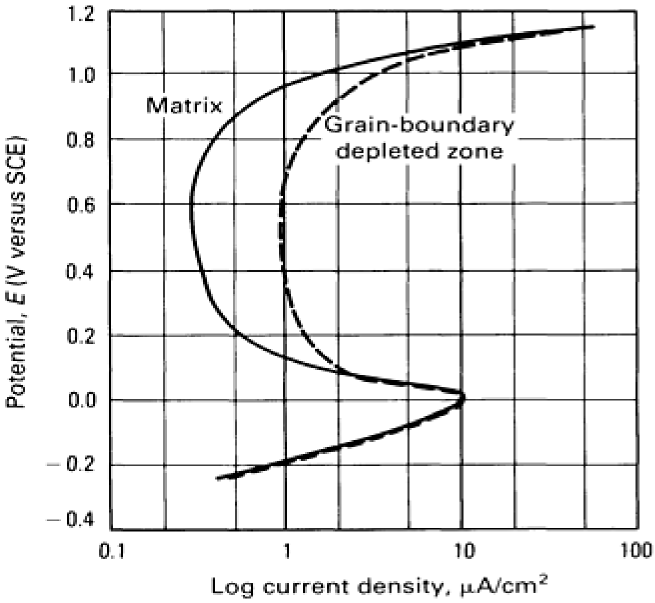

Fig. 1 Anodic polarization behavior of an active-passive alloy with grain-boundary depleted zones (schematic)

Intergranular corrosion is usually not the result of active grain boundaries and a passive matrix. The corroding surface is at one potential. Differences in composition produce different corrosion rates at the same potential in the passive region. When more than one metallic phase is present in an alloy, its polarization behavior will be the volume average sum of the behavior of each phase (Fig. 2). Active-passive surfaces are possible in this case.

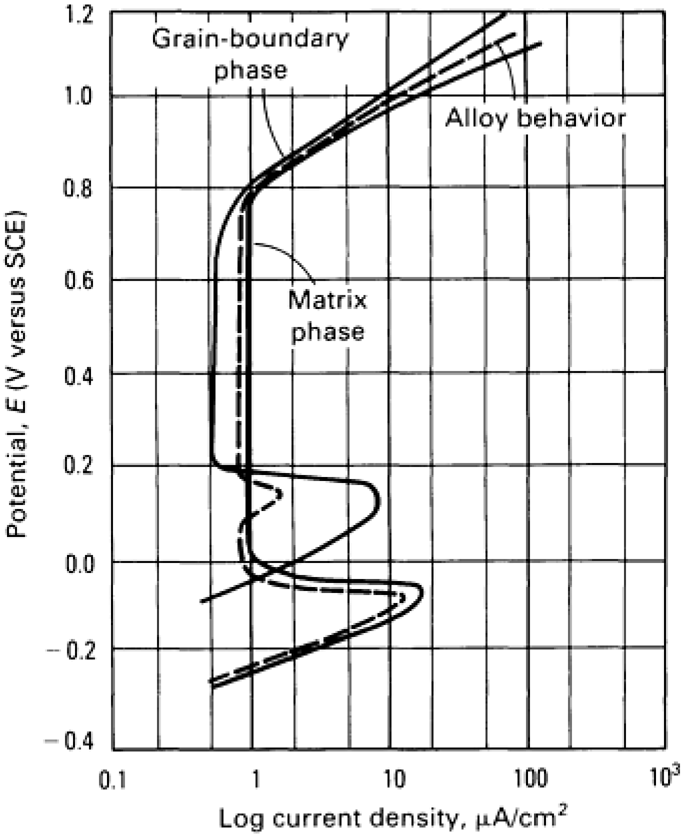

Fig. 2 Anodic polarization behavior of a two-phase active-passive alloy (schematic)

When an alloy is undergoing intergranular corrosion, its rate of weight loss will usually accelerate with time. As the grain-boundary area dissolves, the unaffected grains are undermined and fall out; this increases the weight loss. Typical weight loss versus time curves for an alloy undergoing intergranular corrosion are shown in Fig. 3.

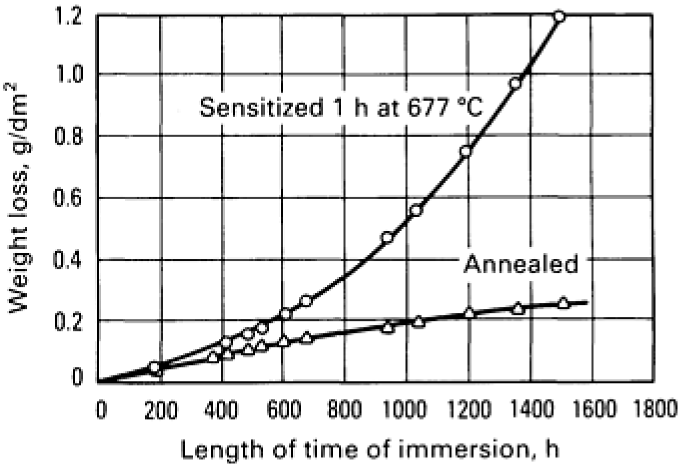

Fig. 3 Corrosion of type 304 steel in inhibited boiling 10% (H_2SO_4). Inhibitor: 0.47 g Fe^{3+}/L of solution added as $Fe_2(SO_4)_3$. Source: Ref 1

Intergranular Corrosion and Other Forms of Corrosion. Susceptibility to intergranular corrosion cannot be taken as a general indication of increased susceptibility to other forms of corrosion, such as pitting or general corrosion. The environments that cause intergranular corrosion for a particular alloy system are often very specific. Susceptibility to intergranular corrosion may mean susceptibility to intergranular stress-corrosion cracking, but some nickel-base alloys are actually more resistant to stress-corrosion cracking (SCC) when they are sensitized to intergranular corrosion (Ref 2).

Intergranular corrosion can occur in many allow systems; comprehensive coverage of all such corrosion is beyond the scope of this article. Intergranular corrosion has been most widely investigated in stainless steels, and the behavior of these alloys will be the principal example of intergranular corrosion. Intergranular attack in nickel-base and aluminum alloys will also be discussed.

Metallurgical Effects on the Corrosion of Stainless Steels

As described in the article "Corrosion of Stainless Steels" in this Volume, metallurgical variables can influence the corrosion behavior of austenitic, ferritic, duplex, and martensitic stainless steels. The distribution of carbon is probably the most important variable influencing the susceptibility of these alloys to intergranular corrosion, but nitrogen and metallic phases are also important.

Austenitic Stainless Steels

Intergranular Corrosion. At temperatures above about 1035 °C (1900 °F), chromium carbides are completely dissolved in austenitic stainless steels. However, when these steels are slowly cooled from these high temperatures or reheated into the range of 425 to 815 °C (800 to 1500 °F), chromium carbides are precipitated at the grain boundaries. These carbides contain more chromium than the matrix does.

The precipitation of the carbides depletes the matrix of chromium adjacent to the grain boundary. The diffusion rate of chromium in austenite is slow at the precipitation temperatures; therefore, the depleted zone persists, and the alloy is sensitized to intergranular corrosion. This sensitization occurs because the depleted zones have higher corrosion rates than the matrix in many environments. Figure 4 illustrates how the chromium content influences the corrosion rate of iron-chromium alloys in boiling 50% H_2SO_4 containing ferric sulfate ($Fe_2(SO_4)_3$). In all cases, the alloys are in the passive state. The wide differences in the corrosion rate are the result of the differences in the chromium content.

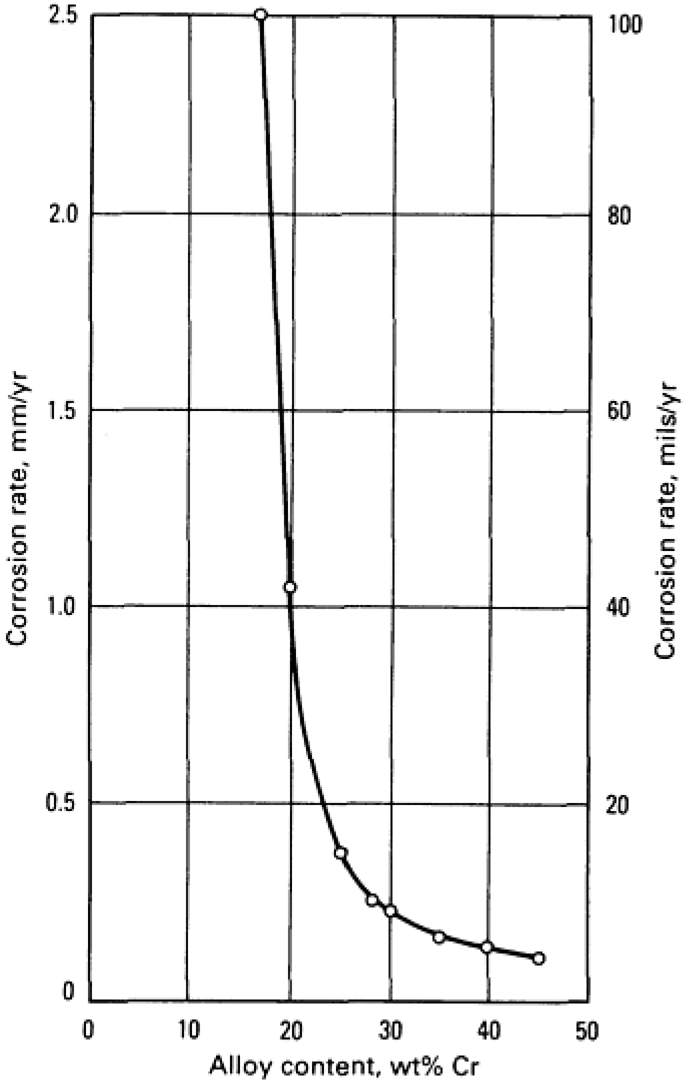

Fig. 4 The effect of chromium content on the corrosion behavior of iron-chromium alloys in boiling 50% H_2SO_4 with $Fe_2(SO_4)_3$. Source: Ref 3

If the austenitic stainless steels are cooled rapidly to below about 425 °C (800 °F), the carbides do not precipitate, and the steels are immune to intergranular corrosion. Reheating the alloys to 425 to 815 °C (800 to 1500 °F), as for stress relief, will cause carbide precipitation and sensitivity to intergranular corrosion. The maximum rate of carbide precipitation occurs at about 675 °C (1250 °F). Because this is a common temperature for the stress relief of carbon and low-alloy steels, care must be exercised in selecting stainless steels to be used in dissimilar-metal joints that are to be stress relieved.

Welding is the common cause of the sensitization of stainless steels to intergranular corrosion (see the article "Corrosion of Weldments" in this Volume). Although the cooling rates in the weld itself and the base metal immediately adjacent to it are sufficiently high to avoid carbide precipitation, the weld thermal cycle will bring part of the heat-affected zone (HAZ) into the precipitation range. Carbides will precipitate, and a zone somewhat removed from the weld will become susceptible to intergranular corrosion (Fig. 5). Welding does not always sensitize austenitic stainless steels. In thin sections, the thermal cycle may be such that no part of the HAZ is at sensitizing temperatures long enough to cause carbide precipitation. Once the precipitation has occurred, it can be removed by reheating the alloy to above 1035 °C (1895 °F) and cooling it rapidly.

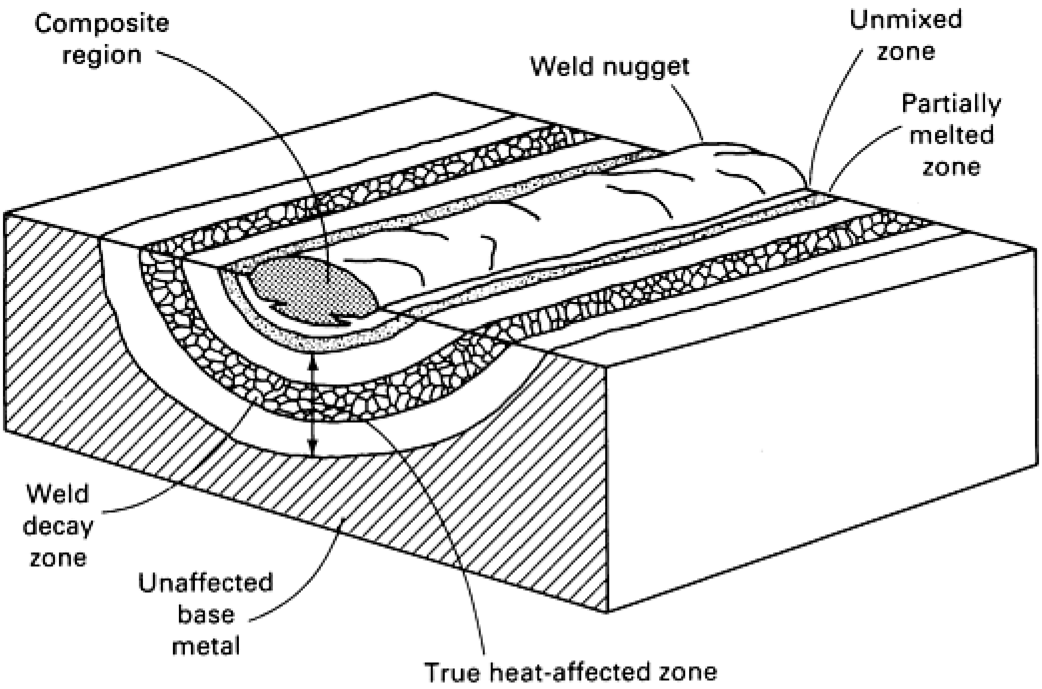

Fig. 5 Schematic diagram of components of weldment in austenitic stainless steel. Source: Ref 4

Avoiding Intergranular Corrosion. Susceptibility to intergranular corrosion in austenitic stainless steels can be avoided by controlling their carbon contents or by adding elements whose carbides are more stable than those of chromium. For most austenitic stainless steels, restricting their carbon contents to 0.03% or less will prevent sensitization during welding and most heat treatment. This method is not effective for eliminating sensitization that would result from long-term service exposure at 425 to 815 °C (800 to 1500 °F).

Titanium and niobium form more stable carbides than chromium and are added to stainless steels to form these stable carbides, which remove carbon from solid solution and prevent precipitation of chromium carbides. The most common of these stabilized grades are types 321 and 347. Type 321 contains a minimum of 5 × C + N % titanium, and type 347 a minimum of 8 × C % niobium. Nitrogen must be considered when titanium is used as a stabilizer, not because the precipitation of chromium nitride is a problem in austenitic steels, but because titanium nitride is very stable. Titanium will combine with any available nitrogen; therefore, this reaction must be considered when determining the total amount of titanium required to combine with the carbon.

The stabilized grades are more resistant to sensitization by long-term exposure at 425 to 815 °C (800 to 1500 °F) than the low-carbon grades are, and the stabilized grades are the preferred materials when service involves exposure at these temperatures. For maximum resistance to intergranular corrosion, these grades are given a stabilizing heat treatment at about 900 °C (1650 °F). The purpose of the treatment is to remove carbon from solution at temperatures where titanium and niobium carbides are stable but chromium carbides are not. Such treatments prevent the formation of chromium carbide when the steel is exposed to lower temperatures.

Figure 6 illustrates how both carbon control and stabilization can eliminate intergranular corrosion in as-welded austenitic stainless steels. It also shows that the sensitized zone in these steels is somewhat removed from the weld metal.

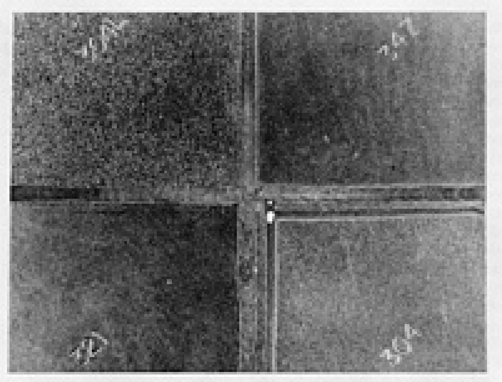

Fig. 6 Weld decay and methods for its prevention. The four different panels were joined by welding and then exposed to a hot solution of HNO_3/HF. Weld decay, such as that shown in the type 304 steel (bottom right), is prevented by reduction of the carbon content (type 304L, top left) or by stabilization with titanium (type 321, bottom left) or niobium (type 347, top right). Source Ref 1

Knife-Line Attack. Stabilized austenitic stainless steels may become susceptible to a localized form of intergranular corrosion known as knife-line attack or knife-line corrosion. During welding, the base metal immediately adjacent to the fusion line is heated to temperatures high enough to dissolve the stabilizing carbides, but the cooling rate is rapid enough to prevent carbide precipitation. Subsequent welding passes reheat this narrow area into the temperature range in which both the stabilizing carbide and the chromium carbide can precipitate. The precipitation of chromium carbide leaves the narrow band adjacent to the fusion line susceptible to intergranular corrosion.

Knife-line attack can be avoided by the proper choice of welding variables and by the use of stabilizing heat treatments. Additional information on knife-line attack can be found in the article "Corrosion of Weldments" in this Volume.

Testing for Intergranular Corrosion. Although testing for intergranular corrosion is discussed in the article "Evaluation of Intergranular Corrosion" in this Volume, a brief discussion is included here. The common methods of testing austenitic stainless steels for susceptibility to intergranular corrosion are described in ASTM A 262 (Ref 5). There are five acid immersion tests and one etching test. The oxalic acid etch test is used to screen samples to determine the need for further testing. Samples that have acceptable microstructures are considered to be insusceptible to intergranular corrosion and require no further testing. Samples with microstructures indicative of carbide precipitation must be subjected to one of the immersion tests.

Several electrochemical tests based on the polarization behavior of susceptible and insusceptible stainless steels have been proposed (Ref 6, 7). Although the tests have received considerable attention, none has yet been adopted in a national standard.

Intergranular Stress-Corrosion Cracking. Austenitic stainless steels that are susceptible to intergranular corrosion are also subject to intergranular SCC. The problem of the intergranular SCC of sensitized austenitic stainless steels in boiling high-purity water containing oxygen has received a great deal of study. This seemingly benign environment has led to cracking of sensitized stainless steels in many boiling water reactors, as described in the article "Corrosion in the Nuclear Power Industry" in this Volume.

Sensitized stainless alloys of all types crack very rapidly in the polythionic acid that forms during the shutdown of desulfurization units in petroleum refineries (Ref 8, 9). Because this service involves long-term exposure of sensitizing temperatures, the stabilized grades should be used. More detailed information can be found in the article "Corrosion in Petroleum Refining and Petrochemical Operations" in this Volume.

Effect of Ferrite and Martensite. Phases other than carbides can also influence the corrosion behavior of austenitic stainless steels. Ferrite, which is the result of an unbalanced composition, appears to reduce the pitting resistance of the steels. The presence of martensite may render the steels susceptible to hydrogen embrittlement under some conditions. The martensite can be produced by the deformation of unstable austenite. Although this phenomenon can occur in a

number of commercial stainless steels, it is most common in the lower-nickel steels such as type 301, in which the transformation is used to increase formability.

Effect of Sigma Phase. The effect of σ phase on the corrosion behavior of austenitic stainless steel has received considerable attention. This hard, brittle intermetallic phase precipitates in the same temperature range as chromium carbide and may produce susceptibility to intergranular corrosion in some environments.

Because it is hard and brittle, σ affects, mechanical as well as corrosion properties. Although it is often associated with δ-ferrite, it can form directly from austenite.

The effects of σ phase on the corrosion behavior of austenitic stainless steels are most serious in highly oxidizing environments. The problem is of practical concern only if the phase is continuous. Although discrete particles of σ phase may be attacked directly, such corrosion does not seem to contribute significantly to the penetration of the steel.

The most important corrosion problem with σ phase in austenitic stainless steels occurs before it is microscopically resolved (Ref 10). When the low-carbon molybdenum-containing austenitic stainless steels (such as type 316L and CF3M) or the stabilized grades (such as type 321 and type 347) are exposed at 675 °C (1245 °F), they may become susceptible to intergranular corrosion in nitric acid (HNO_3) and, in some cases, $Fe_2(SO_4)_3$-H_2SO_4. This susceptibility cannot be explained by carbide precipitation, and σ phase usually cannot be found in the optical microstructure. However, because some of the susceptible steels do exhibit continuous networks of σ phase, it has been assumed that this constituent is the cause of the intergranular corrosion. The hypothesis is that even when σ phase is not visible in the optical microstructure its effects are felt through some precursor or invisible phase. Invisible σ phase must be considered when testing for susceptibility to intergranular corrosion, but it seems to affect corrosion resistance only in very oxidizing environments, such as HNO_3.

Unsensitized austenitic stainless steels (that is, solution-annealed material containing no carbides or other deleterious phases) are subject to intergranular corrosion in very highly oxidizing environments, such as HNO_3 containing hexavalent chromium (Ref 11). None of the regularly controlled metallurgical variables influences this type of intergranular attack. Additional information on, and micrographs of, σ phase in austenitic stainless steels can be found in the article "Wrought Stainless Steels" in *Metallography and Microstructures,* Volume 9 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Ferritic Stainless Steels

Intergranular Corrosion. The mechanism for intergranular corrosion in ferritic stainless steels is largely accepted as being the same as that in austenitic stainless steels. Chromium compounds precipitate at grain boundaries, and this causes chromium depletion in the grains immediately adjacent to the boundaries (Ref 12, 13). This lowering of the chromium content leads to increased corrosion rates in the oxidizing solutions usually used to evaluate intergranular corrosion.

There are several differences between the sensitization of ferritic and austenitic stainless steels to intergranular corrosion. The first is that the solubility of nitrogen in austenite is great enough that chromium nitride precipitation is not a significant cause of intergranular corrosion in austenitic steels. It is, however, a significant cause in ferritic stainless steels. The second is the temperature at which it occurs. Sensitization in austenitic steels is produced by heating between 425 and 815 °C (800 and 1500 °F). In conventional ferritic alloys, sensitization is caused by heating above 925 °C (1700 °F). This difference is the result of the relative solubilities of carbon and nitrogen in ferrite and austenite. Because the sensitization temperatures are different for austenitic and ferritic steels, it is not surprising that the welding of susceptible steels produces different zones of intergranular corrosion. In austenitic steels, intergranular corrosion occurs at some distance from the weld, where the peak temperature reached during welding is approximately 675 °C (1250 °F). Because the sensitization of ferritic stainless steels occurs at higher temperatures, the fusion zone and the weld itself are the most likely areas for intergranular corrosion. Detailed information on sensitization and corrosion of ferritic stainless steels welds is available in the article "Corrosion of Weldments" in this Volume.

The mere presence of chromium carbides and nitrides in ferritic stainless steels does not ensure that they will be subject to intergranular corrosion. On the contrary, the usual annealing treatment for conventional ferritic stainless steels is one that precipitates the carbides and nitrides at temperatures (700 to 925 °C, or 1300 to 1700 °F) at which the chromium can diffuse back into the depleted zones. These same treatments would of course sensitize austenitic stainless steels because of the much slower rate of diffusion of chromium in austenite.

Avoiding Intergranular Corrosion. Clearly, the most straightforward method of preventing intergranular attack in ferritic stainless steels is to restrict their interstitial contents. The results shown in Table 1 give an indication of the levels of carbon and nitrogen required to avoid intergranular corrosion of iron-chromium-molybdenum alloys in boiling 16% H_2SO_4-copper-copper sulfate ($CuSO_4$) solutions. Evaluation was by bending. The samples that passed had no cracks.

Table 1 Results of ASTM A 763, Practice Z, on representative as-welded ferritic stainless steels

Welds were made using the gas tungsten arc welding technique with no filler metal added.

Alloy	Interstitial content, wt%		Result
	C	**N**	
18Cr-2Mo	0.002	0.004	Pass
	0.010	0.004	Fail
	0.002	0.009	Fail
26Cr-1Mo	0.002	0.005	Pass
	0.004	0.010	Partial failure
	0.003	0.016	Fail
	0.013	0.006	Fail

For 18Cr-2Mo alloys to be immune to intergranular corrosion, it appears that the maximum level of carbon plus nitrogen is 60 to 80 ppm; for 26Cr-1Mo steels, this level rises to around 150 ppm. The notation of partial failure for the 26Cr-1Mo steel containing 0.004% C and 0.010% N indicates that only a few grain boundaries opened upon bending and that it probably represents the limiting composition. Using the 50% H_2SO_4-$Fe(SO_4)_3$ test, it was determined that the interstitial limits for the 29Cr-4Mo steel were 0.010% C (max) and 0.020% N (max), with the additional restriction that the combined total not exceed 250 ppm (Ref 13). As their alloy contents increase, the iron-chromium-molybdenum steels seem to grow more tolerant of interstitials with regard to intergranular corrosion.

The levels of carbon and nitrogen that are needed to keep 18Cr-Mo alloys free of intergranular corrosion are such that very low interstitial versions of 18% Cr alloys have received little commercial attention. The 26Cr-1Mo and 29Cr-4Mo steels have been made in considerable quantity with very low interstitials, for example, 20 ppm C and 100 ppm N.

The low-interstitial ferritic stainless steels respond to heat treatment in a manner somewhat similar to that of austenitic stainless steels. As the results of welding in Table 1 show, rapid cooling from high temperature will preserve resistance to intergranular corrosion. However, depending on alloy content and interstitial levels, these alloys may be sensitive to a cooling rate from temperatures above about 600 °C (1110 °F) (Ref 2, 15). Less pure iron-chromium-molybdenum alloys can also be affected by a cooling rate from around 800 °C (1470 °F), but at higher temperatures, it is impossible to quench them fast enough to avoid intergranular attack.

Isothermal heat treatments can also produce sensitivity to intergranular corrosion in low-interstitial ferritic stainless steels (Ref 16). For example, the effects of annealing at 620 °C (1150 °F) on the intergranular corrosion of 26% Cr alloys with 0 to 3% Mo were studied (Ref 17). The alloys contained 0.007 to 0.013% C and 0.020 to 0.024% N. As little as 10 min at

temperature can lead to intergranular corrosion; however, continuing the treatment for 1 to 2 h can cure the damage (Table 2). Increasing the molybdenum content delays the onset of sensitization and makes it less severe. It does, however, delay recovery.

Table 2 Corrosion rates of 26% Cr ferritic stainless steels containing 0 to 3% Mo that were annealed for 15 min at 900 °C (1650 °F), water quenched, annealed for increasing times at 620 °C (1150 °F), then water quenched

Testing was performed according to recommendations in ASTM A 763, Practice X (ferric sulfate-sulfuric acid test).

Alloy	Corrosion rate, $mg/dm^2/d$						
	900-°C (1650-°F) anneal	**Annealing time at 620 °C (1150 °F)**					
		10 min	**30 min**	**1 h**	**2 h**	**4 h**	**5 h**
26-0	50	15,700	270	62	81	85	43
		15,600	264	50	67	85	43
26-1	43	5950[(a)]	8030[(a)]	990	50	40	53
	37	8220[(a)]	12,400[(a)]	890	50	37	50
26-2	78	15,600	940	138	80	74	270
	77	15,500	500	132	80	70	226
26-3	50	104	214	258	98	102	58
	50	95	160	96	93	97	58

(a) 56 h in test solution.

The very low levels of interstitials needed to ensure that ferritic stainless steels are immune to intergranular corrosion suggest that stabilizing elements might offer a means of preventing this type of corrosion without such restrictive limits on the carbon and nitrogen. Both titanium and niobium can be used, and each has its advantages (Ref 18). In general, weld ductility is somewhat better in the titanium-containing alloys, but the toughness of the niobium steels is better. As noted above, titanium-stabilized alloys are not recommended for service in HNO_3, but the niobium-containing steels can be used in this environment. Additional information on materials selection for HNO_3 environments is available in the section "Corrosion by Nitric Acid" in the article "Corrosion in the Chemical Processing Industry" in this Volume.

Table 3 shows the results of Cu-$CuSO_4$-16% H_2SO_4 tests on 26Cr-1Mo and 18Cr-2Mo steels with additions of either titanium or niobium. Inspection of the data suggests that the required amount of titanium cannot be described by a simple ratio as it is in austenitic steels. The amount of titanium or niobium required for ferritic stainless steels to be immune to intergranular corrosion in the $CuSO_4$-16% H_2SO_4 test has been investigated (Ref 19). It has been determined that for 26Cr-1Mo and 18Cr-2Mo alloys, the minimum stabilizer is given by:

$$Ti + Nb = 0.2 + 4 (C + N) \quad \textbf{(Eq 1)}$$

According to Ref 19, these limits are valid for combined carbon and nitrogen contents in the range of 0.02 to 0.05%. It should be emphasized that the limits set in Eq 1 are truly minimal and are needed in the final product if intergranular attack is to be avoided.

Table 3 Results of ASTM A 763, Practice Z, tests on as-welded ferritic stainless steels with titanium or niobium

Welds were made using gas tungsten arc welding with no filler metal added.

Alloy	(C + N), wt%	Ti, wt%	Nb, wt%	Ti or Nb/(C + N), %	Result
18Cr-2Mo	0.022	0.16	. . .	7.3	Fail
	0.028	0.19	. . .	6.8	Fail
	0.027	0.23	. . .	8.5	Pass
	0.057	0.37	. . .	6.5	Pass
	0.079	0.47	. . .	5.9	Pass
18Cr-2Mo	0.067	. . .	0.32	4.8	Fail
	0.067	. . .	0.61	9.1	Pass
	0.030	. . .	0.19	6.3	Pass
26Cr-1Mo	0.026	0.17	. . .	6.5	Fail
	0.026	0.22	. . .	8.5	Fail
	0.026	0.26	. . .	10.0	Pass
26Cr-1Mo	0.026	. . .	0.17	6.5	Fail
	0.025	. . .	0.33	13.2	Pass

This guideline is empirical and cannot be explained on the basis of stoichiometry. The alloys in the study (Ref 19) were fully deoxidized with aluminum before the stabilizing additions were made. Therefore, it is unlikely that the excess stabilizer is required because it reacts with oxygen.

The susceptibility of titanium-stabilized steels to intergranular attack in HNO_3 has been noted earlier. Because there is evidence that titanium carbide can be directly attacked by HNO_3, this mechanism is usually used to explain intergranular corrosion in titanium-containing steels. Another explanation that could be advanced about the intergranular attack of titanium-bearing steels under highly oxidizing conditions is an invisible σ phase such as that encountered in type 316L and discussed above.

Testing for Intergranular Corrosion. Standardized test methods for detecting the susceptibility of ferritic stainless steels to intergranular corrosion are described in ASTM A 763 (Ref 20). The methods are similar to those described in A 262 (Ref 5) for austenitic stainless in that there is an oxalic acid etch test and three acid immersion tests. The principal difference between the two standards is the introduction of microscopic examination of samples exposed to the boiling acid solutions. The presence or absence of grain dropping becomes the acceptance criterion for these samples.

Effects of Austenite and Martensite. The austenitic and martensitic phases are discussed together for ferritic stainless steels because they are interrelated; one can occur as the result of the other.

High-purity iron-chromium alloys are ferritic at all temperatures up to the melting point if they contain more than about 12% Cr. However, the γ loop in iron-chromium alloys can be greatly expanded by the addition of carbon and nitrogen. For example, it was found that the ferrite-austenite boundary was extended to 29% Cr in alloys that contained 0.05% C and 0.25% N (Ref 21).

Although the formation of austenite in ferritic stainless steels can be avoided by restricting their interstitial contents or by combining the interstitials with such elements as titanium or niobium, many of the ferritic stainless steels that are produced commercially will undergo partial transformation to austenite. Once the austenite is formed, the question is then what it will transform into. In one study, for example, the transformation products were dependent on the chromium content and the cooling rate (Ref 22). Slow cooling leads to the transformation of austenite into ferrite and carbides in all of the steels examined, but quenching can either produce martensite or retain the austenite.

In addition, the martensite start (M_s) temperature for a 17% Cr steel was measured at 176 °C (349 °F), and it was found that the transformation was 90% complete at 93 °C (199 °F) (Ref 22). The M_s for a 21% Cr steel was -160 °C) (-255 °F), and martensite did not form in quenched 25% Cr alloys. Untempered martensite obviously reduces the toughness and ductility of ferritic stainless steels, and its presence is one cause of the poor ductility of welded type 430. In discussing this work (Ref 22), other researchers observed that welded type 430 (17% Cr) had poor ductility but that welded type 442 (21% Cr) had good ductility (Ref 23). These findings were attributed to the transformation of austenite to martensite in the lower-chromium steel but not in the 21% Cr steel. Both weldments were subject to intergranular corrosion, however.

The austenite retained in the higher-chromium steels is saturated with carbon, and when it is heated into the carbide precipitation region to, for example, 760 °C (1400 °F), it loses carbon and becomes unstable enough to transform to martensite upon cooling. This transformation product must then be tempered to restore ductility.

Another study found that martensite in type 430 corroded at a higher rate than the surrounding ferrite in boiling 50% H_2SO_4 + $Fe_2(SO_4)$ (Ref 13). This difference was attributed to the partitioning of chromium between ferrite and austenite at high temperatures. Because the austenite is lower in chromium, the martensite that forms from it would also be lower in chromium. The 50% H_2SO_4-$Fe_2(SO_4)$ test is quite sensitive to changes in chromium content in the 12 to 18% Cr range (Fig. 4). The test is less sensitive at higher chromium contents; therefore, no preferential attack was noted in austenite formed in type 446. This same austenite was preferentially attacked by boiling 5% H_2SO_4, presumably because of its higher interstitial content.

These corrosion experiments help to elucidate the effect of metallurgical factors on the corrosion behavior of ferritic stainless steels. However, these experiments describe situations rarely encountered in practice, because the mechanical properties of steels with such microstructures limit their usefulness.

Effect of Sigma and Related Phases. In contrast to the case of austenitic steels, the occurrence of σ phase in most commercial ferritic stainless steels can be predicted from the iron-chromium phase diagram. Fortunately, the kinetics of σ formation are very sluggish, and σ phase is not normally encountered in the processing of commercial ferritic stainless steels.

The formation of σ phase in the Fe-Cr system has been thoroughly researched, and the literature has been well summarized (Ref 24). The phase has the nominal composition of FeCr, but it can dissolve about 5% of either iron or

chromium. It forms congruently from ferrite at 815 °C (1500 °F). The sluggishness of the reaction makes it difficult to define the low-temperature limits of the σ-phase field, but the ferrite/ferrite + σ phase boundary has been estimated at 9.5% Cr at 480 °C (895 °F) (Ref 24). Cold work accelerates the precipitation of σ phase.

There is relatively little information on how σ phase affects the corrosion behavior of ferritic stainless steels; however, continuous networks would be expected to be more troublesome than isolated colonies. Because σ phase contains more chromium than ferrite, its presence could also affect the corrosion behavior by either local or general depletion of the chromium content of the matrix.

One study investigated the corrosion behavior of an Fe-47Cr alloy that was heat treated so that it was either entirely ferrite or entirely σ phase (Ref 25). These data are shown in Table 4. The types of environments studied induced reducing (active), oxidizing (passive), and pitting corrosion conditions. The differences were greatest in the oxidizing and pitting environments. These results indicate that σ phase is more likely to corrode than ferrite in many instances and that no chromium depletion mechanism need be invoked to explain how σ phase can reduce the corrosion resistance.

Table 4 The effect of crystal structure on the corrosion behavior of an Fe-47Cr alloy

Solution	Corrosion rate, $g/dm^2/d$		
	Ferrite	**σ phase**	**Ratio[(a)]**
Reducing			
10% HCl boiling	1461	7543	5.2
10% H_2SO_4 boiling	2939	7422	2.5
50% H_2SO_4 boiling	5088	5280	1.04
Oxidizing			
50% H_2SO_4 + $Fe_2(SO_4)_3$ boiling	0.0195	0.196	10
50% H_2SO_4 + $CuSO_4$ boiling	0.0170	0.415	24
65% HNO_3 boiling	0.0205	0.861	42
HNO_3 + HF at 65 °C (150 °F)	0.00	0.06	. . .
Pitting

Source: Ref 25

(a) Corrosion rate of σ phase ÷ corrosion rate of ferrite.

In molybdenum-containing ferritic steels, χ phase, which is closely related to σ phase, can be found (Ref 26). It occurs in the temperature range of 550 to 950 °C (1020 to 1740 °F). It has the nominal composition Fe_2CrMo, but there are deviations from stoichiometry. In an investigation of the effect of heat treatment on the microstructure of 29Cr-4Mo alloys, both χ and σ phases were found in material held in the 700- to 925-°C (1290- to 1695-°F) range (Ref 27). Long-term aging of the 29Cr-4Mo steel did not render it susceptible to intergranular corrosion in the boiling 50% H_2SO_4 + $Fe_2(SO_4)_3$ solution.

This work also included 29Cr-4Mo-2Ni alloys, and χ and σ phases were seen to form much more quickly in these steels than in nickel-free materials. This observation is consistent with earlier results that nickel additions up to about 2% can accelerate the formation of σ phase in iron-chromium alloys (Ref 28). At higher levels, nickel decreases the rate of σ-phase precipitation. Sigma and χ reduce the ductility of the 29Cr-4Mo-2Ni alloys, but do not cause it to undergo intergranular corrosion. However, long-term aging at 815 °C (1500 °F) did render them susceptible to crevice corrosion in 10% hydrated ferric chloride ($FeCl_3 \cdot 6H_2O$) at 50 °C (120 °F). In this case, the ferrite was preferentially attacked--perhaps because it was depleted in chromium and molybdenum by precipitation of the second phase.

There is some evidence that the invisible χ or σ phase may affect the properties of stabilized 18Cr-2Mo ferritic stainless steels aged at approximately 620 °C (1150 °F). For example, it was shown that aging for even relatively short times could produce extensive intergranular corrosion in 18Cr-2Mo-Ti steels exposed to boiling 50% H_2SO_4 + $Fe_2(SO_4)_3$ (Ref 29). The steels were not subject to intergranular attack in 10% HNO_3 + 3% hydrofluoric acid (HF) or in boiling 16% H_2SO_4 + 6% $CuSO_4$ + Cu, and both of these solutions are known to produce intergranular attack in improperly stabilized ferritic stainless steels. Similar behavior has been noted in niobium-stabilized 18Cr-2Mo steels (Ref 30). In neither case was χ or σ phase clearly present at the grain boundaries.

Duplex Stainless Steels

Duplex stainless steels are those that are composed of a mixture of austenite and ferrite. The common cast stainless steels, such as CF-8 and CF-8M, are mostly austenite with some ferrite. These alloys are often considered to be simple analogs of wrought alloys with similar compositions; however, they do not always have the same response to heat treatment. The corrosion evaluation of these alloys deserves further study. Additional information on cast duplex stainless steels can be found in the article "Corrosion of Cast Steels" in this Volume.

Wrought duplex stainless steel may have either a ferrite matrix (type 329) or an austenitic matrix (U50). The most recent duplex alloys, such as 2205, are approximately 50:50 mixtures. The modern alloys are produced with low carbon contents, usually less than 0.03%, and intergranular corrosion resulting from carbide precipitation generally has not been a practical problem.

These alloys are usually high in chromium (25 to 27%) and molybdenum (2 to 4%). As a result, these alloys are prone to the formation of intermetallic phases such as σ and χ if they are not cooled rapidly through the 900- to 700-°C (1650- to 1290-°F) range (Ref 31). Although these intermetallic compounds do affect the corrosion resistance of the alloys, they have a more drastic effect on the mechanical properties. If a duplex alloy has satisfactory mechanical properties, it probably will not experience intergranular corrosion. In both wrought and cast alloys, it appears that the high rate of diffusion of chromium in the ferrite generally minimizes depleted zones and, therefore, intergranular corrosion.

Metallurgical Effects on the Corrosion of High-Nickel Alloys

The metallurgy of high-nickel corrosion-resistant alloys is more complicated than that of the iron-chromium-nickel and iron-chromium-nickel-molybdenum austenitic stainless steels. As the nickel content rises, carbon becomes less soluble in the matrix. In austenitic stainless steels, carbides usually precipitate as $M_{23}C_6$, where M is principally chromium. This form of carbide can also be found in sensitized high-nickel alloys, but M_3C_7 and M_6C carbides are also found. Molybdenum may be a constituent in these carbides.

Whether or not these carbides damage the corrosion resistance of these alloys depends on the temperature at which they precipitate. Continuous grain-boundary precipitates are likely to produce depleted zones that will lead to susceptibility to intergranular corrosion. Isolated carbides that persist from high temperatures will not affect corrosion behavior.

Various intermetallic phases, such as σ; Laves (or η), for example, Fe_2Mo; and $(Ni,Cr)_7Mo_6$, can also form in these alloys and affect their corrosion performance. These intermetallic phases are often the major cause of intergranular corrosion in nickel-base alloys.

The intergranular corrosion behavior of high-nickel alloys was reviewed in considerable detail (Ref 32, 33). Isothermal heat treatments produced susceptibility to intergranular corrosion in all the alloys examined in these studies.

It is clear that keeping the carbon as low as possible is beneficial to the resistance of these alloys to intergranular corrosion. Alloying additions of titanium and niobium are also beneficial, although they do not produce stabilized alloys in the same sense that stainless steels are stabilized. In other words, no simple ratio of Ti, Nb to C can be given that will make a particular alloy immune to intergranular corrosion.

Fortunately, the problems produced by the isothermal heat treatment experiments are not usually manifested in welding. When welded by qualified procedures, most modern high-nickel alloys are resistant to intergranular corrosion. Additional information on the corrosion of nickel alloys and nickel alloy weldments can be found in the articles "Corrosion of Nickel-Base Alloys" and "Corrosion of Weldments," respectively, in this Volume.

Metallurgical Effects on the Corrosion of Aluminum Alloys

Intergranular corrosion in aluminum alloys can be the result of the direct attack of a precipitate that is less corrosion resistant (more active) than the matrix or the attack of a denuded zone adjacent to a noble phase.

Aluminum-magnesium alloys that contain more than 3% Mg (for example, 5083) may become susceptible to intergranular corrosion because of the preferential attack of Mg_2Al_8. In aluminum-magnesium-zinc alloys such as 7030, the compound $MgZn_2$ is attacked (Ref 34).

In aluminum-copper alloys such as 2024, $CuAl_2$ precipitates, which is more noble than the matrix. It appears to act as a cathode in accelerating the corrosion of a depleted zone adjacent to the grain boundary. A similar phenomenon seems to occur in aluminum-zinc magnesium-copper alloys such as 7075 (Ref 34).

Although the aluminum alloys are more resistant to intergranular corrosion in the solution-treated condition, avoiding precipitates is not a practical means of avoiding intergranular corrosion in these systems. The precipitates are important for the strengthening of the alloys and are necessary for their performance. Whether or not the alloy will be subject to intergranular corrosion in a particular environment is an important part of the alloy selection process.

Exfoliation is a form of intergranular corrosion that may occur when aluminum alloys have their grains elongated in layers parallel to their surfaces. Intergranular corrosion can occur on the elongated grain boundaries. The corrosion product that forms has a greater volume than the volume of the parent metal. The increased volume forces the layers apart, and strips of metal exfoliate (delaminate). Additional information on the exfoliation and intergranular corrosion of aluminum alloys can be found in the articles "Corrosion of Aluminum and Aluminum Alloys" and "Evaluation of Exfoliation Corrosion" in this Volume.

Grooving Corrosion in Carbon Steel

When electric resistance welded (ERW) carbon steel pipe is exposed to aggressive waters, preferential corrosion, or grooving corrosion, of the weld is sometimes observed (Ref 35). This localized corrosion appears to be caused by the redistribution of sulfide inclusions along the weld line during the welding process.

It has been suggested that the welding process concentrates manganese sulfides in the weld and that the metal flow during the upset portion of the welding preferentially exposes the inclusions to the corrodent (Ref 35). The high temperatures in welding also break down the manganese sulfides, and this leads to the local enrichment of the matrix in sulfur or to the formation of iron sulfide. Whether the redistribution of the sulfides makes the weld metal less corrosion resistant than the base metal or whether it makes the environment locally more corrosive is not clear. However, the weld metal is attacked at a greater rate than the base metal is. The grooves seem to form from the coalescence of pits that start near the sulfide inclusions.

In another study, the influence of sulfur content on the occurrence of grooving corrosion was investigated (Ref 36). It was concluded that sulfur content should not be a problem in steels containing less than 0.02% S. Postweld heat treatment also appears to influence susceptibility to grooving corrosion, although the data are somewhat mixed. Maximum susceptibility to grooving is produced by treatments at approximately 750 °C (1380 °F). Susceptibility decreases with higher-temperature heat treatments. Of the temperatures investigated, the highest, 1000 °C (1835 °F), was the most beneficial.

Dealloying Corrosion

Dealloying (also referred to as selective leaching or parting corrosion) is a corrosion process in which one constituent of an alloy is preferentially removed, leaving behind an altered residual structure (Ref 37). The phenomenon was first reported by Calvert and Johnson in 1866 on brass (copper-zinc) alloys (Ref 38). Since that time, dealloying has been reported in a number of copper-base alloy systems as well as in gray iron, noble metal alloys, medium- and high-carbon steels, iron-nickel-chromium alloys, and nickel-molybdenum alloys. Table 5 lists some of the alloy-environment combinations for which dealloying has been reported.

Table 5 Combinations of alloys and environments subject to dealloying and elements preferentially removed

Alloy	Environment	Element removed
Brasses	Many waters, especially under stagnant conditions	Zinc (dezincification)
Gray iron	Soils, many waters	Iron (graphitic corrosion)
Aluminum bronzes	Hydrofluoric acid, acids containing chloride ions	Aluminum (dealuminification)
Silicon bronzes	High-temperature steam and acidic species	Silicon (desiliconification)
Tin bronzes	Hot brine or steam	Tin (destannification)
Copper nickels	High heat flux and low water velocity (in refinery condenser tubes)	Nickel (denickelification)
Copper-gold single crystals	Ferric chloride	Copper
Monels	Hydrofluoric and other acids	Copper in some acids, and nickel in others
Gold alloys with copper or silver	Sulfide solutions, human saliva	Copper, silver
High-nickel alloys	Molten salts	Chromium, iron, molybdenum, and tungsten
Medium- and high-carbon steels	Oxidizing atmospheres, hydrogen at high temperatures	Carbon (decarburization)
Iron-chromium alloys	High-temperature oxidizing atmospheres	Chromium, which forms a protective

		film
Nickel-molybdenum alloys	Oxygen at high temperature	Molybdenum

Mechanisms of Dealloying.

Although numerous attempts have been made to clarify the mechanisms of dealloying, two theories are most prevalent. In the first, two metals in an alloy are dissolved, and one redeposits on the surface (Ref 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52). In the second theory, one metal is selectively dissolved from an alloy, leaving a porous residue of the more noble species (Ref 53, 54, 55, 56, 57, 58, 59, 60). Still others believe that both mechanisms take place (Ref 61, 62, 63, 64, 65, 66, 67, 68, 69).

Regardless of the mechanism, however, the metal in the affected area becomes porous and loses much of its strength, hardness, and ductility. Failure may be sudden and unexpected because dimensional changes do not always occur and the corrosion sometimes appears to be superficial, although the selective attack may have left only a small fraction of the original thickness of the part unaffected.

Dealloying in Aqueous Environments

Dezincification. As described in the article "Corrosion of Copper and Copper Alloys" in this Volume, copper-zinc alloys containing more than 15% Zn are susceptible to a dealloying process called dezincification. Dezincification is the most common form of dealloying. In the dezincification of brass, selective removal of zinc leaves a relatively porous and weak layer of copper and copper oxide (analyses of dezincified areas usually indicate 90 to 95% Cu, with the remainder being copper oxide). Corrosion of a similar nature continues beneath the primary corrosion layer, resulting in gradual replacement of sound brass by weak, porous copper. Unless arrested, dealloying eventually penetrates the metal, weakening it structurally and allowing liquids or gases to leak through the porous mass in the remaining structure.

Dezincification may be either plug-type or uniform. The term plug-type dealloying refers to the dealloying that occurs in local areas; surrounding areas are usually unaffected or only slightly corroded. An example of plug-type dezincification in 70Cu-30Zn α-brass is shown in Fig. 7. In uniform-layer dealloying, the active component of the alloy is leached out over a broad area of the surface (Fig. 8). Dezincification is the usual form of corrosion for uninhibited brasses in prolonged contact with waters high in oxygen and carbon dioxide (CO_2). It is frequently encountered with quiescent or slowly moving solutions. Slightly acidic water, low in salt content and at room temperature, is likely to produce uniform attack, but neutral or alkaline water, high in salt content and above room temperature, often produces plug-type attack. Additional examples of dealloying corrosion are shown in Fig. 9, 10, 11.

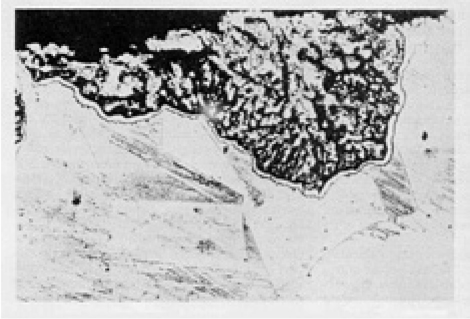

Fig. 7 Plug-type dezincification in an α-brass (70Cu-30Zn) exposed for 79 days in 1 *N* NaCl at room temperature. Note porous structure within the plug. The dark line surrounding the plug is an etching artifact. 160×. Source: Ref 61

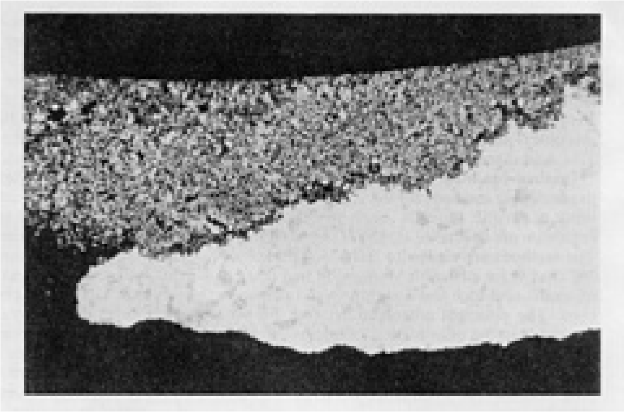

Fig. 8 Uniform-layer dezincification in an admiralty brass 19-mm ($\frac{3}{4}$-in.) diam heat-exchanger tube. The top layer of the micrograph, which consists of porous, disintegrated particles of copper, was from the inner surface of the tube that was exposed to water at pH 8.0, 31 to 49 °C (87 to 120 °F), and 207 kPa (30 psi). Below the dezincified layer is the bright yellow, intact, admiralty brass outer tube wall. 35×. Courtesy of James J. Dillon. Permission granted by Nalco Chemical Company, 1987

(d) Close-up of area in (c) showing the porous redeposited copper. 60×. (e) Small cracks prevalent throughout the fitting along stringers of β brass. 35×. (f) Detail of attack shown in (e). Initially, dezincification starts at β grains, then progresses along contiguous grain boundaries. 235×. Courtesy of W.W. Nash, Rockwell International

Brasses with copper contents of 85% or more resist dezincification. Dezincification of brasses with two-phase structures is generally more severe, particularly if the second phase is continuous; it usually occurs in two stages; first in the high-zinc β phase, followed by the lower-zinc α phase.

Dezincification also appears to be one of the principal contributing factors in the SCC of copper-zinc and copper-zinc-tin alloys. The preferential dissolution or loss of zinc at the fracture interface during SCC results in the corrosion products having a higher concentration of zinc than the adjacent alloy. This dynamic loss of zinc near the crack aids in propagating the stress-corrosion fracture. Additional information on the role of dealloying in SCC behavior in copper-base alloys can be found in Ref 70, 71, 72, 73, 74 and in the article "Corrosion of Copper and Copper Alloys" in this Volume.

Tin tends to inhibit dealloying, especially in cast alloys. The addition of a small amount of phosphorus, arsenic, or antimony to admiralty metal (an all-α, 71Cu-28Zn-1Sn brass) inhibits dezincification. Inhibitors are not entirely effective in preventing dezincification of the α-β brasses, because they do not prevent dezincification of the βphase.

Where dezincification is a problem, red brass, commercial bronze, inhibited admiralty metal, and inhibited aluminum brass can be successfully used. Where selection of a low-zinc alloy is unacceptable, inhibited yellow brasses are generally preferred. Additional information on the effect of various alloying elements on dealloying corrosion and other forms of corrosion in copper-base materials can be found in the article "Corrosion of Copper and Copper Alloys" in this Volume.

Dealuminification. Dealloying occurs in some copper-aluminum alloys, particularly those containing more than 8% Al. It is especially severe in alloys with a continuous γphase and usually occurs as plug-type dealloying. Figure 12 illustrates dealuminification of the γ-2 constituent in the β-eutectoid phase of an aluminum bronze (81Cu-11Al-4Fe-4Ni) casting. Heat treating to produce an α + β microstructure prevents dealuminification.

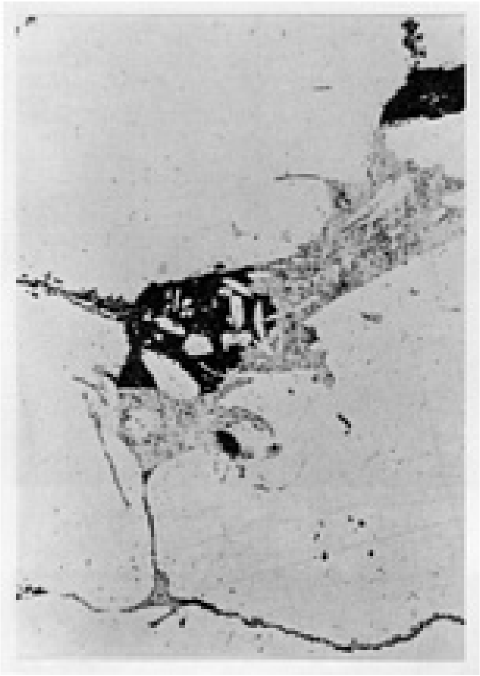

Fig. 12 Dealuminification of a cast aluminum bronze furnace electrode pressure ring exposed to recirculating cooling water (pH = 7.8 to 8.3, conductivity = 1000 to 1100 μS). The preferentially attacked γ phase left behind a residue of copper (darkened regions in eutectoid and along grain boundaries). The α particles within the eutectoid (light-gray areas) are unattacked. Etched with $FeCl_3$. 260×. Courtesy of Robert D. Port. Permission granted by Nalco Chemical Company, 1987

Denickelification. Dealloying of nickel in 70Cu-30Ni (C71500) is rare, but it has been observed at temperatures over 100 °C (212 °F), in low-flow conditions, and in high local heal flux. Figure 13 shows the residual copper layer of a 67.5Cu-31Ni-0.8Fe-0.7Mn alloy that underwent denickelification.

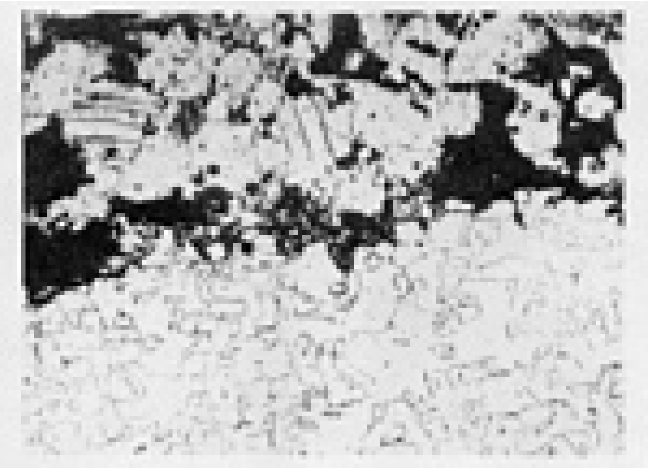

Fig. 13 Residual copper layer from a C71500 feedwater pressure tube that underwent denickelification. The tube was subjected to 205-°C (400-°F) steam on the external surface and boiling water on the internal surface (175 °C, or 350 °F, at pH 8.6 to 9.2). Courtesy of James J. Dillon. Permission granted by Nalco Chemical Company, 1987

Destannification and Desiliconification. Dealloying of tin in cast tin bronzes has been observed as a rare occurrence in hot brine or steam. Silicon bronzes have been subject to desiliconification in isolated cases involving high-temperature steam plus acidic species (Ref 37).

Dealloying of Noble Metal Systems. In addition to the copper alloys discussed above, alloys such as copper-gold and silver-gold are subject to dealloying. Investigations into the failure mechanisms of Cu-25at.%Au single crystals have indicated that dealloying may be an important nucleation mechanism for transgranular SCC of this system (Ref 75). For example, cracks that formed on the tensile surface of a Cu-25at.%Au single-crystal sample after three-point bending in air and in the absence of a corroding medium are shown in Fig. 14. Prior to the bend test, the sample had been immersed in 2% ferric chloride ($FeCl_3$) for 10 days in the absence of applied stress. This resulted in the formation of an approximately 30- m thick layer (gold-rich sponge). Most of the cracks in the sponge layer stopped at the boundary between the sponge and the unattacked alloy. However, some cracks propagated for distances up to 20 m into the unattacked, normally ductile alloy.

The brittle fracture surface produced on an Cu-25at.%Au single-crystal sample after three-point bending in air is shown in Fig. 15. The sample was produced by immersing a Cu25at.%Au single crystal in 2% $FeCl_3$ for 30 days in the absence of applied stress. This resulted in a completely dealloyed (100% Au) sponge that was a single crystal having the same orientation as the origial Cu-25at.%Au alloy. The sponge sample failed in a brittle manner under an increasingly small applied load. However, it is likely that the actual failure occurred by ductile fracture of the gold ligaments constituting the sponge, as shown in Fig. 16.

In another study, microscopic examination of an electrochemically sulfidized polycrystalline Cu-13Au alloy (300-h anodic polarization at E_H = 0 mV in a sulfide-containing buffer solution of pH = 5 and pS^{2-} = 15) revealed the formation of a two-layer structure. This structure consisted of an outer layer of cuprous sulfide (Cu_2S) and an inner reaction layer that was comprised of porous gold-rich metal with Cu_2S inside its pores (Ref 76). It is believed that similar processes of preferential sulfidation are responsible for the tarnishing of silver-gold dental alloys in human saliva (Ref 77). Detailed information on the corrosion of noble metal alloys can be found in the articles "Corrosion of the Noble Metals" and "Tarnish and Corrosion of Dental Alloys" in this Volume.

Graphitic Corrosion. Perhaps the second most frequently observed type of dealloying is the graphitic corrosion of gray iron, which occurs in relatively mild aqueous environments and on buried pipe. The graphite in gray iron is cathodic to iron and remains behind as a porous mass when iron is leached out. Graphitic corrosion usually occurs at a low rate. The graphite mass is porous and very weak, and graphitic corrosion produces little or no change in metal thickness.

Graphitic corrosion does not occur in ductile iron or malleable iron, because no graphite network is present to hold together the residue. White iron has essentially no free carbon and is not subject to graphitic corrosion. Examples of graphitic corrosion are shown in Fig. 17 and 18. Three case histories of graphitic corrosion in gray iron components are presented in the article "Failures of Iron Castings" in *Failure Analysis and Prevention,* Volume 11 of *ASM Handbook,* formerly 9th Edition of *Metals Handbook.*

Fig. 17 A 200-mm (8-in.) diam gray iron pipe that failed because of graphitic corrosion. The pipe was part of a subterranean fire control system. The external surface of the pipe was covered with soil; the internal surface was covered with water. Severe graphitic corrosion occurred along the bottom external surface where the pipe rested on the soil. The small-diameter piece in the foreground is a gray iron pump impeller on which the impeller vanes have disintegrated because of graphitic corrosion. See also Fig. 18. Courtesy of Robert D. Port. Permission granted by Nalco Chemical Company, 1987

graphitically corroded cast iron surrounding flakes of graphite. Etched with nital. 530×. Courtesy of Harvey M. Herro. Permission granted by Nalco Chemical Company, 1987

Graphitic corrosion is often erroneously referred to as graphitization. Graphitization is a microstructural change that sometimes occurs in carbon or low-alloy steels that are subjected to moderately high temperatures (~455 to 595 °C, or 850 to 1100 °F) for extended periods of time (≥40,000 h). Graphitization results from the decomposition of pearlite into ferrite and carbon (graphite) and can embrittle steel parts, especially when the graphite particles form along a continuous zone through a load-carrying member.

Selective Dissolution in Molten Salts and Liquid Metals

Preferential removal of key alloying elements can also take place when multicomponent alloys are exposed to liquid-metal or molten-salt environments. For example, austenitic stainless steels exposed to liquid sodium lose nickel, and this results in the formation of a ferritic surface layer. More detailed explanations of corrosion phenomena in liquid-metal environments can be found in the articles "Fundamentals of High-Temperature Corrosion in Liquid Metals" and "General Corrosion" (see the section "Corrosion in Liquid Metals") in this Volume.

Selective dissolution in molten-salt environments differs from that in aqueous systems in that the rate of dissolution is related to the bulk diffusion of the selectively leached element. Bulk diffusion does not play a role in either of the two dealloying mechanisms discussed earlier in this article. In addition, selective dissolution in molten salts can occur even when the leached element is at low concentrations. The articles "Fundamentals of High-Temperature Corrosion in Molten Salts" and "General Corrosion" (see the section "Molten-Salt Corrosion") in this Volume discuss corrosion in molten fluorides, chloride salts, nitrates, sulfates, hydroxide melts, and carbonate melts in more detail.

Decarburization and Selective Oxidation

Preferential removal of alloying elements also occurs in high-temperature gaseous environments. Two examples are decarburization and selective oxidation of chromium.

Decarburization is a loss of carbon from the surface of a ferrous alloy as a result of heating in a medium that produces a carbon gradient. Unless special precautions are taken, the risk of losing carbon from the surface of steel is always present in any heating to high temperatures in an oxidizing atmosphere. A marked reduction in fatigue strength is noted in steels with decarburized surfaces.

Figure 19(a) shows a chromium-plated blanking die made from AISI A2 tool steel that cracked after limited service. Cold etching of a disk cut from the blanking die revealed a light-etching layer that is particularly prominent at the working face and along the adjacent sides (Fig. 19b). Microscopic examination (Fig. 19c) revealed that the surface at the working face was decarburized to a depth of about 0.05 mm (0.002 in.). The soft zone beneath the hard chromium plating permitted the plating to flex under the influence of the blanking stresses, and this caused cracking of the plating and surface region. Additional information on decarburization can be found in Volumes 11 and 12 of the 9th Edition of *Metals Handbook.*

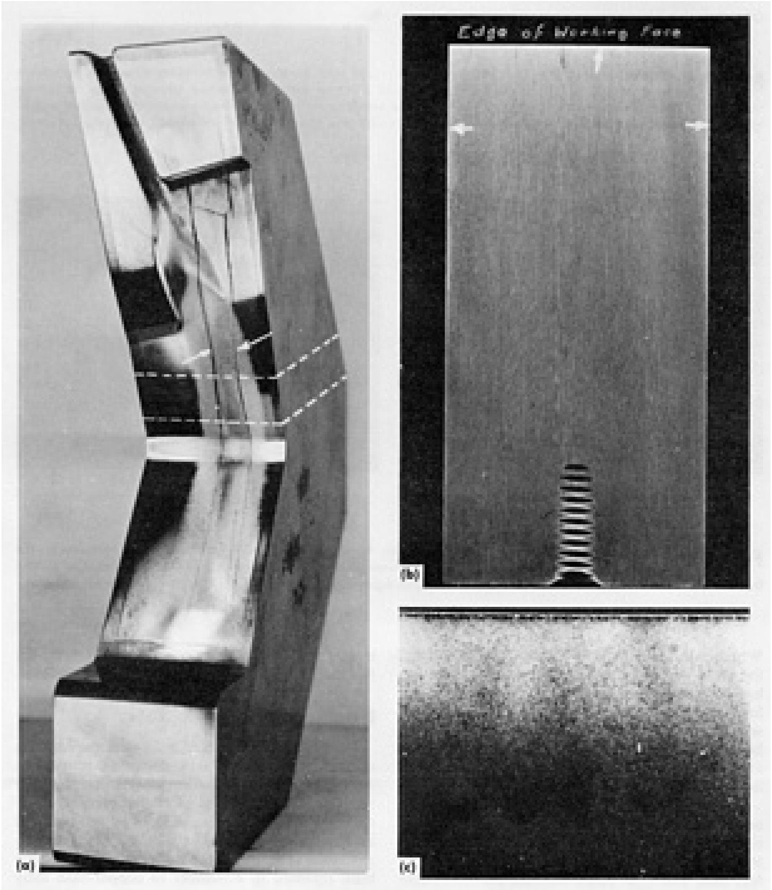

Fig. 19 Failed chromium-plated blanking die made from AISI A2 tool steel. (a) Cracking (arrows) that occurred shortly after the die was placed in service. (b) Cold etched (10% aqueous HNO_3 disk cut from the blanking die (outlined area) revealing a light-etching layer. Actual size. (c) Micrograph showing the decarburized layer that was unable to support the more brittle, hard chromium plating. Etched with 3% nital. 60×. Courtesy of G.F. Vander Voort, Carpenter Technology

Selective Oxidation of Chromium. Exposure of stainless steels to low oxygen atmospheres at high temperatures (980 °C, or 1800 °F) has been shown to result in the selective oxidation of chromium (Ref 78). When there is competition for oxygen, the elements with higher free energies for their oxide formation (higher affinity for oxygen) are oxidized to a greater degree. In the case of stainless steels, this results in a more protective scale. More detailed information on oxide scale formation and high-temperature corrosion can be found in the articles "Fundamentals of Corrosion in Gases" and "General Corrosion" (see the section "High-Temperature Corrosion") in this Volume.

Evaluation of Dealloying Corrosion (Ref 61)

Reactions that lead to dealloying corrosion are relatively slow, and a lengthy exposure period is required to cause dealloying that is extensive enough to facilitate evaluation. Consequently, there is considerable interest in accelerated tests for evaluation of the dealloying tendencies of alloys. Many techniques have been implemented. For example, electrolyte compositions have been adjusted by using more concentrated solutions or solutions having variations in oxidizing power (Ref 67). Specific ions have been added to stimulate dealloying; for example, saturated cuprous chloride solutions have been used to accelerate the dezincification of copper-base alloys (Ref 79). Electrochemical stimulation has also been used. Unfortunately, the test methods employed can often be criticized as having biased the experimental result, and although specific techniques are now available that can cause dealloying to occur in the laboratory, there is still no firm basis for predicting the likelihood of dealloying in service based on these tests.

New techniques that may have predictive capacity in assessing the likelihood of dealloying involve the use of electrochemical hysteresis methods to generate experimental potential versus pH diagrams for alloys. Superposition of these experimental diagrams over the theoretical *E*-pH (Pourbaix diagrams) for the constituent metals of the alloy

provides a basis for predicting the tendency for dealloying as a function of potential and pH. An example of such a superimposed diagram for an α-brass in 0.1 *M* sodium chloride (NaCl) is shown in Fig. 20. For initially copper-free chloride solutions, ranges of potential are indicated in which selective leaching of zinc predominates, in which alloy dissolution with replating is expected, and in which alloy dissolution without replating occurs. More detailed information on *E*-pH diagrams can be found in the article "Thermodynamics of Aqueous Corrosion" in this Volume.

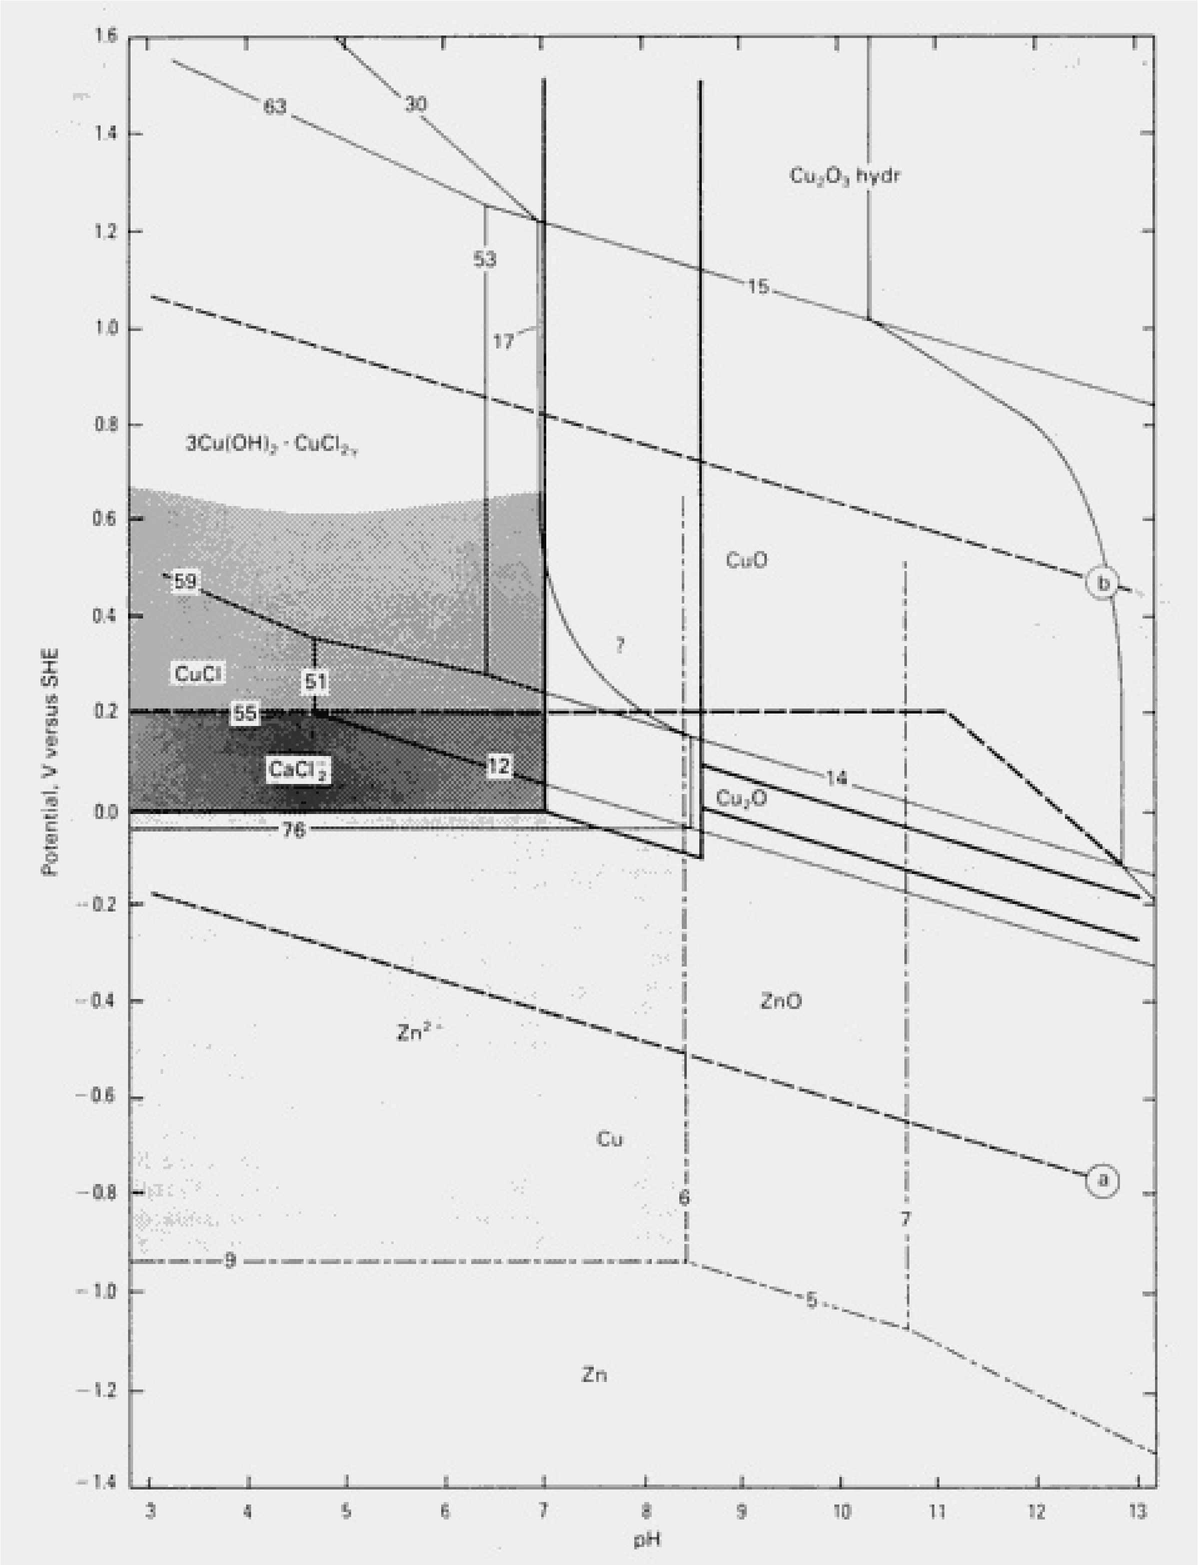

Fig. 20 Superimposed *E*-pH diagram of a 70Cu-30Zn alloy in 0.1 *M* NaCl. Lightly shaded area indicates the domain in which selective removal of zinc is expected in solutions free of copper ions. Intermediate shaded area indicates the domain in which both copper and zinc dissolve. Dark shaded area indicates the region in which

copper is expected to deposit. Source: Ref 61

Mechanically Assisted Degradation

William Glaeser and Ian G. Wright, Battelle Columbus Laboratories

Introduction

MECHANICALLY ASSISTED DEGRADATION of metals, in the context of this article, is defined as any type of degradation that involves both a corrosion mechanism and a wear or fatigue mechanism. This article will discuss five such forms of degradation: erosion, fretting, fretting fatigue, cavitation and water drop impingement, and corrosion fatigue. Only the mechanisms of these forms of degradation will be discussed. The ability of specific metals and alloys to withstand mechanically assisted degradation is treated in detail in many of the articles in the Section "Specific Alloy Systems" in this Volume. The analyses of failures involving these mechanisms, as well as means of failure prevention, are detailed in *Failure Analysis and Prevention,* Volume 11 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Erosion

Erosion can be defined as the removal of surface material by the action of numerous individual impacts of solid or liquid particles. Erosive wear should not be confused with abrasive or sliding wear, because the mechanisms of material removal, and therefore the materials selection criteria (though rudimentary), are different. In its mildest form, erosive wear is often manifested as a light polishing of the upstream surfaces of components penetrating the flowstream, or of bends or other stream-deflecting structures. This is illustrated in Fig. 1, which shows carbon steel heat transfer tubes in a fluidized-bed combustor. The tubes have been polished through the action of particles of sand impacting at a velocity of about 1.8 m/s (6 ft/s). The black appearance of these tubes is due to the oxide scale, which has been polished (that is, thinned) by the erosive action but not completely removed. In this case, metal wastage is probably a result of high-temperature corrosion assisted by erosion.

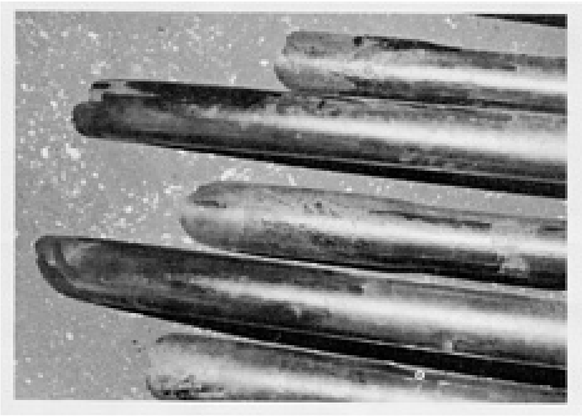

Fig. 1 Polishing of heat transfer tubes from erosion by sand in a fluidized-bed combustor

Where the erosive action is more severe, any scales or deposits are removed, and the polished, eroded surface is base metal. Such surfaces on low-alloy steels are often very susceptible to rusting; therefore, swabbing the tubes with a damp cloth can give a useful indication of the erosion zones and patterns. Figure 2 shows such rusting on the underside of a tube from a different fluidized-bed combustor. This rusting indicates that erosion occurred in a uniform zone around the bottom of the tube, up to the 9 o'clock position.

Fig. 2 Carbon steel heat transfer tube from a fluidized bed that was damaged by erosion and subsequent rusting

Erosion attack can be quite localized, as shown by the polished zones on the tube supports from a steam boiler (Fig. 3). Localized fly ash laden gas flow between the tube rows (supported on the lugs) eroded through the oxide scale and polished the metal surface beneath.

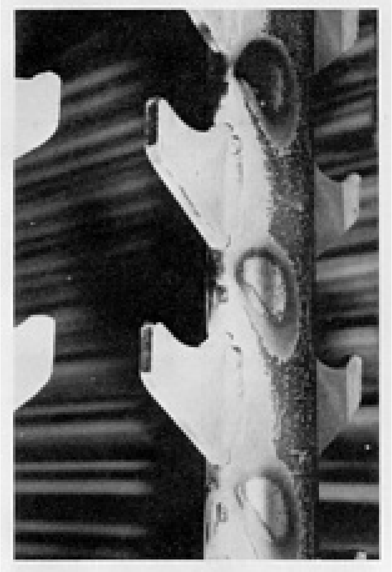

Fig. 3 Erosion of a tube support by ash-laden flue gas

In more severe cases, erosion can result in very rapid attack that quickly leads to thinning and penetration. Conditions that give rise to such rapid erosion usually involve high velocities, large amounts of entrained solid or liquid particles, and abrupt changes in direction of the fluid. These conditions can lead to segregation and concentration of the eroding particles. Examples of such rapid erosion are shown in Fig. 4, 5, and 6.

Fig. 4 Hardfaced stainless steel plug and seat, from a slurry flow control valve, that were eroded by high-velocity flow through the narrow orifice created during throttling

Fig. 5 Eroded tube inserts from the inlet end of a fire-tube boiler. The inserts were eroded by particle-laden flue gas, which was forced to run as it entered the boiler.

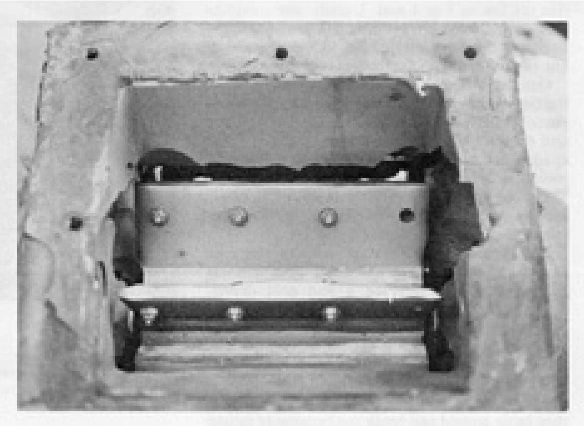

Fig. 6 Erosion of a rotary valve handling dust from a cyclone. The wear plates in the valve show some material loss, but the major damage is to the casing. Gaps between the casing and the valve allowed leakage of high-velocity air with entrained dust.

Erosion is typically thought to involve the action of a dilute dispersion of small solid (or liquid) particles entrained in a fluid jet, and it is from studies in this type of regime that most of the current understanding of erosion phenomena is derived. Strictly controlled laboratory studies of simplified systems or part processes in actual or simulated situations have provided a basis for the analysis of erosion damage produced under quite limiting circumstances: by the impacts of individual particles where particle motion is largely unconstrained in the approach to the target, during impact, and in rebounding from the target. There are many variables that can affect erosion. Important system variables are the relative velocities of the erodent and target; the angle of impact; the mass, size, size distribution, shape, hardness, and composition of the erodent particles; the number density of the particles in the conveying fluid or the frequency of impact; and the density and viscosity of the fluid.

The factors that affect the resistance of materials to erosion are difficult to define. Simple correlations of erosion rate have been attempted with target material hardness, melting temperature, elastic modulus, and so on, with some success for pure elements but less-than-universal application to steels and other alloys or ceramic materials. The relative importance of specific materials properties will likely change, depending on the predominating mechanisms of erosion, which in turn depend on any of the large number of systems variables and on the way in which the target material absorbs the energy of impact. For discrete impacts at a shallow angle to the target surface, it appears that the primary mode of material loss is through the displacement of material in the path of the erodent and the eventual loss of the displaced material by subsequent cutting or by fracture, if the material is embrittled.

This form of erosion can be equated to micromachining. The simple, elegant model discussed in Ref 1 and 2 and its refinements, relating erosion essentially to material hardness, has been found to predict erosion rates of approximately the right magnitude, even if the ability of the model to rank different alloys is sometimes poor. This model can be simply stated as:

$$\frac{\text{Erosion loss}}{\text{Quantity of impacting erodent}} = C \cdot F(\theta)\,\frac{\rho v^2}{\text{HV}} \qquad \textbf{(Eq 1)}$$

where C is a system constant, θ is the angle of impact, ρ is the density of the erodent, v is the erodent velocity, and HV is the hardness of the target.

Other refinements to this model, as well as approaches to sophisticated models, have been proposed and are fully discussed in other reviews (Ref 3, 4, 5). In the later refinements (Ref 2) of this model, the velocity dependence of erosion

is increased from 2 to around 2.3. Nevertheless, the general relationship between erosive loss and erodent kinetic energy is not changed.

For impacts at larger angles to the target surface, fluid flow considerations indicate that in most practical cases the erodent particles will actually strike the surface at a variety of shallower angles, depending on the size and velocity of the particles and the drag exerted on them by the conveying fluid. For impacts normal to the target surface, therefore, it is likely that only a small fraction of the particles will actually impact at 90°. The forms of material loss will involve both surface displacement and cutting, as well as modes that result from normal impacts. For most metallic materials, normal impacts will result in indentation and local displacement of the surface by sharp particles, but less angular particles will cause deformation and/or eventual fatigue, depending on the rate at which the deformation can be accommodated. Most ceramic materials suffer cracking from normal impacts; the form and extent of the cracking depend on the intensity of the impact (particle size and velocity, and shape) and on the structure of the ceramic.

Erosion models that describe erosion by deformation and fracture are based on elastic-plastic indentation fracture mechanics. The volume of the target surface removed following an individual impact is usually taken to be the volume enclosed by the radial and lateral cracks resulting from the impact. The depth of the lateral cracks can be related to the hardness of the target, while the length of the radial crack is a function of both hardness and toughness. The exact form of the relationship among erosion loss, hardness, and fracture toughness depends on assumed details of the geometry of the damage and mode of material removal. The predicted velocity dependence of erosion is usually around 3. Further discussion of these erosion models can be found in Ref 6 and 7.

In practice, erosive conditions cover a wide spectrum. In situations where the concentration of erodent particles is so great that the independent action of individual particles is unlikely, the form of damage may be more like scouring from particles embedded in a massive backing than that from discrete particle impacts. Rules derived for abrasive wear (see the article "Wear Failures" in *Failure Analysis and Prevention,* Volume 11 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*) may then be more appropriate. In a large number of systems of practical importance, the density and viscosity of the carrier fluid are significantly different from those associated with airborne dilute phase erosion; therefore, the motion of the erodent particles before, during, and after impact may be quite different from that considered in most erosion models. The actual mechanisms of erosion, as well as the relationships with, for example, nominal angle of impact, may not correspond with those where air is the carrier fluid. Overall, at the present state of development, analytical relationships between systems and materials variables, as well as material loss through erosion, can be used only as a guide to the relative importance of the variables encountered. Testing under conditions that accurately simulate the situation under consideration is probably the best method of forming a basis for decision making. More information on failures caused by erosion is available in the article "Liquid-Erosion Failures" in *Failure Analysis and Prevention,* Volume 11 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Fretting Corrosion

Fretting corrosion is a combined wear and corrosion process in which material is removed from contacting surfaces when motion between the surfaces is restricted to very small amplitude oscillation (as low as 3 or 4 nm). Usually, the condition exists in machine components that are considered fixed and not expected to wear. Pressed-on wheels can often fret at the shaft/wheel hole interface.

Oxidation is the most common element in the fretting process. In oxidizing systems, fine metal particles removed by adhesive wear are oxidized and trapped between the fretting surfaces. The oxides act like an abrasive (such as lapping rouge) and increase the rate of material removal. This type of fretting in ferrous alloys is easily recognized by the red material oozing from between the contacting surfaces.

Fretting can also persist in contacts where no corrosion exists. For example, gold fretting against gold will produce a fine gold debris. Fretting occurs in the vacuum of outer space.

Fretting damage can be very serious and catastrophic. For example, in gas turbines, the blades are often anchored in dovetail slots in the hub. Vibrations in the blade system can cause fretting in the blade roots and loosening. The loose blades then rattle around and break out because of fatigue or impact wear. A piece of blade moving into the gas flow through the turbine can cause severe damage, destroying rows of blades and causing engine failure. Another fretting problem that has injury potential is the loosening of wheels or flywheels from shafts or axles. Railroad car wheels, for example, are shrink fitted onto their axles. If the wheel loosens from running vibrations and comes off during operation of

the train, it can cause derailment and has the potential of becoming a loose rolling missile capable of penetrating nearby buildings.

Electrical connectors for low-current circuits are generally gold or gold-base alloys. Because of the high cost of gold, very thin electroplated gold coatings are used for contacts. Gold plate thicknesses as small as 0.25 μm (0.01 mil) are used. When electric contacts are subjected to vibrations of continual expansion and contraction from periodic thermal excursions, the small relative motion between the contacts produces fretting wear and the eventual removal of the gold plate. As the gold is removed, the substrate is subjected to atmospheric corrosion, and the contact resistance rises to intolerable levels. In addition, fretting debris becomes trapped between the surfaces and causes degraded conductivity. Fretting of electrical contacts is not anticipated in the design, and although it is common, it often comes as a surprise to the user. A typical progression of fretting damage induced between a solid gold rider on cobalt-gold plated copper is shown in Fig. 7.

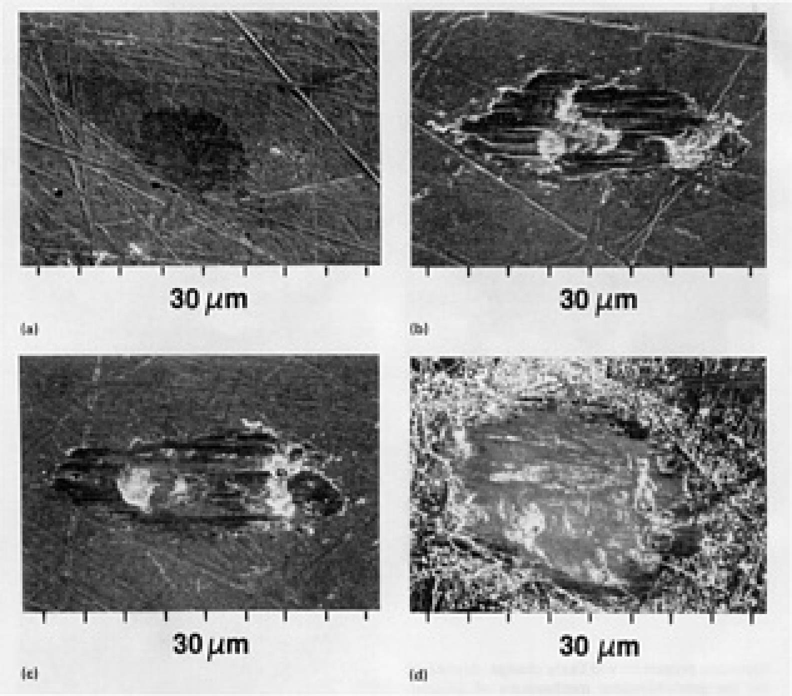

Fig. 7 Fretting of cobalt-gold plated copper flats in contact with solid gold in an electrical contact. (a) After 1000 cycles. (b) After 10^4 cycles. (c) After 10^5 cycles. (d) After 10^6 cycles. Source: Ref 8

Fretting corrosion has been a continuing problem in nuclear reactors. The condition is found on heat-exchanger tubes and on fuel elements. In both cases, long, flexible tubes are in contact with support surfaces and subjected to vibrations generated by fluid flow as the coolant flows around them. The supports for heat-exchanger tubes and fuel elements cannot be rigid, because the tubes must be able to expand or contract under thermal excursions without binding (this is also true for any tube heat-exchanger system). Tube impact fretting caused by flow-induced tube vibrations can reduce wall thickness, requiring eventual replacement. Extensive experimentation has revealed that the interaction of tube support clearance, excitation force, and type of tube motion controls wear rates (Ref 9). Other mechanical parts susceptible to fretting damage include couplings, riveted and pin joints, surgical implants, rolling contact bearings, and bridge bearings.

Factors Affecting Fretting

The following factors are known to influence the severity of fretting. If fretting conditions exist, fretting cannot be eliminated completely but can be reduced in severity.

Contact Load. As long as fretting amplitude is not reduced, fretting wear will increase linearly with increasing load.

Amplitude. There appears to be no measurable amplitude below which fretting does not occur. However if the contact conditions are such that deflection is only elastic, it is not likely that fretting damage will occur. Fretting wear loss

increases with amplitude. The effect of amplitude can be linear, or there can be a threshold amplitude above which rapid increase in wear occurs (Ref 10). The transition is not well established and probably depends on the geometry of the contact.

Frequency. When the fretting is measured in volume of material removed per unit sliding distance, there does not appear to be a frequency effect.

Number of Cycles. An incubation period occurs during which fretting wear is negligible (Ref 11). After the incubation period, a steady-state wear rate is observed. Figure 8 shows local cold welding on a fretted steel surface early in the fretting process (500 cycles). As the fretting continues, a more general surface roughening occurs, as shown in Fig. 9.

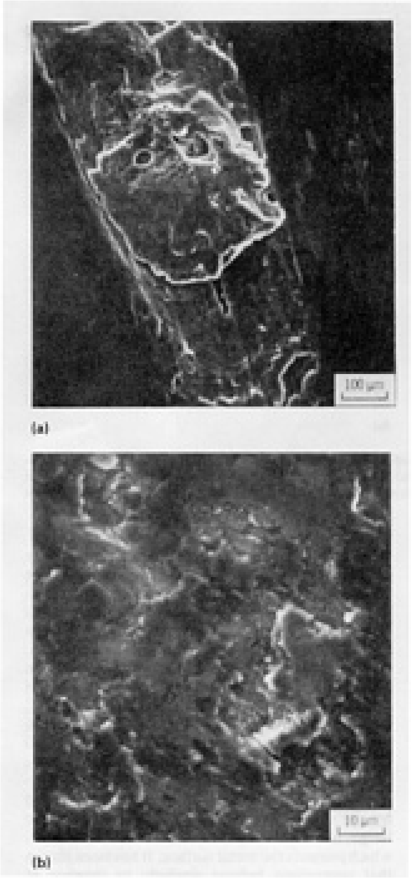

Fig. 9 Damage to Monel alloy after fretting in air at room temperature for (a) 1000 cycles and (b) 5 × 10^4 cycles. Courtesy of R.C. Bill, NASA Lewis Research Center

Relative Humidity. For materials that rust in air, fretting wear is higher in dry air than in saturated air. The effect of humidity is shown in Fig. 10 and 11. In dry air, both the iron and nickel produce debris that remains in the contact region. The debris separates the surfaces and reduces the contacts. As humidity is increased, the debris becomes more mobile, escaping the contact and allowing metal-to-metal contact, as shown in Fig. 10 and 11. Diffraction analysis of the debris from the iron surfaces shows it to be α-Fe_2O_3 (Ref 12).

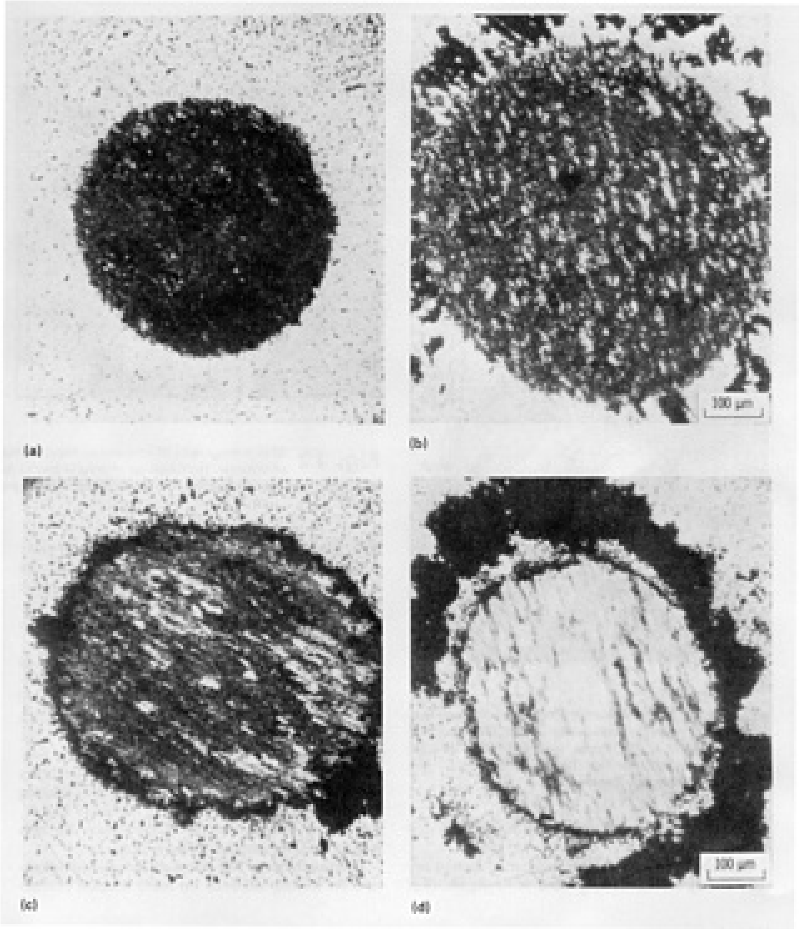

Fig. 10 Effect of relative humidity on fretting damage to high-purity iron tested in air. (a) Dry air. (b) 10% relative humidity. (c) 35% relative humidity. (d) Saturated air. All specimens shown after 3 × 10^5 cycles. See also Fig. 11. Courtesy of R.C. Bill, NASA Lewis Research Center

Temperature. The effect of elevated temperature on fretting depends on the oxidation characteristics of the metals. If increased temperature encourages the growth of a protective tough oxide layer that prevents metal-to-metal contact, the fretting rate will be lower. Low-carbon steel tends to show a sudden decrease in fretting wear rate at about 200 °C (390 °F) (Ref 13). For titanium alloys, an increase in wear rate has been observed between 350 and 500 °C (660 and 930 °F), and a rapid decrease in wear has been observed above 550 °C (1020 °F) (Ref 14, 15). Even the difference between room-temperature wear and wear at 650 °C (1200 °F) is significant (Fig. 12 and 13). Figure 12 shows the surface damage from room-temperature fretting, illustrating the inadequate protection afforded by the oxide. Figure 13 shows the effect of the tough, thick oxide layer formed at 650 °C (1200 °F), which protects the metal surface. It has been shown that superalloys behave similarly to titanium at elevated temperatures (Ref 16). A glassy layer of compacted oxide particles has been found on the fretted surface after high temperature. This layer reduces the fretting wear considerably. The formation of this glassy oxide layer has been linked to an increase of 130% in fretting fatigue strength of Inconel 718 (Ref 17).

Fretting Fatigue

Fretting decreases the fatigue life of parts operating under fatigue loading. Gas turbines experience this problem with clamped joints and shrink-fitted parts. These parts are subjected to high-frequency low-amplitude vibrations, often in combination with bending fatigue stress states (Ref 18). The combined action of fretting and reversing bending stress causes accelerated crack initiation and an increase in the rate of crack propagation. The result is a decrease in the fatigue strength of a given alloy. The effect on 4130 steel is shown in Fig. 14. In this case, the fatigue strength of the alloy is reduced under fretting, and the sensitivity to load is increased.

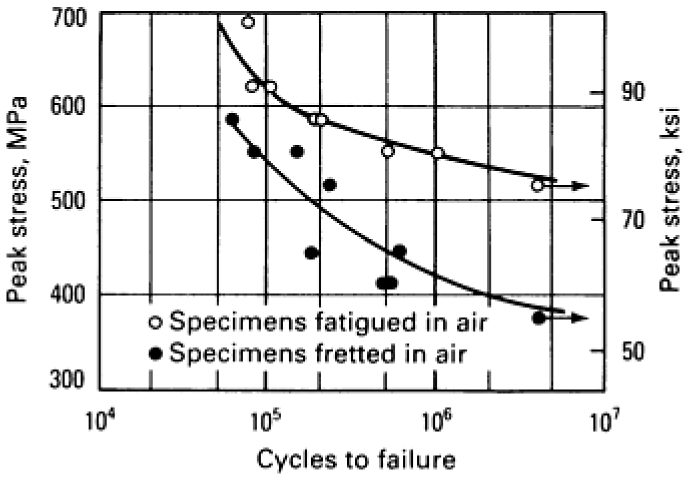

Fig. 14 Comparison of fatigue life for 4130 steel under fretting and nonfretting conditions. Specimens were water quenched from 900 °C (1650 °F), tempered 1 h at 450 °C (840 °F), and tested in tension-tension fatigue. Normal stress was 48.3 MPa (7 ksi); slip amplitude was 30 to 40 μm.

Fretting fatigue begins as a crack in the fretting scar zone. An example of a fretting fatigue crack is shown in Fig. 15. The crack is located at the boundary of the fretting scar. This is one attribute of fretting fatigue that identifies the origin of the fatigue. The fatigue crack, once initiated at the boundary of the fretted zone, propagates into the surface at an angle to the surface (Fig. 16). Other examples of the crack habit are shown in Fig. 17 and 18. As the crack opens, fretting debris jams into it, adding to the propagation force. In a corrosive environment, the corroding medium can also penetrate the crack and add corrosion fatigue to the process. Once the crack propagation reaches a depth where it is no longer influenced by surface contact stress, it progresses as a fatigue crack normal to the surface. When the part breaks, the fretting fatigue fracture leaves a characteristic lip at the surface, as shown in Fig. 16.

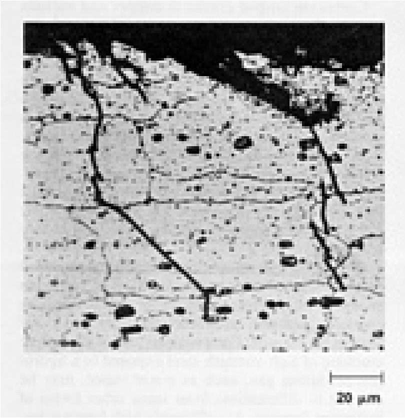

Fig. 18 Section showing fretting damage and fatigue cracks in Al-6Zn-3Mg alloy. Courtesy of R.B. Waterhouse, University of Nottingham

Wire rope can fail by fretting fatigue. As the rope flexes, wire strands rub against each other and produce fretting at the wire-wire contacts. If the fretting occurs in a zone that is also subject to cyclic fatigue stresses, failure occurs. An example of wire rope fretting fatigue is shown in Fig. 19. Note the lip in the detail micrograph in Fig. 20.

Cavitation Erosion and Water Drop Impingement

Cavitation erosion occurs on metal surfaces in contact with a liquid. Pressure differentials in the fluid generate gas or vapor bubbles in the fluid. When these bubbles encounter a high-pressure zone, they collapse and cause explosive shocks to the surface. These surface shocks cause localized deformation and pitting. Cavitation pits eventually link up and cause a general roughening of the surface and material removal. Cavitation is similar to particle erosion in its damage. However, surface features formed by cavitation are different from those formed by particle erosion. Cavitation produces rounded microcraters in the surface, while particle erosion produces imprints of the impacting particles. Crater formation moves surface material to the edges of the craters, and these extrusions eventually break off, causing loss of material from the surface. The sharp pressure pulses caused by the collapsing bubbles are highly localized and can remove weak or soft portions of microstructural phases (for example, ferrite from pearlite) (Ref 20).

Scattered shallow dimples or depressions are the earliest evidence of cavitation erosion in ductile surfaces. This represents an incubation period before the actual loss of material. Damage is seen first in the weaker elements of the microstructure.

Material removal is different for soft materials and hard materials. Soft materials suffer local plastic deformation and penetration. Babbitt, for example, will become pitted with steep-sides pits that group together in patterns reflecting the fluid dynamics.

Hard materials experience localized microcracking and chipping from the pressure pulses. Brittle materials such as glass and some plastics appear to develop surface cracking at minute surface flaws.

In materials that depend on passivating films for corrosion protection, cavitation will cause an apparent accelerated attack. In a corrosive medium, the cavitation will remove the protective film, and corrosion will weaken the material to the mechanical removal process. Figure 21 shows cavitation damage to an ACI CN-7M stainless steel impeller that was used to pump ammonium nitrate solution at 140 °C (280 °F).

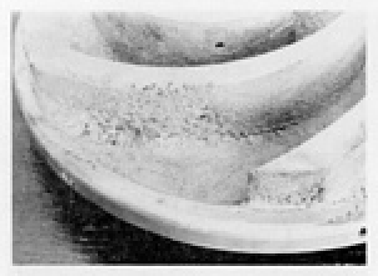

Fig. 21 Cavitation damage to an ACI CN-7M cast pump impeller used to pump ammonium nitrate solution at 140 °C (280 °F). Courtesy of A.R. Wilfley and Sons, Inc., Pump Division

Hardfacing materials and cemented carbides react differently to cavitation than to abrasion (Ref 21). The carbides are selectively eroded from the Stellite alloys, while cemented carbides suffer loss of the cobalt or nickel binder. Cavitation occurs in hydraulic equipment, fluid pump impellers, ship propellers, hydrodynamic bearings, fluid seals, inlets to heat-exchanger tubes, diesel engine wet cylinder liners, hydrofoils, liquid-metal power plants, and steam turbines.

Water drop impingement erosion is similar to cavitation in that it causes pitting of surfaces and may involve a cavitation mechanism. Two areas are most notable for water drop inpingement: steam turbines and helicopter rotor blades. In turbines, condensation of steam produces droplets that are carried into the rotor blades with consequent surface damage. Rain drop erosion on helicopter blades is the result of elastic compression waves produced by multiple impacts and their interaction; this generates tensile stresses just below the surface and causes cracking.

Water drop impingement damage can appear to be somewhat different from cavitation damage in ductile materials. The cavities in the surface show a directionality that is related to the angle of attack of the drops.

Corrosion Fatigue

Corrosion fatigue occurs in metals as a result of the combined action of a cyclic stress and a corrosive environment. Corrosion fatigue is dependent on the interactions among loading, environmental, and metallurgical factors. For a given material, the fatigue strength (or fatigue life at a given maximum stress value) generally decreases in the presence of an aggressive environment. The effect varies widely, depending primarily on the particular metal-environment combination. The environment may affect the probability of fatigue crack initiation, the fatigue crack growth rate, or both. Figure 22 shows an example of corrosion fatigue failure in Ti-6Al-4V alloy.

Fig. 22 Corrosion fatigue of Ti-6Al-4V alloy tested in ambient air. Intergranular cracking and fatigue striations are evident on the fracture surface; the grain appears to have separated from the rest of the microstructure. Source: Ref 22

Corrosion Fatigue Crack Initiation. The influence of an aggressive environment on fatigue crack initiation of a material is illustrated in Fig. 23, which compares the smooth-specimen stress-life (*S-N*) curves obtained from inert and aggressive environments. Because as much as 95% of the structure life is spent on fatigue-crack initiation, *S-N* curve comparison will provide a good indication of the effect of environment on crack initiation. As shown in Fig. 23, an aggressive environment can promote crack initiation and can shorten the fatigue life of the structure.

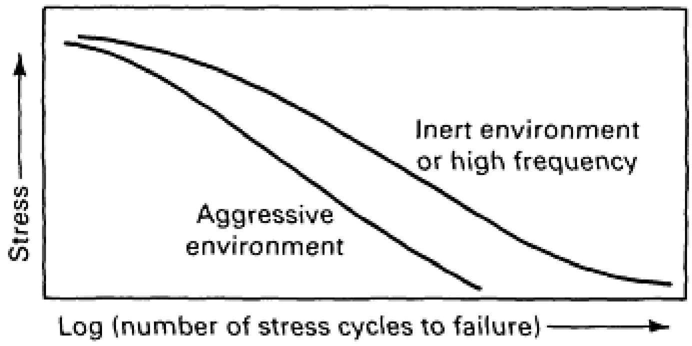

Fig. 23 Comparison of *S-N* curves for a material in an inert environment (top curve) and an aggressive environment (lower curve)

Corrosion fatigue cracks are always initiated at the surface unless there are near-surface defects that act as stress concentration sites and facilitate subsurface crack initiation. Surface features at origins of corrosion fatigue cracks vary with the alloy and with specific environmental conditions. In carbon steels, cracks often originate at hemispherical corrosion pits and often contain significant amounts of corrosion products. The cracks are often transgranular and may exhibit a slight amount of branching. Surface pitting is not a prerequisite for corrosion fatigue cracking of carbon steels, nor is the transgranular fracture path; corrosion fatigue cracks sometimes occur in the absence of pits and follow grain boundaries or prior-austenite grain boundaries.

In aluminum alloys exposed to aqueous chloride solutions, corrosion fatigue cracks frequently originate at sites of pitting or intergranular corrosion. Initial crack propagation is normal to the axis of principal stress. This is contrary to the behavior of fatigue cracks initiated in dry air, where initial growth follows crystallographic planes. Initial corrosion

fatigue cracking normal to the axis of principal stress also occurs in aluminum alloys exposed to humid air, but pitting is not a requisite for crack initiation.

Corrosion fatigue cracks in copper and various copper alloys initiate and propagate intergranularly. Corrosive environments have little additional effect on the fatigue life of pure copper over that observed in air, although they change the fatigue crack path from transgranular to intergranular. Copper-zinc and copper-aluminum alloys, however, exhibit a marked reduction in fatigue resistance, particularly in aqueous chloride solutions. This type of failure is difficult to distinguish from stress-corrosion cracking (SCC) except that it may occur in environments that normally do not cause failures under static stress, such as sodium chloride or sodium sulfate solutions.

Environmental effects can usually be identified by the presence of corrosion damage or corrosion products on fracture surfaces or within growing cracks. Corrosion products, however, may not always be present. For example, corrosion fatigue cracking of high-strength steel exposed to a hydrogen-producing gas, such as water vapor, may be difficult to differentiate from some other forms of hydrogen damage. At sufficiently high frequencies, the fracture surface features produced by corrosion fatigue crack initiation and propagation do not differ significantly from those produced by fatigue in nonaggressive environments.

Corrosion Fatigue Crack Propagation. Although corrosion fatigue phenomena are diverse, several variables are known to repeatedly influence crack growth rate:

- Stress intensity range
- Load frequency
- Stress ratio
- Aqueous environment electrode potential
- Environment
- Metallurgical variables

Effects of such variables as temperature, load history and waveform, stress state, and environment composition are unique to specific materials and environments (Ref 23, 24, 25, 26, 27, 28, 29, 30, and 31).

Stress Intensity Range. For embrittling environments, crack growth are generally increases with increasing stress intensity (ΔK); the precise dependence, however, varies markedly. Materials that are extremely environment sensitive, such as ultrahigh-strength steel in distilled water (Fig. 24), are characterized by high growth rates that depend on ΔK to a reduced power. Time-dependent corrosion fatigue crack growth occurs mainly above the threshold stress intensity for static load cracking and is modeled through linear superposition of SCC and inert environment fatigue rates (Ref 32, 33).

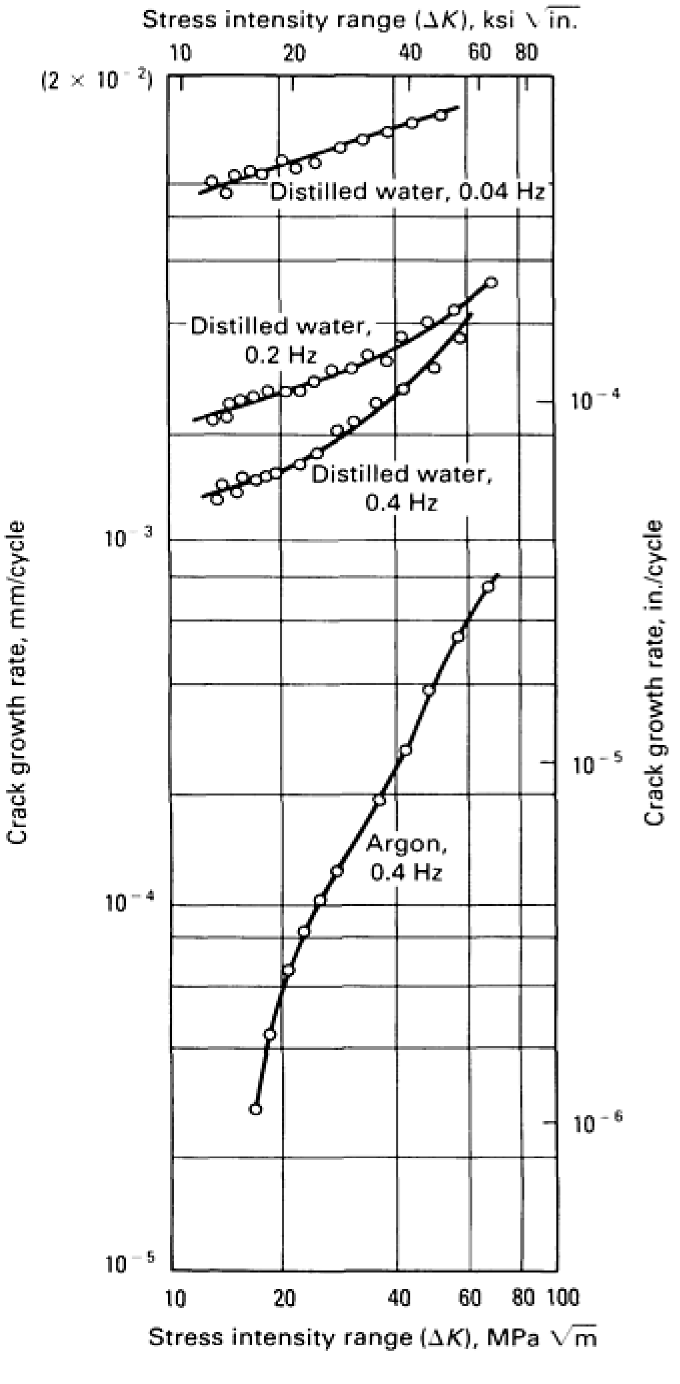

Fig. 24 Effect of stress intensity range and loading frequency on corrosion fatigue crack growth in ultrahigh-strength 4340 steel exposed to distilled water at 23 °C (73 °F)

Frequency. Cyclic load frequency is the most important variable that influences corrosion fatigue for most material, environment, and stress intensity conditions. The rate of brittle cracking above that produced in vacuum generally decreases with increasing frequency. Frequencies exist above which corrosion fatigue is eliminated. The dominance of frequency is related directly to the time dependence of the mass transport and chemical reaction steps required for brittle cracking. Basically, insufficient time is available for chemical embrittlement at rapid loading rates; damage is purely mechanical, equivalent to crack growth in vacuum.

Stress Ratio. Rates of corrosion fatigue crack propagation generally are enhanced by increased stress ratio, *R*, which is the ratio of the minimum stress to the maximum stress. Stress ratio has only a slight influence on fatigue crack growth

rates in a benign environment (see the article "Fatigue Crack Growth Data Analysis" in *Mechanical Testing,* Volume 8 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*).

Electrode potential, like loading frequency, strongly influences corrosion fatigue crack propagation rates in aqueous environments. Controlled changes in the potential of a specimen can result in either the complete elimination or the dramatic enhancement of brittle fatigue cracking. The precise influence depends on the mechanism of the environmental effect and on the anodic or cathodic magnitude of the applied potential.

Environment. Increasing the chemical activity of the environment--for example, by lowering the pH of a solution, by increasing the concentration of the corrosion species, or by increasing the pressure of a gaseous environment--generally decreases the resistance of a material to corrosion fatigue. Decreasing the chemical activity of the environment improves resistance to corrosion fatigue.

In aluminum alloys and high-strength steels, for example, corrosion fatigue behavior is related to the relative humidity or partial pressure of water vapor in the air. Corrosion fatigue crack growth rates for these materials generally increase with increasing water vapor pressure until a saturation condition is reached. Figure 25 shows the appearance of the fracture surfaces of an aluminum alloy fatigue tested in argon and in air with water vapor present.

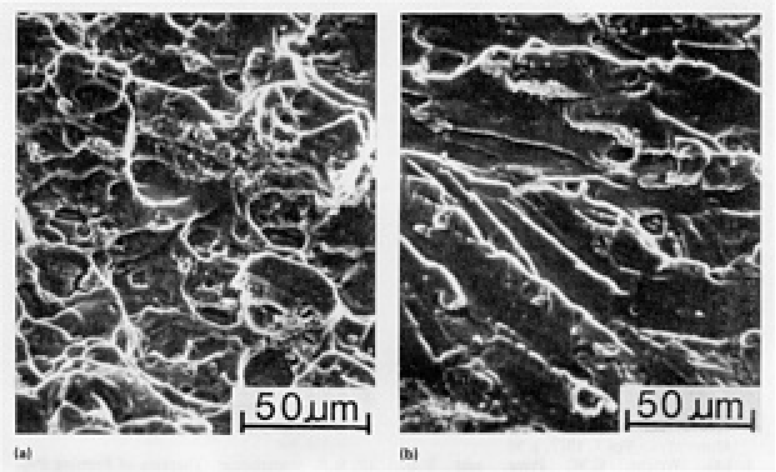

Fig. 25 Effect of water vapor on the fracture surface appearance of aluminum alloy 2219-T851 fatigue tested (a) in 1-atm dry argon and (b) in 0.2-torr water vapor. Testing conditions were the same except for frequency, which was 20 Hz in (a) and 5 Hz in (b). The magnifications, while too low to resolve fatigue striations clearly, indicate the general change in fracture morphology. Crack propagation was from left to right. Source: Ref 34

Temperature can have a significant effect on corrosion fatigue. The effect is complex and depends on temperature range and the particular material-environment combination in question, among other factors. The general tendency, however, is for fatigue crack growth rates to increase with increasing temperature.

Other factors, including the metallurgical condition of the material (such as composition and heat treatment) and the loading mode (such as uniaxial), affect corrosion fatigue crack propagation. These factors are discussed in the article "Environmental Effects on Fatigue Crack Propagation" in *Mechanical Testing,* Volume 8 of *ASM Handbook,* formerly 9th Edition *Metals Handbook* and "Corrosion-Fatigue Failures" in *Failure Analysis and Prevention,* Volume 11 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.* The article "Evaluation of Corrosion Fatigue" in this Volume contains detailed information on testing methods and the use of fracture mechanics to predict corrosion fatigue behavior.

Relationship Between Corrosion Fatigue and SCC. The relationship between corrosion fatigue and two other environmental cracking mechanisms, SCC and hydrogen embrittlement, is shown in Fig. 26. Many investigations have attempted to link the mechanisms of corrosion fatigue and other environmental cracking processes (especially SCC); examples of these include Ref 35, 36, 37. There are, however, many unanswered questions about the mechanisms of these phenomena. Experimental evidence relating SCC and corrosion fatigue is presented in the article "Evaluation of Corrosion Fatigue" in this Volume.

Environmentally Induced Cracking

Chairman: Bruce Craig, Metallurgical Consultants, Inc.

Introduction

THIS ARTICLE has been so titled to incorporate the forms of corrosion that produce cracking of metals as a result of exposure to their environment. This cracking may take the form of relatively slow, stable crack extension or, as is often the case, unpredictable catastrophic fracture.

The article is divided into four sections: stress-corrosion cracking, hydrogen damage (frequently referred to as hydrogen embrittlement), liquid-metal embrittlement, and solid metal induced embrittlement. In general, these different phenomena show many similarities, and it would at first seem appropriate to propose an all-encompassing mechanism to account for these behaviors. For example, all of these phenomena are generally dependent on yield strength and applied stress. As both of these factors increase, resistance to stress-corrosion cracking, hydrogen damage, liquid-metal embrittlement, and solid metal induced embrittlement decreases. However, as will be presented in the discussion of each of these phenomena, there are many differences encountered between the various forms of environmentally assisted cracking, and in fact, substantial differences are observed for behavior of metals and alloys within a specific form of cracking.

At this time, the understanding of each of these forms of cracking is largely phenomenological. No satisfactory theory exists for any of these mechanisms that totally explains all behavior observed either under laboratory or field conditions. Although many theories exist that are specific to the behavior of certain alloy systems or environments, none is universal enough to explain, for example, the diverse behavior of hydrogen damage for systems that develop hydrides versus alloys of iron that do not form hydrides. There are many of these contradictory factors that impede the development of an all-encompassing theory.

Additionally, there has been a continuing controversy over the last 20 years concerning the actual micromechanistic causes of stress-corrosion cracking, which some investigators consider to be related to hydrogen damage and not strictly an active-path corrosion phenomenon. Although certain convincing data exist for a role of hydrogen in stress-corrosion cracking of certain alloys, sufficient data are not available to generalize this concept.

As the understanding of these forms of cracking increases, the complexity of each also increases. For example, liquid-metal embrittlement has been a recognized form of cracking induced by liquid metals. However, it has recently been shown that certain metals can become embrittlers below their melting point and that embrittlement by these metals becomes progressively worse as the temperature approaches the melting point. This behavior, although similar to liquid-metal embrittlement, is sufficiently different to warrant reclassifying as solid metal induced embrittlement many of the environmentally assisted fractures that were previously termed liquid-metal embrittlement.

Because satisfactory mechanistic models have not been developed for any of these forms of environmental cracking, the prediction of environmentally assisted cracking is essentially non-existent. However, prediction of these types of failures is most important, because measurable corrosion usually does not occur before or during crack initiation or propagation. When corrosion does occur, it is highly localized (that is, pitting, crevice attack) and may be difficult to detect.

The field of environmentally assisted cracking is one of the most active in corrosion research, and it is continually changing. Therefore, the reader is encouraged to consult the most current literature for more detail on specific theories and alloy behavior. Additional information can also be found in the articles "Evaluation of Stress-Corrosion Cracking" and "Evaluation of Hydrogen Embrittlement" in this Volume.

Stress-Corrosion Cracking

R.H. Jones, Battelle Pacific Northwest Laboratories; R.E. Ricker, National Bureau of Standards

Stress-corrosion cracking (SCC) is a term used to describe service failures in engineering materials that occur by slow environmentally induced crack propagation. The observed crack propagation is the result of the combined and synergistic interaction of mechanical stress and corrosion reactions. This is a simple definition of a complex subject, and like most simplifications, it fails to identify the boundaries of the subject. As a result, before this problem can be discussed in detail, one must clearly define the type of loading involved, the types of materials involved, the types of environments that cause this type of crack propagation, and the nature of the interactions that result in this phenomenon. The term stress-corrosion cracking is frequently used to describe any type of environmentally induced or assisted crack propagation. However, in this discussion, the focus will be on the normal usage of the term as defined below.

One frequent misconception is that SCC is the result of stress concentration at corrosion-generated surface flaws (as quantified by the stress intensity factor, K); when a critical value of stress concentration, K_{crit}, is reached, mechanical fracture results. Although stress concentration does occur at such flaws, these do not exceed the critical value required to cause mechanical fracture of the material in an inert environment ($K_{SCC} < K_{crit}$). Precorrosion followed by loading in an inert environment will not result in any observable crack propagation, while simultaneous environmental exposure and application of stress will cause time-dependent subcritical crack propagation. The term synergy was used to describe this process because the combined simultaneous interaction of mechanical and chemical forces results in crack propagation where neither factor acting independently or alternately would result in the same effect. The exact nature of this interaction is the subject of numerous scientific investigations and will be covered in the discussion "Crack Propagation Mechanisms" in this section.

The stresses required to cause SCC are small, usually below the macroscopic yield stress, and are tensile in nature. The stresses can be externally applied, but residual stresses often cause SCC failures. However, compressive residual stresses can be used to prevent this phenomenon. Static loading is usually considered to be responsible for SCC, while environmentally induced crack propagation due to cyclic loading is defined as corrosion fatigue (see the section "Corrosion Fatigue" in the article "Mechanically Assisted Degradation" in this Volume). The boundary between these two classes of phenomena is vague, and corrosion fatigue is often considered to be a subset of SCC. However, because the environments that cause corrosion fatigue and SCC are not always the same, these two should be considered separate phenomena.

The term stress-corrosion cracking is usually used to describe failures in metallic alloys. However, other classes of materials also exhibit delayed failure by environmentally induced crack propagation. Ceramics exhibit environmentally induced crack propagation (Ref 1) and polymeric materials frequently exhibit craze cracking as a result of the interaction of applied stress and environmental reactions (Ref 2, 3, 4, 5). Until recently, it was thought that pure metals were immune to SCC; however, it has been shown that pure metals are susceptible to SCC (Ref 6, 7). This discussion will focus on the SCC of metals and their alloys and will not be concerned with stress-environment interactions in ceramics and polymers.

Environments that cause SCC are usually aqueous and can be condensed layers of moisture or bulk solutions. Typically, SCC of an alloy is the result of the presence of a specific chemical species in the environment. Thus, the SCC of copper alloys, traditionally referred to as season cracking, is virtually always due to the presence of ammonia in the environment, and chloride ions cause or exacerbate cracking in stainless steels and aluminum alloys. Also, an environment that causes SCC in one alloy may not cause SCC in another alloy. Changing the temperature, the degree of aeration, and/or the concentration of ionic species may change an innocuous environment into one that causes SCC failure. Also, an alloy may be immune in one heat treatment and susceptible in another. As a result, the list of all possible alloy-environment combinations that cause SCC is continually expanding, and the possibilities are virtually infinite. A partial listing of some of the more commonly observed alloy-environment combinations that result in SCC is given in Table 1.

Table 1 Alloy-environment systems exhibiting SCC

Alloy	Environment
Carbon steel	Hot nitrate, hydroxide, and carbonate/bicarbonate solutions
High-strength steels	Aqueous electrolytes, particularly when containing H_2S
Austenitic stainless steels	Hot, concentrated chloride solutions; chloride-contaminated steam
High-nickel alloys	High-purity steam
α-brass	Ammoniacal solutions
Aluminum alloys	Aqueous Cl^-, Br^-, and I^- solutions
Titanium alloys	Aqueous Cl^-, Br^-, and I^- solutions; organic liquids; N_2O_4
Magnesium alloys	Aqueous Cl^- solutions
Zirconium alloys	Aqueous Cl^- solutions; organic liquids; I_2 at 350 °C (660 °F)

In general, SCC is observed in alloy-environment combinations that result in the formation of a film on the metal surface. These films may be passivating layers, tarnish films, or dealloyed layers. In many cases, these films reduce the rate of general or uniform corrosion, making the alloy desirable for resistance to uniform corrosion in the environment. As a result, SCC is of greatest concern in the corrosion-resistant alloys exposed to aggressive aqueous environments. The exact role of the film in the SCC process is the subject of current research and will be covered in the discussion "Crack Propagation Mechanisms" in this section. Table 2 lists some alloy-environment combinations and the films that may form at the crack tip.

Table 2 Alloy-environment combinations and the resulting films that form at the crack tip

Metal or alloy	Environment	Initiating layer
α-brass, copper-aluminum	Ammonia	Dealloyed layer (Cu)
Gold-copper	$FeCl_3$	Dealloyed layer (Au)
	Acid sulphate	Dealloyed layer (Au)
Iron-chromium nickel	Chloride	Dealloyed layer (Ni)
	Hydroxide	Dealloyed layer or oxide

	High-temperature water	Dealloyed layer or oxide
α-brass	Nitrite	Oxide
Copper	Nitrite	Oxide
	Ammonia (cupric)	Porous dissolution zone
Ferritic steel	High-temperature water	Oxide
	Phosphate	Oxide (?)
	Anhydrated ammonia	Nitride
	$CO/CO_2/H_2O$	Carbide
	CS_2/H_2O	Carbide
Titanium alloys	Chloride	Hydride
Aluminum alloys, steels	Various media	Near-surface hydrogen

The Phenomenon of SCC

Stress-corrosion cracking is a delayed failure process. That is, cracks initiate and propagate at a slow rate (for example, 10^{-6} m/s) until the stresses in the remaining ligament of metal exceed the fracture strength. The sequence of events involved in the SCC process is usually divided into three stages:

- Crack initiation and stage 1 propagation
- Stage 2 or steady-state crack propagation
- Stage 3 crack propagation or final failure

Distinction among these stages is difficult because the transition occurs in a continuous manner and the division is therefore arbitrary. To enhance the understanding of this process, these steps will be discussed in the context of typical experimental techniques and results. Stress-corrosion cracking experiments can be classified into three different categories:

- Tests on statically loaded smooth samples
- Tests on statically loaded precracked samples
- Tests using slowly straining samples

More detailed information on these tests can be found in the article "Evaluation of Stress-Corrosion Cracking" in this Volume.

Tests on statically loaded smooth samples are usually conducted at various fixed stress levels, and the time to failure of the sample in the environment is measured. Figure 1 illustrates the typical results obtained from this type of test. In Fig. 1, the logarithm of the measured time to failure, t_f, is plotted against the applied stress, $\sigma_{applied}$, and the time to failure can be seen to increase rapidly with decreasing stress; a threshold stress, σ_{th}, is determined where the time to failure approaches infinity. The total time to failure at a given stress consists of the time required for the formation of a crack (the incubation or initiation time, t_{in}, and the time of crack propagation, t_{cp}. These experiments can be used to determine the maximum stress that can be applied to avoid SCC failure, to determine an inspection interval to confirm the absence of SCC crack propagation, or to evaluate the influence of metallurgical and environmental changes on SCC. However, the actual time for the formation or initiation of cracks is strongly dependent on a wide variety of parameters, such as surface finish and prior history. If a cracklike flaw or a crevice is present in the material, then the time to initiate a crack may be dramatically reduced (Ref 8).

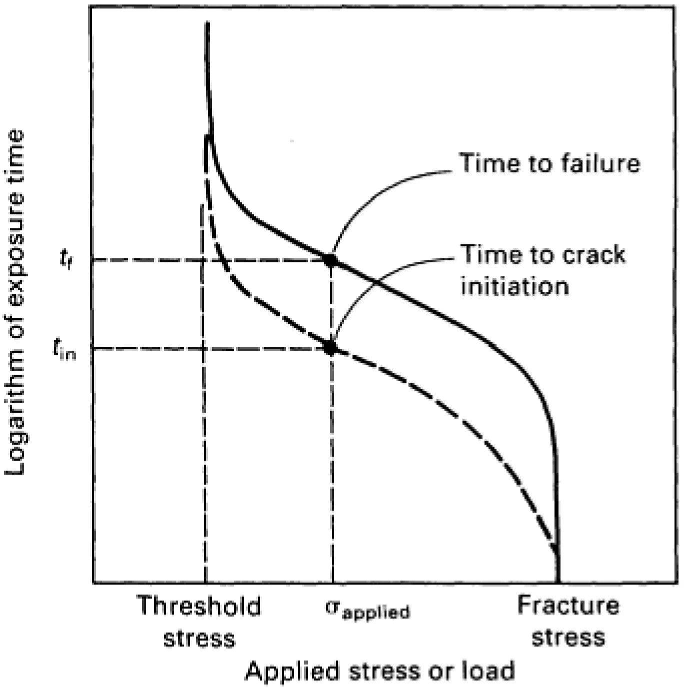

Fig. 1 Schematic of a typical time to failure as a function of initially applied stress for smooth sample stress-corrosion cracking tests

Tests on statically loaded precracked samples are usually conducted with either a constant applied load or with a fixed crack opening displacement, and the actual rate or velocity of crack propagation, *da/dt,* is measured (Ref 9). The magnitude of the stress distribution at the crack tip (the mechanical driving force for crack propagation) is quantified by the stress intensity factor, *K,* for the specific crack and loading geometry. As a result, the crack propagation rate, *da/dt,* is plotted versus *K* as illustrated in Fig. 2. These tests can be configured such that *K* increases with crack length (constant applied load), decreases with increasing crack length (constant crack mouth opening displacement), or is approximately constant as the crack length changes (special tapered samples). Each type of test has its advantages and disadvantages. However, in service, most SCC failures occur under constant-load conditions such that the stress intensity increases as the crack propagates. As a result, it is usually assumed in SCC discussions that the stress intensity is increasing with increasing crack length.

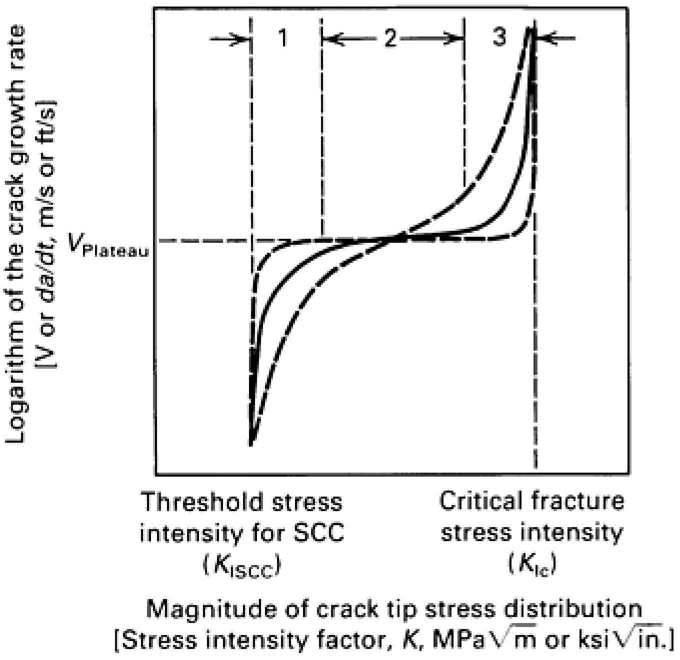

Fig. 2 Schematic diagram of typical crack propagation rate as a function of crack tip stress intensity behavior illustrating the regions of stage 1, 2, and 3 crack propagation as well as identifying the plateau velocity and the threshold stress intensity

Typically, three regions of crack propagation rate versus stress intensity level are found during crack propagation experiments. These are identified according to increasing stress intensity factor as stage 1, 2, or 3 crack propagation (Fig. 2). No crack propagation is observed below some threshold stress intensity level, K_{ISCC}. This threshold stress level is determined not only by the alloy but also by the environment and metallurgical condition of the alloy, and presumably, this level corresponds to the minimum required stress level for synergistic interaction with the environment. At low stress intensity levels (stage 1), the crack propagation rate increases rapidly with the stress intensity factor. At intermediate stress intensity levels (stage 2), the crack propagation rate approaches some constant velocity that is virtually independent of the mechanical driving force. This plateau velocity is characteristic of the alloy-environment combination and is the result of rate-limiting environmental processes such as mass transport of environmental species up the crack to the crack tip. In stage 3, the rate of crack propagation exceeds the plateau velocity as the stress intensity level approaches the critical stress intensity level for mechanical fracture in an inert environment, K_{Ic} (Ref 10).

Slow Strain Rate Testing. Stress-corrosion tests can also be conducted by slowly increasing the load or strain on either precracked or smooth samples. Usually, a tensile machine pulls a smooth sample that is exposed to the corrosive environment at a low cross head speed (10^{-5} to 10^{-9} m/s). The strain to failure in the corrosive environment and the strain to failure in an inert environment can then be plotted against the strain rate, as shown in Fig. 3(a), or the ratio of these measurements can be plotted as shown in Fig. 3(b). The ratio of other tensile property measurements, such as reduction in area and ultimate tensile strength, may be plotted. These tests are called constant extension rates tests (CERT), slow strain rate tests, or straining electrode tests. These are excellent tests for comparing the relative susceptibility of alloys to cracking in an environment or for studying the influence of metallurgical variables on the susceptibility of an alloy. However, the application of this data to the prediction of actual in-service crack propagation rates is difficult and unreliable.

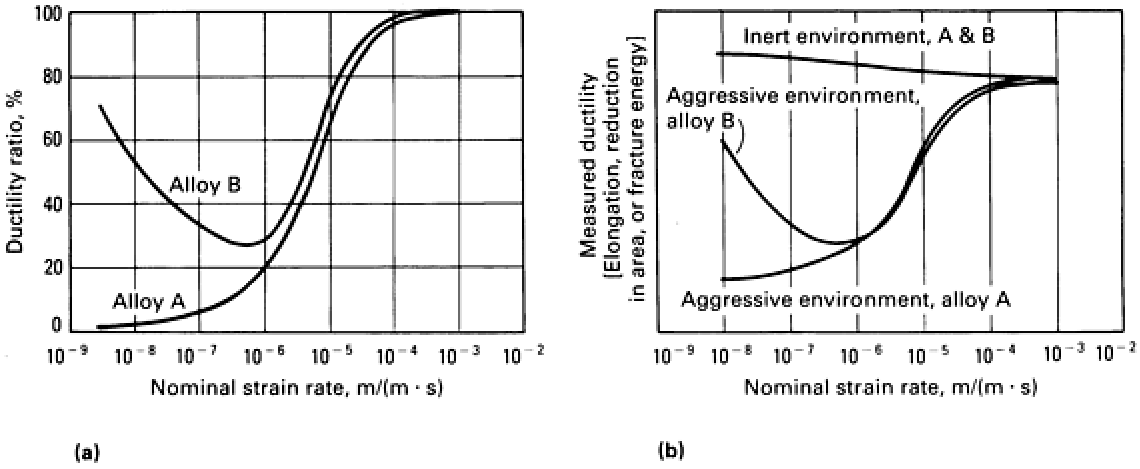

Fig. 3 Strain to failure plots resulting from slow strain rate testing. (a) Schematic of typical ductility versus strain rate behavior of two different types of alloys tested by the slow strain rate technique. (b) The ductility ratio is the ratio of a ductility measurement such as elongation, reduction in area, and fracture energy measured in the aggressive environment to that obtained in the inert reference environment.

Overview of Mechanisms

Many different mechanisms have been proposed to explain the synergistic stress-corrosion interaction that occurs at the crack tip, and there may be more than one process that causes SCC. The proposed mechanisms can be classed into two basic categories:

- Anodic mechanisms
- Cathodic mechanisms

That is, during corrosion, both anodic and cathodic reactions must occur, and the phenomena that result in crack propagation may be associated with either class of reactions. The most obvious anodic mechanism is that of simple active dissolution and removal of material from the crack tip. The most obvious cathodic mechanism is hydrogen evolution, absorption, diffusion, and embrittlement. However, a specific mechanism must attempt to explain the actual crack propagation rates, the fractographic evidence, and the mechanism of formation or nucleation of cracks. Some of the more prominent of the proposed mechanisms will be covered in greater detail in the discussion "Crack Propagation Mechanisms" in this section, but they usually assume that breaking of the interatomic bonds of the crack tip occurs by one of the following mechanisms:

- Chemical solvation and dissolution
- Mechanical fracture (ductile or brittle)

Mechanical fracture includes normal fracture processes that are assumed to be stimulated or induced by one of the following interactions between the material and the environment:

- Adsorption of environmental species
- Surface reactions
- Reactions in the metal ahead of the crack tip
- Surface films

All of the proposed mechanisms contain one or more of these processes as an essential step in the SCC process. Specific mechanisms differ in the processes assumed to be responsible for crack propagation and the way that environmental reactions combine to result in the actual fracture process.

Controlling Parameters

The mechanisms that have been proposed for SCC require that certain processes or events occur in sequence for sustained crack propagation to be possible. These requirements explain the plateau region in which the rate of crack propagation is independent of the applied mechanical stress. That is, a sequence of chemical reactions and processes is required, and the rate-limiting step in this sequence of events determines the limiting rate or plateau velocity of crack propagation (until mechanical overload fracture starts contributing to the fracture process in stage 3). Figure 4 illustrates a crack tip in which crack propagation results from reactions in metal ahead of the propagating crack. Close examination of Fig. 4 will reveal that potential rate-determining steps include:

- Mass transport along the crack to the crack tip
- Reactions in the solution near the crack
- Surface adsorption at or near the crack tip
- Surface diffusion
- Surface reactions
- Absorption into the bulk
- Bulk diffusion to the plastic zone ahead of the advancing crack
- Chemical reactions in the bulk
- The rate of interatomic bond rupture

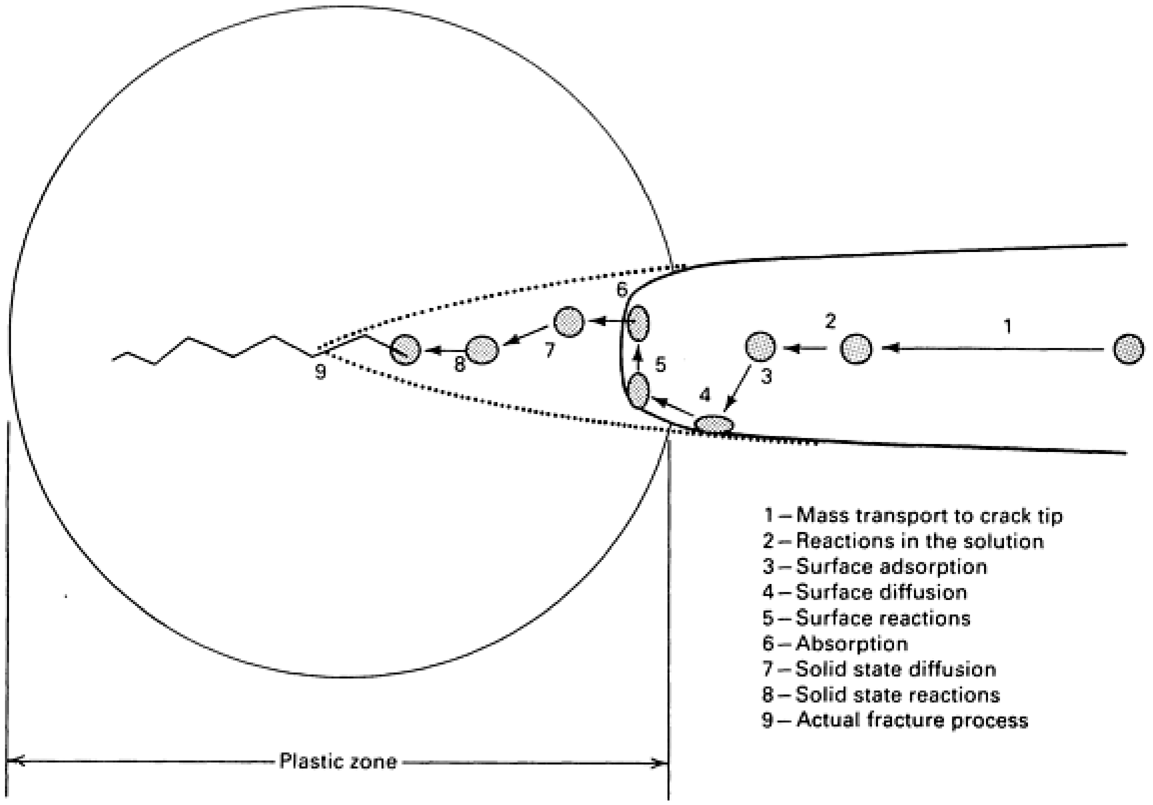

Fig. 4 Schematic of crack tip processes that may be the rate-determining step in environmentally assisted crack propagation

Changes in the environment that modify the rate-determining step will have a dramatic influence on the rate of crack propagation, while alterations to factors not involved in the rate-determining step or steps will have little influence, if any. However, significantly retarding the rate of any one of the required steps in the sequence could make that step the rate-determining step. In aqueous solutions, the rate of adsorption and surface reactions is usually very fast compared to the rate of mass transport along the crack to the crack tip. As a result, bulk transport into this region or reactions in this region are frequently believed to be responsible for determining the steady-state crack propagation rate or plateau velocity. In gaseous environments, surface reactions, surface diffusion, and adsorption may be rate limiting, as well as the rate of bulk transport to the crack tip (Ref 11, 12).

Several different environmental parameters are known to influence the rate of crack growth in aqueous solutions. These include, but are not limited to:

- Temperature
- Pressure
- Solute species
- Solute concentration and activity
- pH
- Electrochemical potential
- Solution viscosity
- Stirring or mixing

Altering any of these parameters may alter the rate of the rate-controlling steps, either accelerating or reducing the rate of crack propagation. Also, it may be possible to arrest or stimulate crack propagation by altering the rate of an environmental reaction. It is well known and generally accepted that the environment at occluded sites, such as a crack tip, can differ significantly from the bulk solution. If an alteration to the bulk environment allows the formation of a critical SCC environment at crack nuclei, then crack propagation will result. If the bulk environment cannot maintain this local crack tip environment, then crack propagation will stop. As a result, slight changes to the environment may have a dramatic influence on crack propagation, while dramatic changes may have only a slight influence.

In addition to the environmental parameters listed above, stress-corrosion crack propagation rates are influenced by:

- The magnitude of the applied stress or the stress intensity factor
- The stress state, which includes (1) plane stress and (2) plane strain
- The loading mode at the crack tip
- Alloy composition, which includes (1) nominal composition, (2) exact composition (all constituents), and (3) impurity or tramp element composition
- Metallurgical condition, which includes (1) strength level, (2) second phases present in the matrix and at the grain boundaries, (3) composition of phases, (4) grain size, (5) grain-boundary segregation, and (6) residual stresses
- Crack geometry, which includes (1) length, width, and aspect ratio, and (2) crack opening and crack tip closure

Important Fracture Features

Stress-corrosion cracks can initiate and propagate with little outside evidence of corrosion and no warning as catastrophic failure approaches. The cracks frequently initiate at surface flaws that are either preexisting or formed during service by corrosion, wear, or other processes. The cracks then grow with little macroscopic evidence of mechanical deformation in metals and alloys that are normally quite ductile. Crack propagation can be either intergranular or transgranular; sometimes, both types are observed on the same fracture surface. Crack openings and the deformation associated with crack propagation may be so small that the cracks are virtually invisible except in special nondestructive examinations. As the stress intensity increases, the plastic deformation associated with crack propagation increases, and the crack opening increases. When the final fracture region is approached, plastic deformation can be appreciable because corrosion-resistant alloys are frequently quite ductile. The features of stress-corrosion fracture surfaces are covered in

greater detail in the article "Modes of Fracture" and the "Atlas of Fractographs" in *Fractography,* Volume 12 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Phenomenology of Crack Initiation Processes

Crack Initiation at Surface Discontinuities. Stress-corrosion cracking frequently initiates at preexisting or corrosion-induced surface features. These features may include grooves, laps, or burrs resulting from fabrication processes. Examples of such features are shown in Fig. 5; these were produced during grinding in the preparation of a joint for welding. The feature shown in Fig. 5(a) is a lap, which subsequently recrystallized during welding and could now act as a crevice at which deleterious cations concentrate. The highly sensitized recrystallized material could also more readily become the site of crack initiation by intergranular corrosion. A cold-worked layer and surface burrs, shown in Fig. 5(b), can also assist crack initiation.

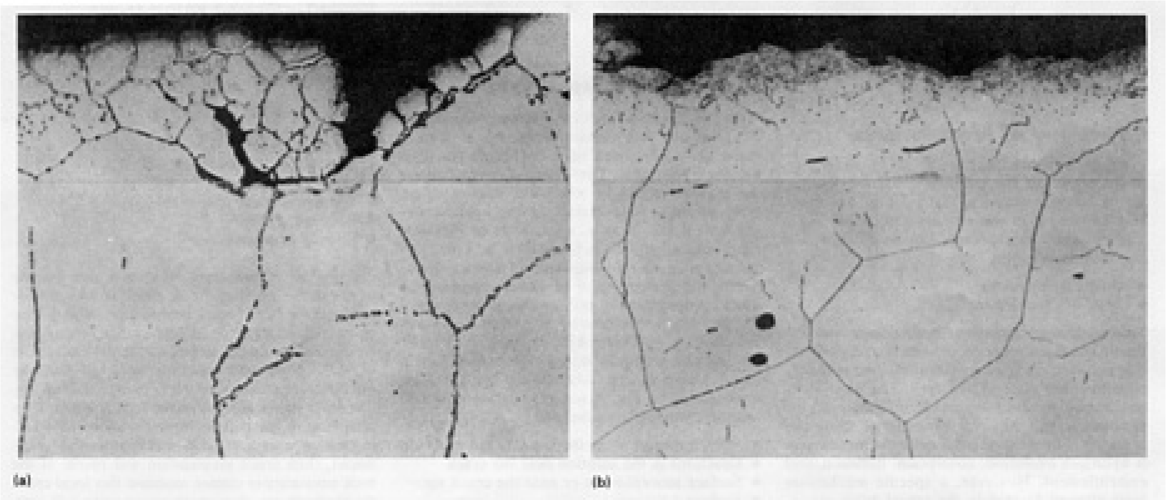

Fig. 5 Optical micrographs showing defects on the inner surface of type 304 stainless steel pipe near weld root (a) and near through crack (b). Both 1000×

Crack Initiation at Corrosion Pits. Stress-corrosion cracks can also initiate at pits that form during exposure to the service environment (Fig. 6) or by prior cleaning operations, such as pickling of type 304 stainless steel before fabrication. Pits can form at inclusions that intersect the free surface or by a breakdown in the protective film. In electrochemical terms, pits form when the potential exceeds the pitting potential. It has been shown that the SCC potential and pitting potential were identical for steel in nitrite solutions (Ref 13).

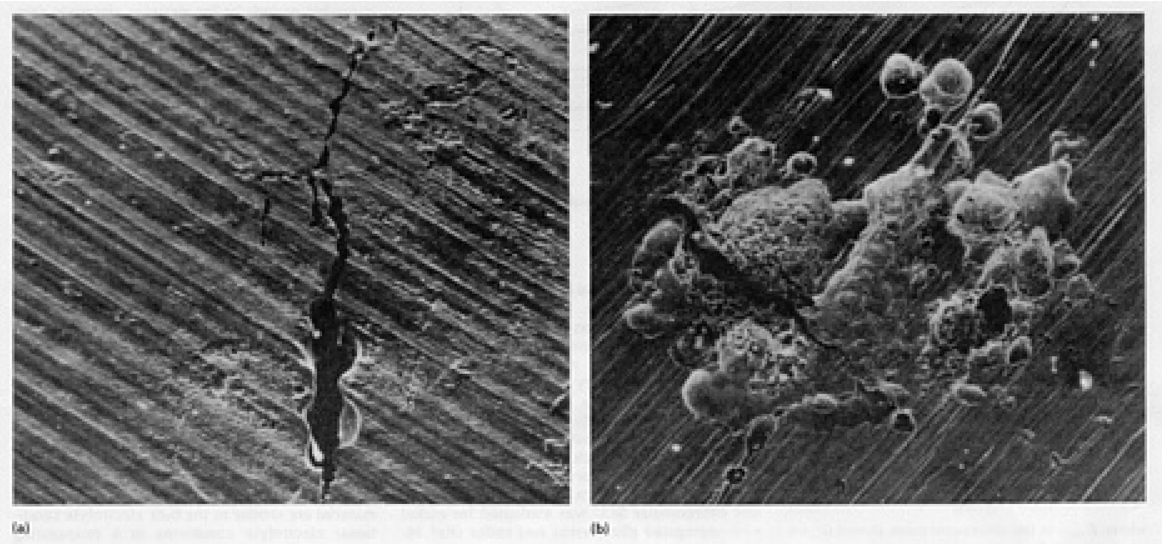

Fig. 6 Stress-corrosion crack initiating from a corrosion pit in a quenched-and-tempered high-strength turbine disk steel (3.39Ni-1.56Cr-0.63Mo-0.11V) test coupon exposed to oxygenated, demineralized water for 800 h under a bending stress of 90% of the yield stress. The transition between pitting and cracking is dependent on the same parameters that control SCC, that is, the electrochemistry at the base of the pit, pit geometry, chemistry of the material, and stress or strain rate at the base of the pit. A detailed description of the relationship between these parameters and crack initiation has not been developed, because of the difficulty in measuring crack initiation. Methods for measuring short surface cracks are under development, but are limited to detecting cracks that are beyond the initiation stage. The pit geometry is important in determining the stress and strain rate at the base of the pit. Generally, the aspect ratio between the penetration and the lateral corrosion of a pit must be greater than about 10 before a pit acts as a crack initiation site. A penetration to lateral corrosion ratio of 1 corresponds to uniform corrosion, and a ratio of about 1000 is generally observed for a growing stress-corrosion crack. As in the case of a growing crack, the pit walls must exhibit some passive film forming capability in order for the corrosion ratio to exceed 1.

A change in the corrosive environment and potential within a pit may also be necessary for the pit to act as a crack initiator. Pits can act as occluded cells similar to cracks and crevices, although in general their volume is not as restricted. There are a number of examples in which stress-corrosion cracks initiated at the base of a pit by intergranular corrosion. In these circumstances, the grain-boundary chemistry and the pit chemistry were such that intergranular corrosion was favored. Crack propagation was also by intergranular SCC in these cases.

Although the local stresses and strain rates at the base of the pit play a role in SCC initiation, there are examples of preexisting pits that did not initiate stress-corrosion cracks. This observation has led to the conclusion that the electrochemistry of the pit is more important than the local stress or strain rate (Ref 13). A preexisting pit may not develop the same local electrochemistry as one grown during service because the development of a concentration cell depends on the presence of an actively corroding tip that establishes the anion and cation current flows. Similarly, an inability to reinitiate crack growth in samples in which active growth was occurring before the samples were removed from solution, rinsed, dried, and reinserted into solution also suggests that the local chemistry is very important.

Crack Initiation by Intergranular Corrosion or Slip Dissolution. Stress-corrosion crack initiation can also occur in the absence of pitting by intergranular corrosion or slip-dissolution processes. Intergranular corrosion-initiated SCC requires that the local grain-boundary chemistry differ from the bulk chemistry. This condition occurs in sensitized austenitic stainless steels or with the segregation of impurities such as phosphorus, sulfur, or silicon in a variety of materials. Slip-dissolution-initiated SCC results from local corrosion at emerging slip planes and occurs primarily in low stacking fault materials. The processes of crack initiation and propagation by the slip-dissolution process are in fact very similar.

Crack Initiation Mechanisms

Although the features causing SCC initiation, such as pits, fabrication defects, and intergranular corrosion, are easily observed and identified, there are few well-developed models of SCC initiation. This lack of models for crack initiation mechanisms is the result of several complicating factors. For example, the initiation of a crack is difficult to measure experimentally, even though it is not difficult to detect the location from which a growing crack has emanated. Furthermore, crack initiation has not been precisely defined, and it is difficult to determine at what point a pit is actually a crack and when intergranular corrosion becomes intergranular SCC. Also, the fracture mechanics concept of design assumes preexisting flaws in materials, although these may not be surface flaws that can become stress-corrosion cracks. It has been demonstrated that the corrosion fatigue threshold of 12% Cr and 2.0% NiCrMoV steels could be related to the minimum depth of surface pits, as shown in Fig. 7. Using a linear-elastic fracture mechanics approach and relating a pit to a half-elliptical surface crack, one researcher has shown that the critical pit dimension could be expressed by the following relationship (Ref 14):

$$a_0 = \frac{1}{\pi}\left(\frac{\Delta K_{th}}{F\Delta\sigma_0}\right)^2 \quad \textbf{(Eq 1)}$$

where ΔK_{th} is the corrosion fatigue threshold, F is a constant, and $\Delta\sigma_0$ is the alternating surface stress. A pit could be represented by a half-elliptical surface crack because it had intergranular corrosion at the base that caused the pit to have cracklike characteristics.

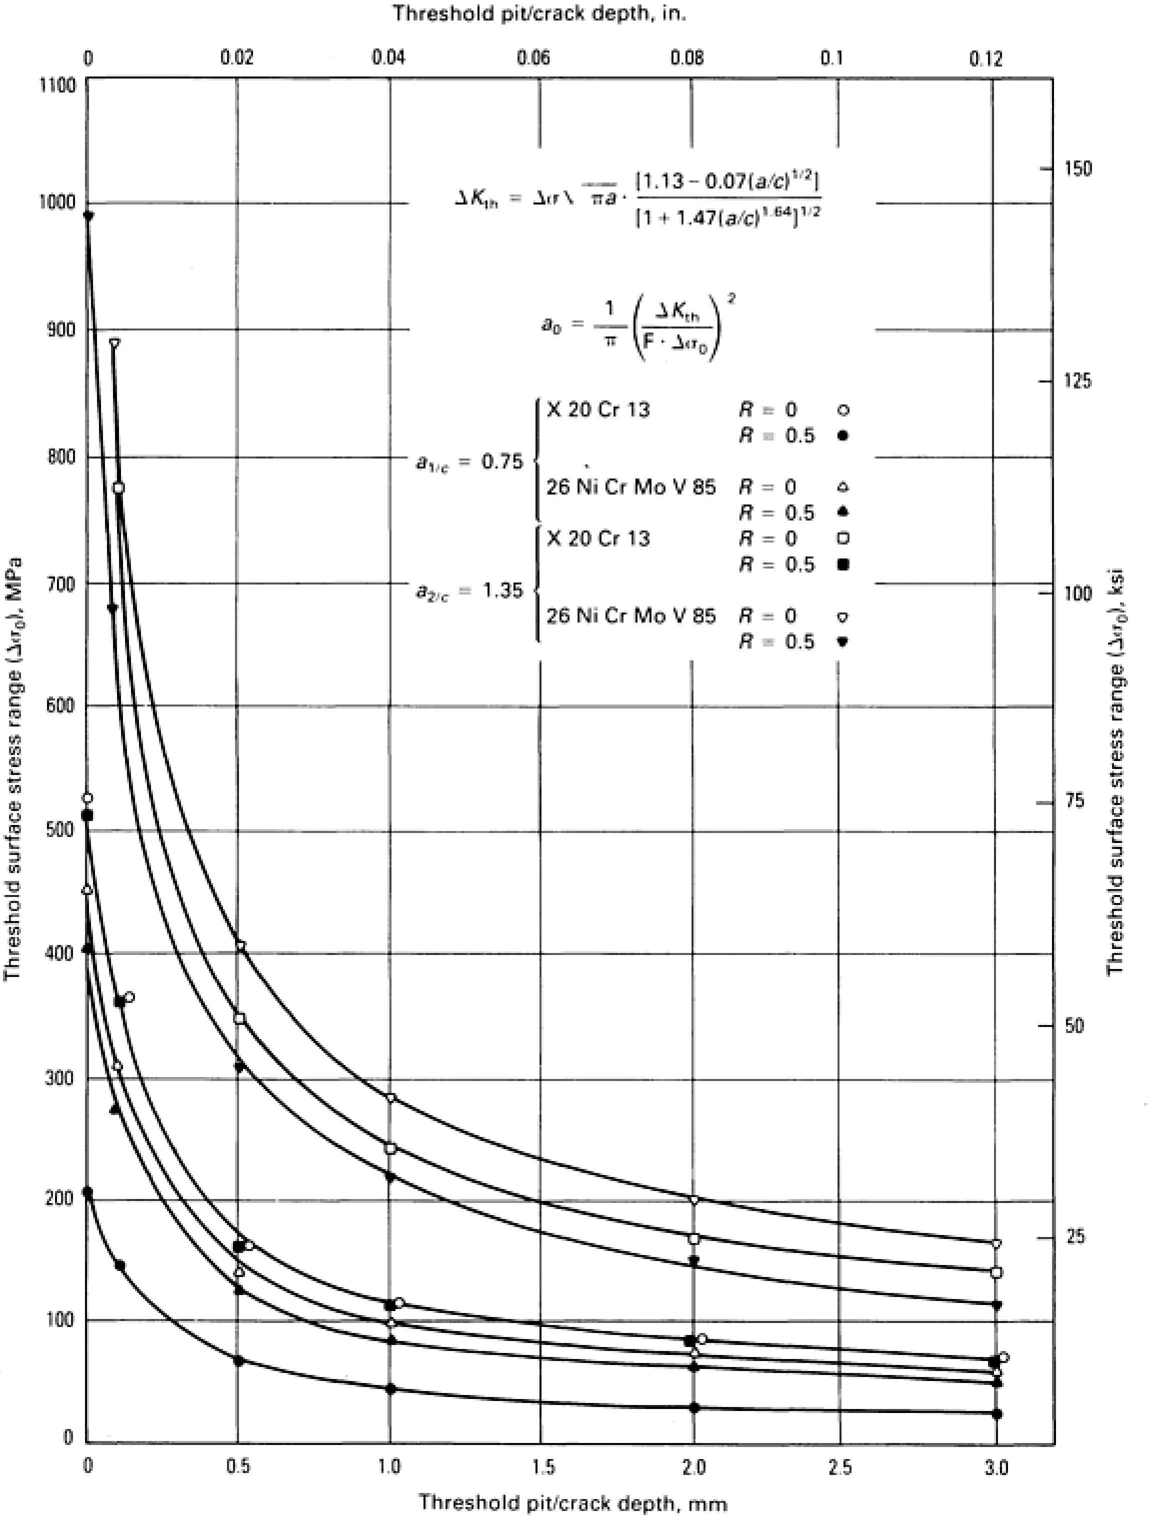

Fig. 7 Relationship between stress amplitude and minimum depth of surface defects for 12% Cr steel and a 2.0% NiCrMoV steel. Source: Ref 14

A model for stress-corrosion crack growth was developed from pits in brass tested in a non-tarnishing ammoniacal solution (Ref 15). The researchers evaluated the corrosion and stress aspects of a pit to develop a model for crack initiation. They assumed that the corrosion conditions in the base of the pit were essentially the same as those on a flat surface and that initiation required that a critical crack tip opening displacement be exceeded. Using linear-elastic fracture mechanics, the researchers developed the following relationship for the time to initiate a crack:

$$t_{inc} = \frac{(K_{ISCC})^2}{\pi B (\sigma^2 - \sigma_0^2)} \exp\left(\frac{-V_m}{V_0}\right)$$ **(Eq 2)**

where K_{ISCC} is the stress-corrosion threshold for crack growth for brass in ammoniacal solution, σ is the applied stress, σ_0 is the stress needed to close the crack, B is a constant, $-V_m$ is the electrochemical potential of the sample, and V_0 is the reversible potential. However, the assumption that the pit corrosion conditions are equal to the flat surface conditions limits the applicability of this model, because it is generally accepted that the electrochemistry in a pit is considerably different from that of a flat surface. Also, this model does not explicitly describe the transition from a pit to a crack, but treats a pit as a small crack in which the crack tip opening and crack depth are affected by corrosion.

The transition between intergranular corrosion and intergranular SCC was evaluated for nickel with segregated phosphorus and sulfur (Ref 16, 17). Because phosphorus and sulfur inhibit the formation of a passive film on nickel, it was expected that intergranular SCC would be similar in these two materials. It was observed, however, that only shallow intergranular corrosion to a depth of about 0.1 mm (0.004 in.) resulted in nickel in which sulfur was segregated to the grain boundary when tested at a strain rate of 10^{-6} in 1 *N* sulfuric acid (H_2SO_4). On the other hand, rapid intergranular SCC resulted in nickel in which phosphorus was segregated to the grain boundaries that was tested under similar conditions. Using crack tip chemistry modeling, it was shown that intergranular corrosion did not convert to a stress-corrosion crack in Ni+S because the sulfur remained on the crack walls, causing the electrolyte in the solution to become saturated and the crack tip corrosion rate to drop to zero. Starting from a flat surface, the corrosion current at the tip of the intergranular corrosion penetration was about 30 mA/cm^2 (195 mA/in.^{2}) and decreased to 0 at a depth of about 0.08 mm (0.003 in.), as shown in Fig. 8. A similar corrosion depth was measured for samples held at 900 mV for extended periods or for straining electrode samples, while for Ni+P a crack growth rate of 10^{-4} mm/s was measured. These results indicate the importance of electrochemistry in the base of a pit or an intergranular penetration and show that the occurrence of intergranular corrosion does not *a priori* indicate that intergranular SCC will follow.

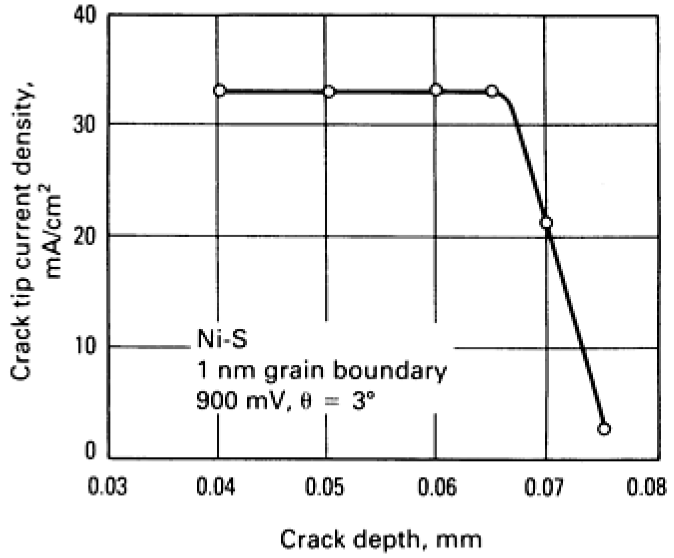

Fig. 8 Effect of crack depth on crack tip corrosion rates for nickel with actively corroding crack walls

Phenomenology of Crack Propagation Processes

Crack initiation and propagation are related but different processes; however, by definition, if a crack initiates, it will propagate. As indicated in the discussion "Crack Initiation Mechanisms" in this section, cracks may initiate at preexisting surface flaws if the necessary electrochemical, mechanical, and metallurgical conditions are met, or corrosion processes may create a surface flaw by pitting or localized corrosion. The conditions that create a pit or localized corrosion at chemical inhomogeneities such as grain boundaries, inclusions, second phases, and interphase boundaries are not

necessarily the same as those needed for sustained crack growth. For example, the electrochemical conditions near the surface of a material are similar to the bulk electrolyte conditions; electrolyte conditions in a propagating crack generally differ from the bulk electrolyte. If the conditions at the tip of the growing pit or localized corrosion penetration cannot achieve the proper pH, potential, or chemistry, crack propagation may not proceed. Also, if the pit aspect ratio is not greater than a critical value, then the local stresses and strains resulting from a sustained sharp crack are not attained and crack growth cannot occur. Lastly, for stress-corrosion crack growth resulting from cathodic hydrogen, a short crack may have to initiate by an anodic dissolution process, while propagation depends on hydrogen activity.

Although there are conditions under which local corrosion or pitting may not result in crack propagation, it is more frequent that they do lead to cracking. Three conditions frequently cited as requirements for sustained SCC are a susceptible material, a corrosive environment, and an adequate stress. The list of susceptible material conditions and corrosive environments that are known to cause SCC has been steadily expanding. For example, pure metals are known to crack when impurities are segregated to grain boundaries, nonsensitized stainless steels crack in high-purity water, and ferritic steels crack in environments other than nitrate and caustic solutions. Similarly, the details of the microstructure and microchemistry of a susceptible material, specific ions and chemistry, pH, potential, the corrosion rates of the local crack tip associated with a corrosive environment, and the crack tip stresses, strains, and strain rates associated with cracking are better known today than they were previously. Knowledge and understanding of the factors and mechanisms of stress corrosion are continuing to expand; however, a number of factors are well established. The phenomenological description of stress corrosion based on these known factors is presented in this section.

Environmental Factors

Environmental effects on SCC are frequently summarized simply by listing alloy-environment combinations in which SCC has been observed, such as that in Table 1. In recent years, the number of such combinations has increased. Added to this list is the observation of the transgranular SCC of copper, the intergranular SCC of pure metals such as iron and nickel, and the SCC of materials in high-purity water in the absence of specific anions. Stress-corrosion cracking of pure metals was thought to be impossible in early lists of material-environment combinations, but it is now realized that specific environment/metal reactions occur that allow crack advance. In the case of intergranular SCC of iron and nickel, this reaction occurs between the environment and impurities segregated to the grain boundaries (a condition that exists in many pure metals and engineering alloys).

This increase in known susceptible materials can be attributed to the use of new SCC tests, refined crack propagation monitoring equipment, improved electrochemical control equipment, and, perhaps most importantly, the increased research activity in this field over the last 20 to 30 years. Expectations for material performance have also increased with time as materials are used in more aggressive environments under more demanding loading conditions. Lists such as that given in Table 1 can be useful in materials selection for a design involving corrosive environments, because it can lead the materials engineer to seek more specific information on the materials and environments in question. However, such lists can also be misleading because service conditions may differ markedly from those in which the susceptibility listed in Table 1 was determined. Because SCC is dependent on bulk alloy chemistry, microstructure, microchemistry, loading parameters, and specific environmental factors such as oxidizing potential and pH, lists of the type given in Table 1 should be used only for a general overview of SCC.

A complete description of SCC must treat both the thermodynamic requirements and kinetic aspects of cracking. A knowledge of the thermodynamic conditions will help determine whether cracking is feasible; kinetic information describes the rate at which cracks propagate. There are thermodynamic requirements both for anodically assisted SCC (where crack propagation is dependent either directly or indirectly on the oxidation of metal atoms from the crack tip and their dissolution in the electrolyte) and for hydrogen-assisted crack growth resulting from the reduction of hydrogen ions at the crack tip.

Thermodynamics of SCC. The thermodynamic conditions for anodically assisted SCC are that dissolution or oxidation of the metal and its dissolution in the electrolyte must be thermodynamically possible and that a protective film, such as an oxide or salt, must be thermodynamically stable. The first condition becomes a requirement because, without oxidation, crack advance by dissolution would not result. That a process is controlled by anodic dissolution does not *a priori* indicate that the total crack extension is the sum of the total number of coulombs of charge exchanged at the crack tip. There are crack advance processes in which the crack advance is controlled by anodic dissolution but in which the total crack length is greater than can be accounted for by the total charge transfer. These processes are covered in the discussion "Crack Propagation Mechanisms" in this section. However, it is important to note that if the brittle crack advance process is initiated and controlled by anodic dissolution, the crack growth rate will be zero if the anodic current

density is zero and will increase with increasing current density. This also holds true for crack advance resulting from brittle crack jump.

The thermodynamic requirement of simultaneous film formation and oxidation for stress-corrosion crack growth can be understood from the diagram shown in Fig. 9, in which the ratio of the corrosion currents from the walls relative to the crack tip is the critical parameter. This ratio must be substantially less than 1 for a crack to propagate; otherwise, the crack will blunt, or the crack tip solution will saturate. Crack initiation can also be controlled by this ratio, because a pit with a high wall corrosion rate will broaden as fast or faster than it will penetrate, resulting in general corrosion rather than crack growth. It is generally believed that the activity of the crack walls relative to the crack tip is a consequence of greater dynamic strain at the tip than along the walls.

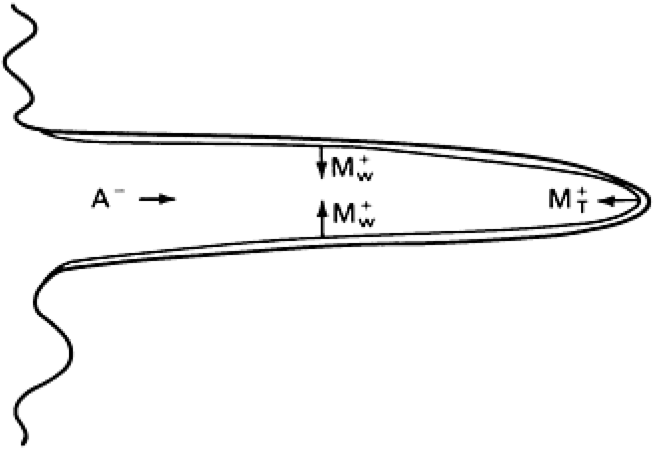

Fig. 9 Schematic of stress-corrosion crack showing important transport and corrosion reactions. A^- represents negatively charged anions migrating to the crack tip, M_W^+ represents metal ions entering the crack solution from the crack walls, and M_T^+ are metal ions entering the crack solution from the crack tip.

A thermodynamic requirement of simultaneous film formation and oxidation of the underlying material led to the identification of critical potentials for the presence or absence of SCC. An example of these critical potentials is shown in Fig. 10 for a passive film forming material such as stainless steel. Zones 1 and 2 are those in which transgranular stress-corrosion crack growth is most likely to occur; intergranular stress-corrosion crack growth can occur over a wider range of potentials than these two zones. Transgranular SCC occurs in zone 1 because the material is in transition from active corrosion to passive film formation such that the simultaneous conditions for film formation on the crack walls and corrosion at the crack tip are met. A similar condition exists in zone 2, with the added factor that these potentials are at or above the pitting potential so that cracks can initiate by pitting.

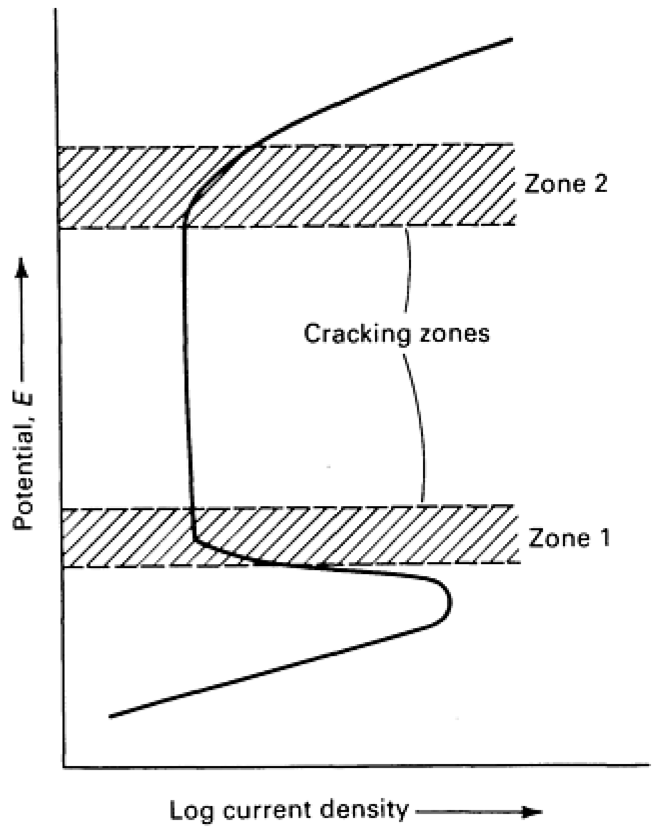

Fig. 10 Potentiokinetic polarization curve and electrode potential values at which stress-corrosion cracking appears

Intergranular SCC occurs over a wider range of potentials than those shown for zones 1 and 2 because chemical inhomogeneities at the grain boundary produce a different electrochemical response relative to the bulk material. Therefore, passive crack walls and active crack tips can result over the potential range from zone 1 to zone 2.

Examples of the critical potentials for SCC are shown in Fig. 11 for several materials. Identification of critical potentials for SCC has led to the use of electrochemical methods for assessing stress-corrosion susceptibility. Zones 1 and 2 are identified by determining the electrochemical potential versus current curves, as shown in Fig. 10 and 11. The shapes of these curves determined at high and low sweep rates are also used to indicate potentials at which the simultaneous conditions of film formation and metal oxidation occur.

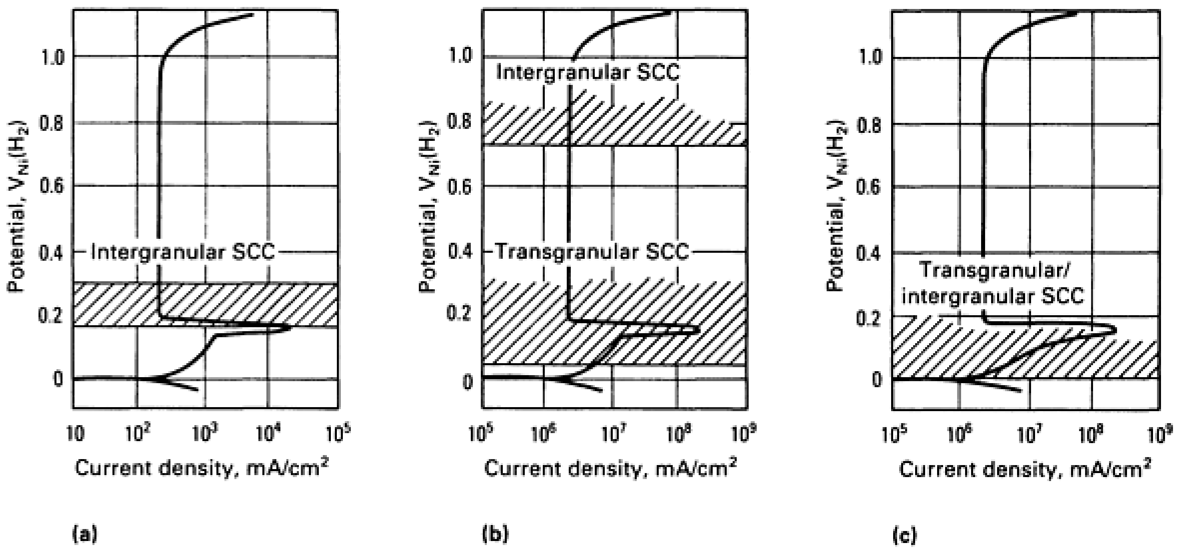

Fig. 11 Potentiokinetic polarization curve and electrode potential values at which intergranular and transgranular stress-corrosion cracking appears in a 10% NaOH solution at 288 °C (550 °F). (a) Alloy 600. (b) Alloy 800. (c) AISI type 304 stainless steel

Application of Potential-pH Diagrams. Critical potentials for SCC can also be related to potential-pH stability diagrams (Pourbaix diagrams), because these diagrams describe the conditions at which film formation and metal oxidation will occur. An example for carbon steel is given in Fig. 12, in which SCC is associated with potentials and pHs at which phosphate, carbonate, or magnetite films are thermodynamically stable while the species Fe^{2+} and $HFeO_2^-$ are metastable. A second example of the potential-pH regimes in which SCC occurs is given in Fig. 13 for a 70Cu-30Zn brass in a variety of solutions.

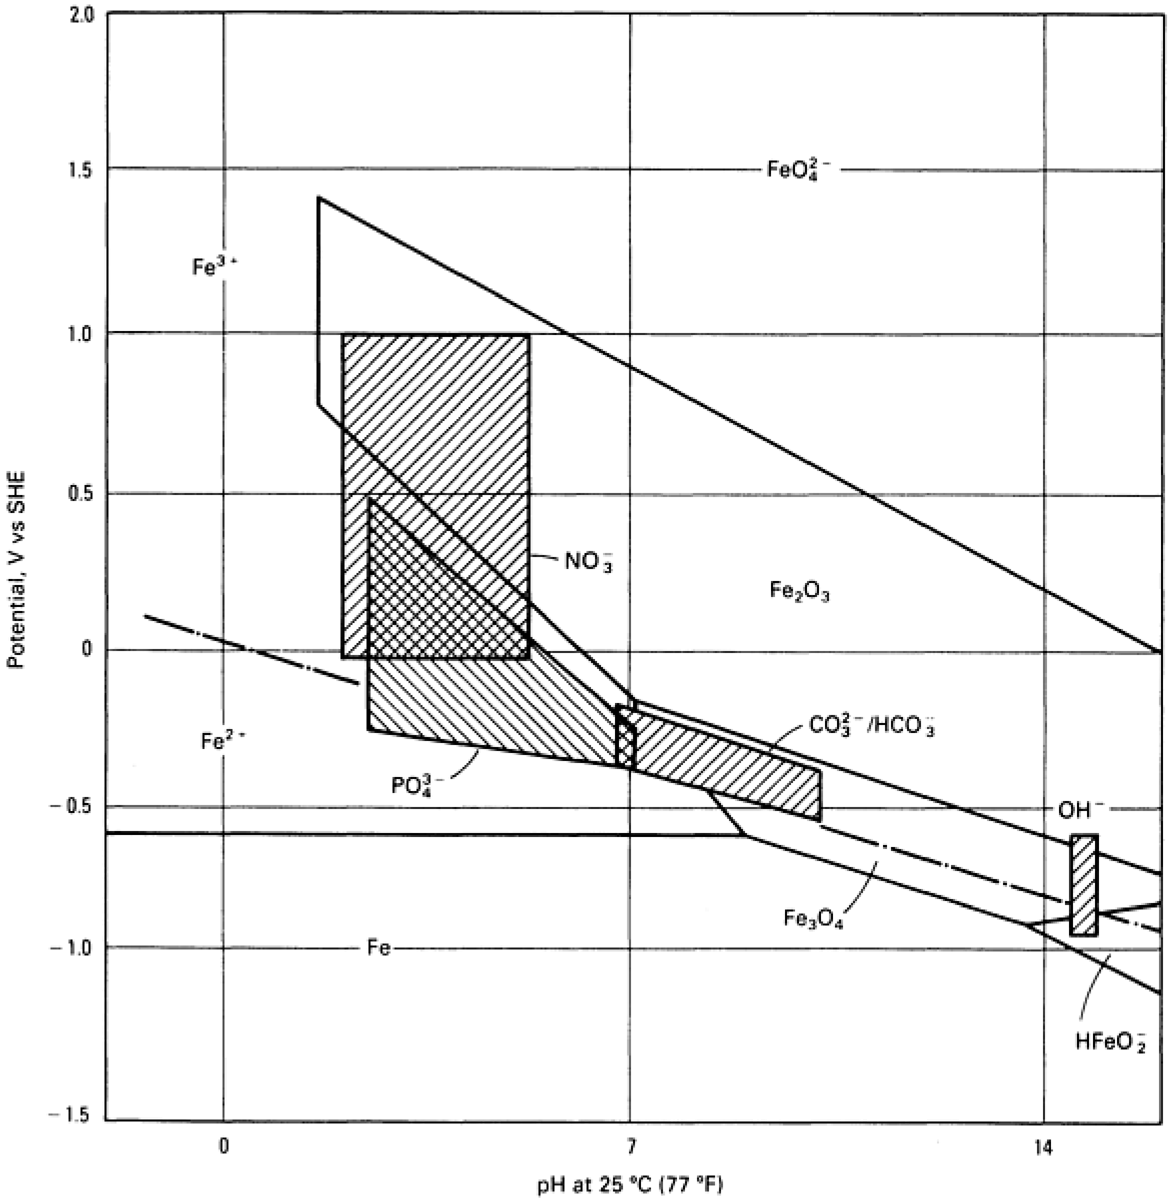

Fig. 12 Relationship between pH-potential conditions for severe cracking susceptibility of carbon steel in various environments and the stability regions for solid and dissolved species on the Pourbaix diagram. Note that severe susceptibility is encountered where a protective film (phosphate, carbonate, magnetite, and so on) is thermodynamically stable, but if ruptured, a soluble species (Fe^{2+}, $HFeO_2^-$) is metastable.

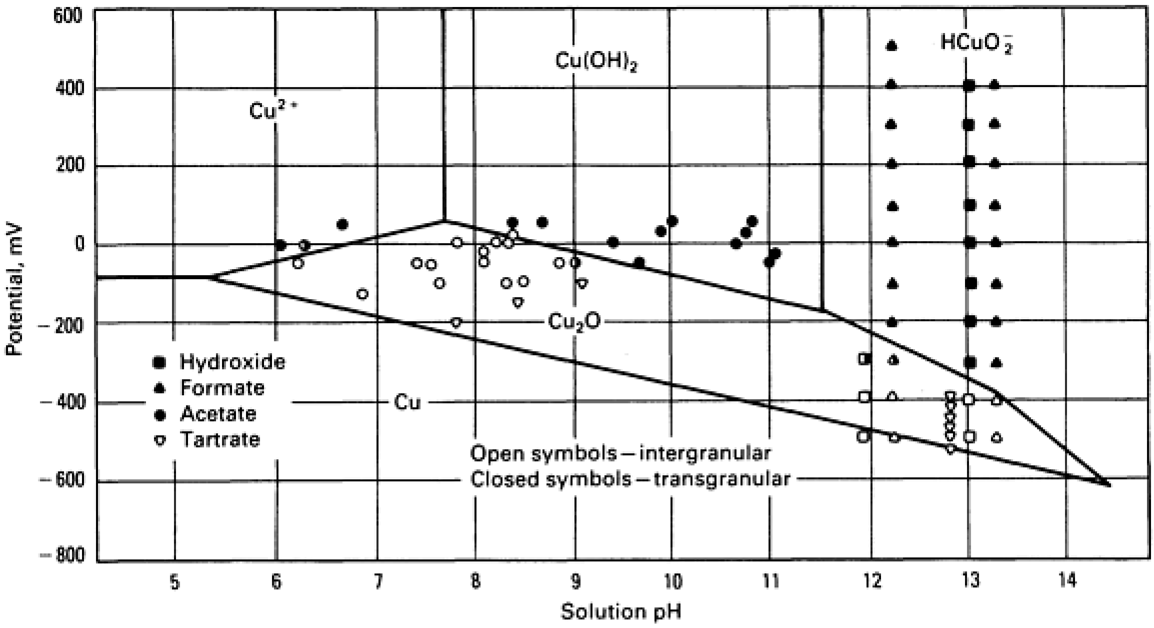

Fig. 13 Potential-pH diagram showing the domains of failure mode for 70Cu-30Ni brass in various solutions, together with the calculated positions of various boundaries relating to the domains of stability of different chemical species

The effect of many environmental parameters, such as pH, oxygen concentration, and temperature, on the thermodynamic conditions for SCC can be related to their effect on the potential-pH diagrams (as shown in Fig. 12 and 13) or on the material potential relative to the various stability regions. Using the potential-pH diagram for iron in water at 25 °C (77 °F) shown in Fig. 14, the effects of changing the pH and oxygen concentration can be illustrated. A decrease in the pH from 9 to 6 at a potential of -0.2 V versus standard hydrogen electrode (SHE) shifts iron from a region of stability to one of active corrosion. Based on the thermodynamic criteria for simultaneous stability and active corrosion, the critical pH would be expected to be 7, with decreasing susceptibility at higher pHs because of increased film stability and at lower pHs because of decreased film stability and the increase of general corrosion. Changes in the oxygen concentration generally alter the electrode potential, with increasing oxygen concentration resulting in more oxidizing conditions. The effects of temperature on the potential-pH diagram must be determined for each temperature of interest as the regions of stability shift with temperature.

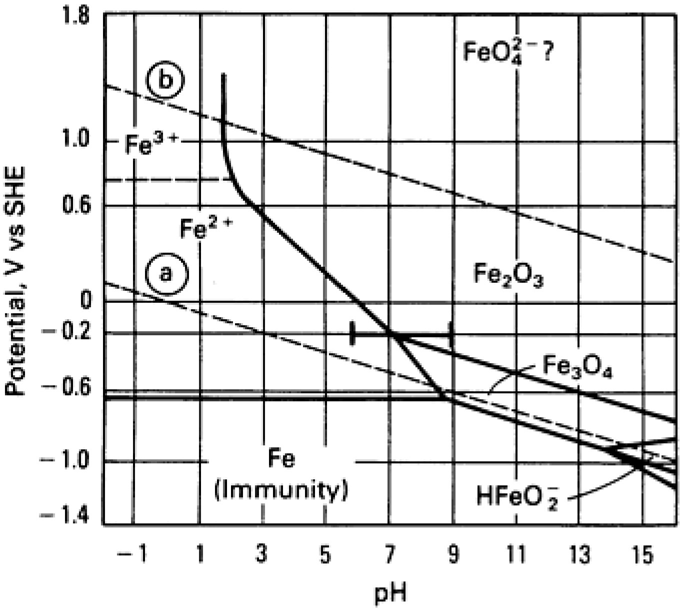

Fig. 14 Potential-pH diagram (Pourbaix) for iron in water at 25 °C (77 °F). A decrease in pH from 9 to 6 at potential of -0.2 V, which shifts iron from a region of stability to one of active corrosion, is indicated by the solid bar.

For materials in which SCC occurs by a hydrogen-induced subcritical crack growth mechanism, the thermodynamic requirement for crack growth is governed by the hydrogen reduction line shown by dashed line *a* in Fig. 14. Hydrogen reduction on iron in water at 25 °C (77 °F) occurs at potentials below this line, but not above it. Therefore, the range of potentials at which hydrogen is available to cause crack growth increases and becomes more oxidizing with decreasing pH.

Application of potential-pH diagrams for identifying specific conditions at which SCC will occur is limited by a number of factors, such as the availability of these diagrams for complex solutions and for the temperatures of interest and the substantial deviation of the chemistry of a crevice or crack from the bulk solution chemistry. Also, the electrode potential at the crack tip can differ from that of the free surface of the material. These differences arise from the need for diffusion of metal ions away from the actively corroding crack tip, migration of anions into the crack, reactions along the crack walls, convection of the electrolyte in the crack, reactions along the crack walls, and, in some cases, by gas bubble formation that causes potential drops. Efforts to measure the local crack tip chemistry and potentials are restricted by crack sizes, which can be substantially smaller than 1 μm. Therefore, mathematical modeling of transport within cracks and the resulting crack tip chemistry, reactions, and potentials have been actively pursued in recent years. The results of measurements in simulated crevices and modeling have clearly shown that the crack tip chemistry can differ from the bulk conditions, but the specifics of these differences are not well known and depend on the material and environment being considered.

For example, based on evaluations by one researcher, the pH within cracks and crevices of structural steels in marine environments ranged from 4 to 11, of stainless steel from 0 to 3, of aluminum from 3 to 4, and of titanium from 1 to 2 (Ref 18). Shifts of up to 300 mV in the crack tip potential in the anodic direction were observed for cathodically polarized steel, while other researchers found only a small shift in the crack tip potential relative to the external potential under steady-state conditions (Ref 16) or a 300-mV shift in the cathodic direction when the crevice walls were active, reducing to a small shift when the walls passivated (Ref 19). Therefore, the critical potentials at which cracking may occur can differ from those given by the bulk equilibrium conditions used to determine the potential-pH diagrams. Although it is possible to determine the equilibrium conditions based on the crack tip conditions, the current knowledge of crack tip conditions is fragmentary at best. Other factors that limit the usefulness of the equilibrium potential-pH diagrams are the lack of available diagrams for specific materials and environments and the variable temperatures, chemistries, and potentials common in many industrial applications.

Kinetics of SCC. A knowledge of the thermodynamic conditions at which SCC can occur is insufficient without a corresponding understanding of the kinetics of crack growth, because the life of a component may be adequate if the crack growth rate is sufficiently slow, even though SCC is thermodynamically possible. As in the thermodynamic conditions for SCC, environmental parameters such as potential, pH, oxygen concentration, temperature, and crack tip chemistry have a strong effect on the crack growth kinetics. The crack tip reactions and the rate-determining steps controlling the crack growth rate are specific to alloy-environment combinations; although a discussion of each system is beyond the scope of this section, some general observations will be made. Also, the crack growth rate depends on the crack advance process even though it is controlled by electrochemical reactions.

Detailed descriptions of various crack growth mechanisms are given in the discussion "Crack Propagation Mechanisms" in this section by categorizing these mechanisms as either anodic dissolution or mechanical fracture models. For the case of a crack growing by anodic dissolution alone, the total crack advance is a function of the total charge transfer at the crack tip, while the crack velocity is a function of the crack tip current density. For a crack growing with mechanical fracture, the total crack advance exceeds the total charge transfer at the crack tip, but the crack velocity may still be controlled by the crack tip current density. A limiting velocity can be described for a crack advancing under pure anodic dissolution by the following Faradaic relationship:

$$\frac{da}{dt} = \frac{i_a M}{zF_\rho} \quad \textbf{(Eq 3)}$$

where i_a is the anodic current density of a bare surface, M is the atomic weight, z is the valence, F is Faraday's constant, and $\rho$is the material density. It has been shown (Ref 20) that this relationship (Eq 3) between the bare surface current density and the crack propagation rate is applicable to a wide variety of materials, as presented in Fig. 15. Equation 2 assumes that the crack tip is maintained in a bare condition, while the crack walls are relatively inactive. A bare crack tip and passive walls can result from the difference between the electrochemical conditions at the tip and other regions in the crack, a difference in the local chemistry of the material at the crack tip that causes the tip to be more active than the crack walls (such as at a sensitized or segregated grain boundary), or a crack tip strain rate that is sufficiently high to prevent the formation of a protective film.

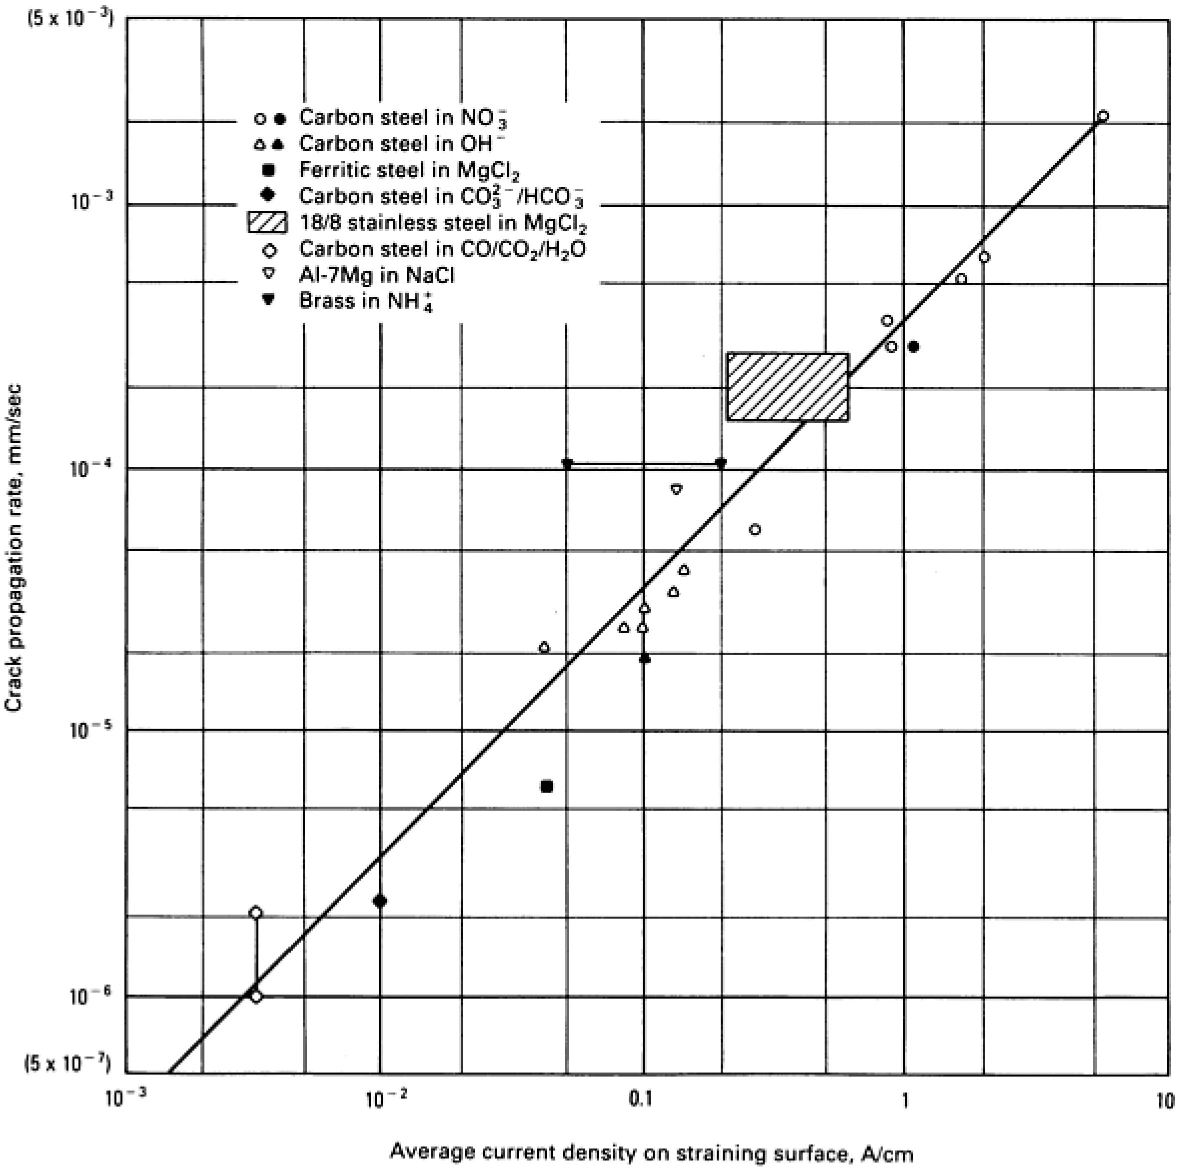

Fig. 15 Relationship between the average crack propagation rate and the oxidation (that is, dissolution and oxide growth) kinetics on a straining surface for several ductile alloy/aqueous environment systems

A number of factors can reduce the crack velocity below that given by Eq 3 and in Fig. 15. The most widely examined crack growth retardation process is that resulting from the crack tip being covered by a film for some fraction of time. The process of crack growth in the presence of a film at the crack tip has been described by several mechanisms, such as slip dissolution and passive film rupture, covered in the discussion "Crack Propagation Mechanisms" in this section. In general, the crack growth rate depends on the rate at which the film is ruptured and reformed. The amount of corrosion that occurs between these two events has been used to describe the crack growth rate. This time period is determined by the crack tip strain rate, film fracture strain, repassivation rate of the surface, maximum corrosion rate while the tip is bare, and the corrosion rate decay with repassivation. Other factors that can reduce the crack growth rate below that given by Eq 3 are limits in the diffusion rate of species into and out of the crack tip, crack deflection away from the principal stress, and changes in the local material chemistry. Transport of species into and out of cracks is considered a major limitation to attaining the crack growth rate predicted by Eq 3. Factors such as the crack geometry or width, reactions or corrosion rate along the walls of the crack, diffusion rate of anions and cations, and metal salt solubility limits all contribute to transport-limited crack velocities.

A lack of clear knowledge about the specific conditions at the tip of a crack has limited the understanding of the role of specific species on crack growth rates. At this time, it is possible only to describe the effect of bulk electrolyte conditions

on crack growth rate; the local conditions may vary significantly. However, knowledge of the local crack tip conditions is most important for understanding the mechanisms of cracking, although a knowledge of the external crack conditions is adequate for monitoring and controlling SCC. Using austenitic stainless steel as an example, the effects of electrochemical potential, oxygen content, and temperature are shown schematically in Fig. 16, 17, and 18. Similar relationships exist for other anion concentrations, such as halides and sulfur species, but the data base is not as well developed as the cases shown. It is important to note that these are not independent effects, because the effects of oxygen concentration and temperature are probably related to the potential. The details of this relationship are complex and are beyond the scope of this section.

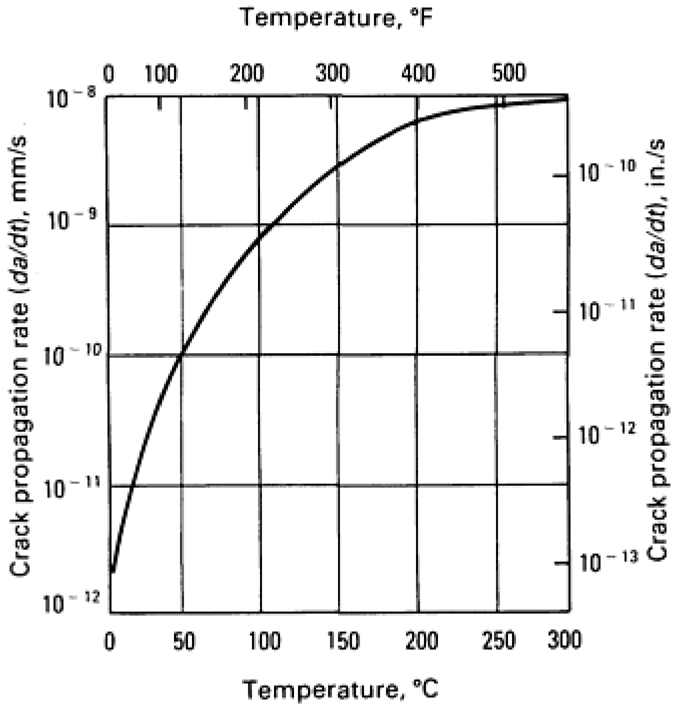

Fig. 18 Schematic of crack growth rate versus temperature for intergranular SCC of type 304 stainless steel

A mechanical fracture process in SCC can produce crack velocities exceeding those given by Eq 3 by some magnification factor, which can be as large as 100. The mechanism of brittle fracture induced by SCC, which is covered in the discussion "Crack Propagation Mechanisms" in this section, is thought to involve the formation of a corrosion product at the crack tip in which a cleavage crack can initiate and propagate some depth into the ductile substrate. As mentioned earlier, this process would produce crack lengths that exceed those accounted for by the total charge transfer/metal oxidation process, but would be dependent on the crack tip corrosion rate because the formation rate of the corrosion product would depend on the corrosion rate.

Early observations and proposals of this process have been made (Ref 21, 22, 23, 24, 25). A current list of materials in which SCC is thought to occur through a film-induced cleavage process as suggested in Ref 25 is given in Table 2, which shows a wide range of materials and environments. An attempt has been made to identify the corrosion product or layer that initiates the cleavage cracking process, but this identification must be considered speculative. The electrochemical conditions controlling the brittle SCC process have not been carefully catalogued; however, for many systems, the main issue is whether cracking can be completely described by anodic dissolution or whether a mechanical fracture process is involved. The greatest uncertainty involves the possibility of a transition between anodic and mechanical SCC processes that is affected by electrochemistry, material chemistry, or mechanics.

The electrochemical factors described in the previous paragraphs were generally drawn from examples of intergranular SCC, but many of the effects would be similar for brittle transgranular SCC. For example, the brittle transgranular crack growth rate follows closely the dependence of the anodic current density on potential. Whether or not there are critical potentials at which transgranular SCC may switch from a brittle mechanical fracture mode to a purely anodic dissolution mode is unknown. However, for many systems, the critical potentials describing SCC are valid control parameters even though the process associated with these critical potentials may be uncertain. For an anodic dissolution controlled process, the critical potentials were associated with the need for an active tip and passive crack walls. These conditions are still necessary for a brittle SCC process because it is dependent on the anodic reaction to produce the corrosion reaction product. This product may be a film or a dealloyed layer, but the rate of formation and therefore the brittle crack growth rate are dependent on the crack tip current density.

Material Chemistry and Microstructure

The relationship between material chemistry and microstructure and SCC is equally as complex as the relationship between the environment and SCC. Bulk alloy composition can affect passive film stability and phase distribution (for example, chromium in stainless steel), minor alloying elements can cause local changes in passive film forming elements (for example, carbon in stainless steel causing sensitization), impurity elements can segregate to grain boundaries and cause local differences in the corrosion rate (for example, phosphorus in nickel or nickel-base alloys), and inclusions can cause local crack tip chemistry changes as the crack intersects them (for example, manganese sulfide in steel). Also, alloys can undergo dealloying, which is thought to be a primary method by which brittle SCC initiates. The following summary will be divided into intergranular and transgranular effects because some of the primary factors can be best described in this way; however, it is important to recognize that many of the material chemistry factors can affect both intergranular and transgranular cracking.

Intergranular Stress-Corrosion Cracking. Material chemistry and microstructure effects on intergranular SCC can generally be divided into the following two categories: grain-boundary precipitation and grain-boundary segregation. Grain-boundary precipitation effects include carbide precipitation in austenitic stainless steels and nickel-base alloys, which causes a depletion of chromium adjacent to the grain boundary and intermetallic precipitation in aluminum alloys, which are anodically active. Grain-boundary segregation of impurities such as phosphorus, sulfur, carbon, and silicon can produce a grain boundary that is up to 50% impurity within a 1- to 2-nm thick region. These impurities can alter the corrosion and mechanical properties of the grain boundary and can therefore cause cracking by anodic dissolution and perhaps mechanical fracture.

Grain-Boundary Precipitation in Stainless Steels. Chromium carbide precipitation in stainless steels occurs in the temperature range from 500 to 850 °C (930 to 1560 °F), with the rate of precipitation controlled by chromium diffusion. For intermediate times, such as occurs with heat treating and welding, chromium depletion occurs adjacent to the grain boundary during chromium carbide growth. This depletion can be described by the minimum chromium concentration adjacent to the carbide and the width of the depleted zone. Minimum chromium concentrations of 8 to 10 at.% have been measured by analytical electron microscopy, while the width of the depleted zone has been measured to range from 10 nm to hundreds of nanometers. After times long enough for carbide growth to reach completion, the chromium profile is eliminated, and the chromium concentration returns to the bulk value.

The intergranular SCC of austenitic stainless steel is primarily dependent on the nature of the chromium-depleted zone, which is generally explained by the depletion of a passive film forming element along a continuous path through the material. The stress-corrosion susceptibility and crack growth rate of austenitic stainless steel can be described by the degree of sensitization (DOS) as measured by corrosion tests such as the Strauss or electrochemical potentiokinetic reactivation (EPR) tests. Quantitative comparisons between susceptibility as measured by the presence or absence of intergranular SCC in an SCC test or the crack growth rate and the DOS or chromium depletion parameters have been successful in cases in which sufficient data have been available, but these correlations are limited to specific alloys, environments, and stress conditions. Semiquantitative comparisons in which intergranular SCC is predicted for DOS values greater than some critical value are less costly to obtain and have been used more extensively.

An example of the time/temperature/DOS curves at several carbon concentrations is shown in Fig. 19. The curves represent the conditions necessary for the development of a constant degree of sensitization, with the strong effect of bulk carbon concentration on the time needed to develop a sensitized microstructure. Therefore, the most common method for reducing the possibility of developing a sensitized microstructure is to reduce the carbon concentration or to control the thermal history of the material. Given that the material is sensitized, control of the environment and stress conditions can be used to reduce the crack propagation rate.

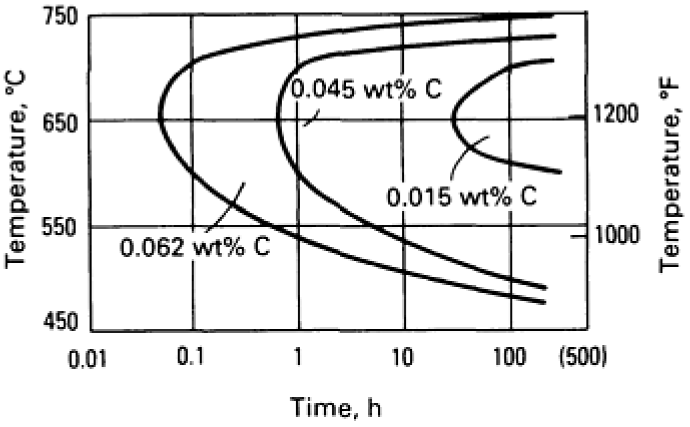

Fig. 19 Time/temperature/sensitization curves determined by EPR tests on type 304 stainless steel alloys of variable carbon contents

Clearly, chromium and carbon are the two most important elements involved in the development of sensitization; however, other elements can play a role. Molybdenum has an effect similar to that of chromium--incorporation into the carbides and depletion adjacent to the grain boundaries--although it is generally present in smaller concentrations (for example, in type 316 stainless steel) than chromium. Nickel increases the activity of carbon in austenitic stainless steel; therefore, increases in nickel concentration can enhance sensitization for a given carbon concentration and thermal history. Manganese, silicon, and nitrogen have also been shown to affect sensitization, but the data that is available on these elements is comparatively sparse. Silicon has been shown to segregate to grain boundaries when present in sufficient quantities or by the nonequilibrium processes that occur when the material is irradiated with neutrons. The presence of silicon in the grain boundaries has been found to be deleterious in oxidizing environments.

Grain-Boundary Precipitation in Nickel Alloys. The cause of intergranular SCC in nickel-base alloys is more complex than in austenitic stainless steel. Chromium carbide precipitation and chromium depletion occur in nickel-base alloys, such as alloy 600, as they do in austenitic stainless steels, but a clear connection between the presence of this microstructure and intergranular SCC has not been made. Carbon solubility is considerably lower and chromium diffusion is faster in nickel-base alloys than in austenitic stainless steels; therefore, the nose in the carbide precipitation or sensitization curves shown in Fig. 19 is shifted to shorter times and higher temperatures. Significant heat-to-heat variations in the chromium depletion of alloy 600 have been observed for a given heat treatment. This variation is attributed to the sensitivity of alloy 600 to carbon concentration and to the variability in mill-anneal heat treatment conditions. Chromium depletion is thought to accelerate cracking in oxygenated water, but has not been identified as a controlling factor in deaerated water or caustic environments at 300 °C (570 °F). The rapid carbide precipitation kinetics in nickel-base alloys allows the development of a healed microstructure in which carbide growth is complete and the chromium profile is eliminated with relatively short heat treatment times.

Some significant differences between the intergranular SCC of nickel-base alloys and that of austenitic stainless steels include the positive effect of a semicontinuous distribution of carbides at the grain boundary in single-phase material and the galvanic couple between the γ' and γ phases in precipitation-hardened alloys. The beneficial effect of a semicontinuous distribution of carbides is thought to be related to dislocation generation from the carbides that results in a crack blunting or stress relaxation at the tip of a crack. The detrimental effect of the γ' phase is thought to result from a galvanic couple that polarizes the γ phase anodically relative to the γ' phase.

Grain-Boundary Precipitation in Aluminum Alloys. Aluminum alloys are also noted for the occurrence of intergranular SCC in aqueous environments, including sodium chloride (NaCl) solutions. The details of the intergranular SCC process in aluminum alloys are very complex and vary with alloy composition, but some features can be summarized. Grain-boundary precipitation has been identified as a contributing factor in the intergranular SCC in aluminum alloys; galvanic effects between the precipitates and matrix are considered to be important. In some cases, the precipitates are anodic, and in others, they are cathodic to the matrix. Peak-aged materials that give maximum hardnesses and microstructures in which slip bands are produced upon straining are considered to be vulnerable to SCC. Overaged structures are considered to be less susceptible. The mechanism of crack growth is thought to be a combination of local

anodic dissolution and hydrogen embrittlement. Whether crack extension is by anodic dissolution or by hydrogen embrittlement remains an open question; however, in aqueous solutions, the primary source of hydrogen is anodic dissolution.

Grain-Boundary Segregation in Aluminum Alloys. Grain-boundary enrichment of magnesium without precipitation of a magnesium-rich phase has recently been identified as a factor in the intergranular SCC of aluminum alloys (Ref 26, 27). This enrichment is associated with increased corrosion activity at the grain boundary and the possible formation of magnesium hydride (MgH) or enhanced hydrogen entry along the grain boundaries. Crack advance is thought to occur by discontinuous crack jumps (possibly nucleated by hydrides) and crack arrest after about 150 to 350 nm of advance, followed by repetition of this process.

Grain-Boundary Segregation in Ferrous and Nickel Alloys. Grain-boundary enrichment of impurities can contribute to the intergranular SCC of iron-base alloys, austenitic stainless steels, and nickel-base alloys. The extent of their effect depends on the electrochemical potential, the presence of other stress-corrosion processes such as chromium depletion, and their concentration in the grain boundary. The enrichment of impurities to grain boundaries by equilibrium segregation can be described by the enrichment ratio, as shown in Fig. 20 for a variety of impurity-alloy combinations (Ref 28). The enrichment ratio defines the upper bound to the grain-boundary concentration that will be achieved under equilibrium conditions, which can be very long times at low temperatures. It can be seen from Fig. 20 that enrichment ratios as high as 10^5 are possible for some impurities and that ratios greater than 10^2 are not uncommon. for the bulk impurity concentrations present in most engineering alloys, grain-boundary impurity concentrations of 10 to 20 at.% are possible. Therefore, an intergranular stress-corrosion crack can propagate along a grain boundary that has a composition vastly different from that of the bulk alloy.

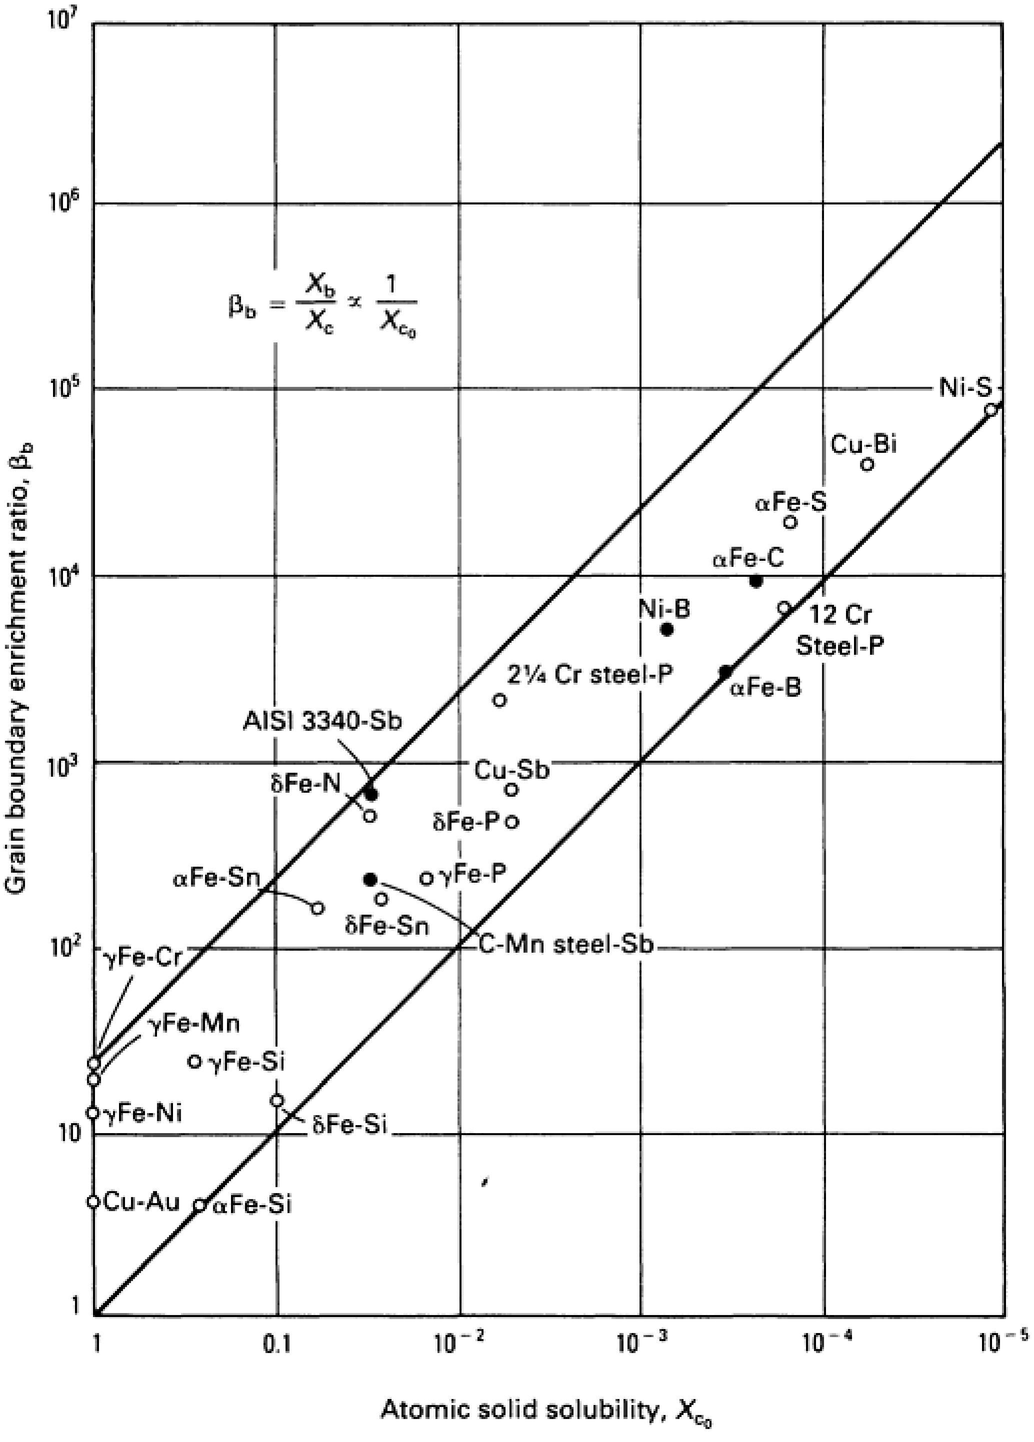

Fig. 20 Correlation between measured grain-boundary enrichment ratios, β, and the inverse of solid solubility, X_{C_0}. The symbols X_b and X_c represent the actual concentration of the species b and c in the bulk.

Ferritic steels exhibit intergranular SCC in hot nitrate, caustic, carbonate, and a variety of other environments. The presence of intergranular SCC is dependent on the electrochemical potential, because intergranular SCC is predominant at potentials in the active-passive transition. Early studies of this effect identified carbon segregation as the primary element of concern where the carbon atoms were said to provide suitable imperfection sites for adsorption of nitrate in an adsorption-induced crack growth mechanism (Ref 29). More recently, phosphorus segregation has been associated with the intergranular SCC of iron alloys in nitrate and caustic solutions (Ref 30, 31); grain-boundary concentrations as low as 2 to 3 at.% have been sufficient to alter the passivity of iron in hot nitrate solutions. A complexity of SCC in ferritic steels is the susceptibility of such steels to intergranular SCC and to hydrogen-induced subcritical crack growth. The

temperatures and electrochemical potentials at which intergranular SCC and cathodic hydrogen-induced subcritical crack growth occur are generally not the same. Stress corrosion tends to dominate at temperatures above about 50 °C (120 °F) and at potentials in the active-passive transition; hydrogen effects are predominant at temperatures below 50 °C (120 °F), at more cathodic potentials, and at lower pH values. Examples of the effect of sulfur and phosphorus on the tendency toward intergranular fracture are given in Fig. 21 and 22, from which it can be seen that sulfur was more effective than phosphorus in causing intergranular fracture of iron at cathodic potentials (Ref 32, 33). For the conditions of this test, a sulfur concentration of about 13 at.% was sufficient to change the fracture mode from transgranular to intergranular.

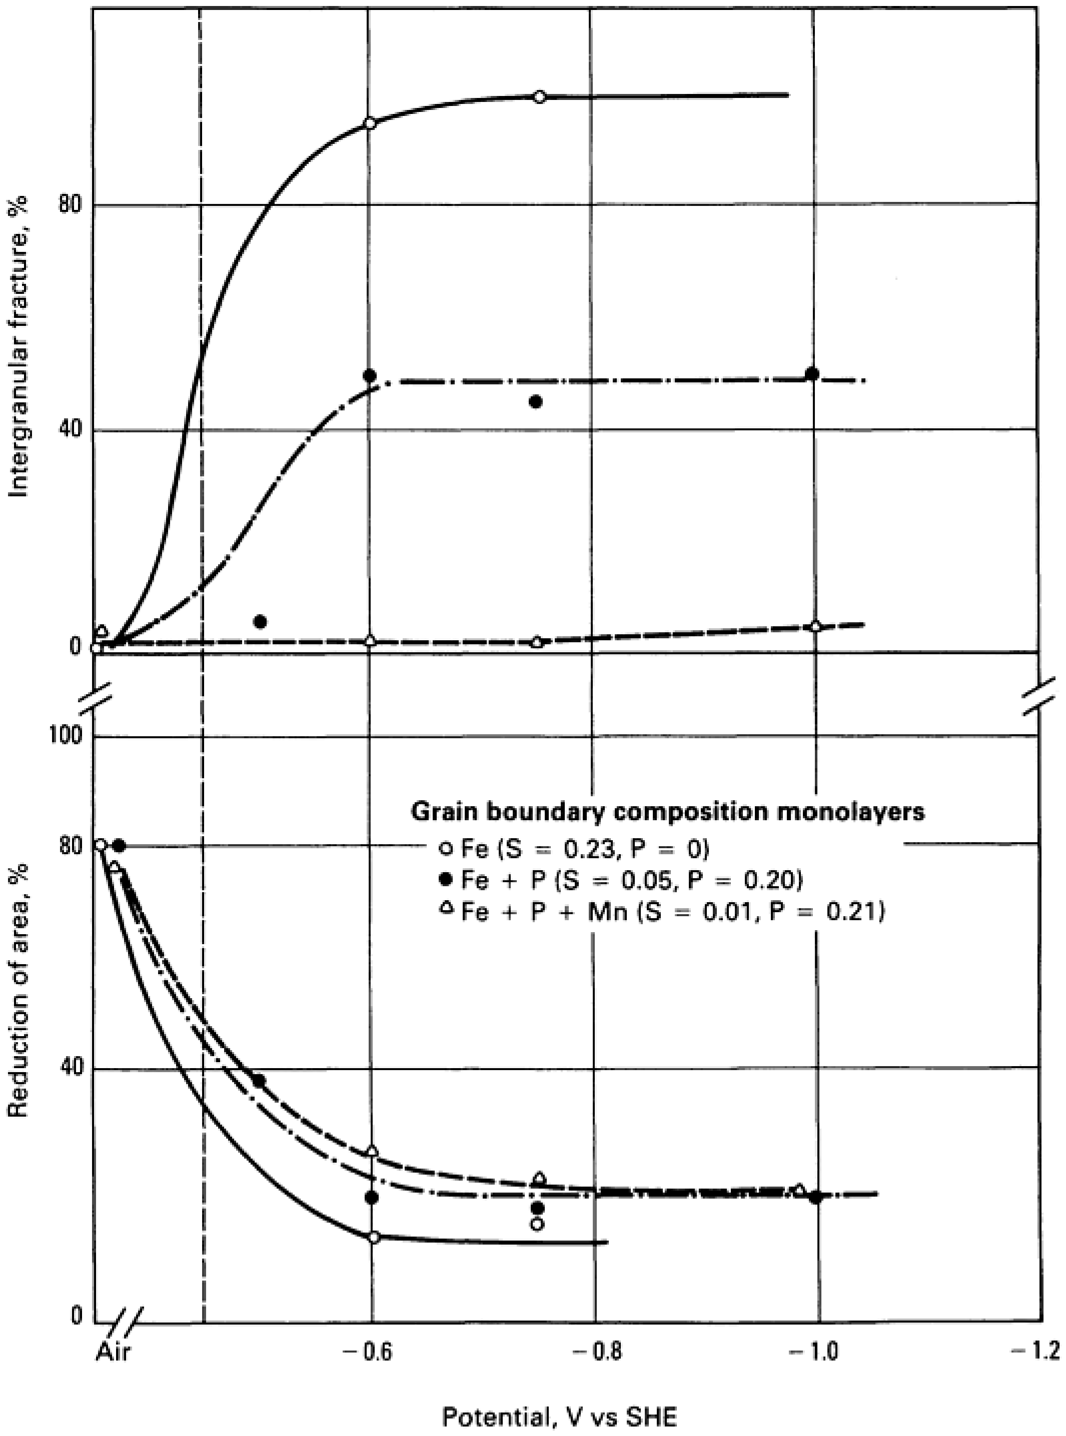

Fig. 21 Percent intergranular fracture, reduction of area, and strain to failure of iron, iron + phosphorus, and iron + phosphorus + manganese alloys tested at various cathodic potentials

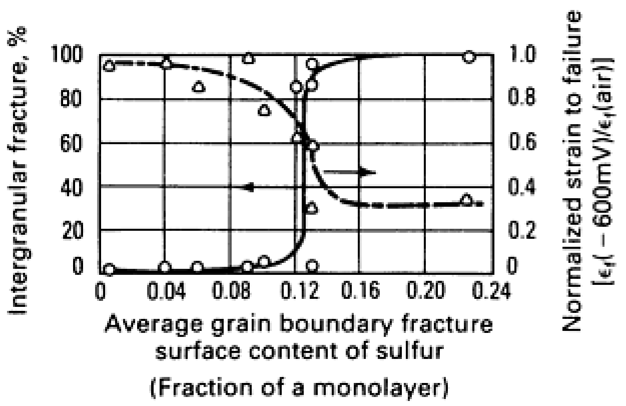

Fig. 22 Percent intergranular fracture and the normalized strain to failure plotted as a function of sulfur content at the grain boundary for straining electrode tests at a cathodic potential of -600 mV (SCE)

Grain-boundary impurity segregation of various impurities, including phosphorus, silicon, sulfur, and nitrogen, has been reported in austenitic stainless steels (Ref 34); however, no direct effect on intergranular SCC has been identified in high-temperature water. Phosphorus segregation has been shown to cause intergranular corrosion in highly oxidizing solutions, and impurity segregation of phosphorus and perhaps silicon has been suggested as a primary factor in irradiation-assisted SCC, which occurs in the oxidizing in-core environment of light water reactors (Ref 35). Phosphorus segregation can apparently contribute to the intergranular SCC of austenitic stainless steels in high-temperature water if the carbon concentration of the alloy is lower than 0.002%. At this low concentration, there is virtually no sensitization; therefore, the phosphorus segregation effect is observed.

Phosphorus is also the primary grain-boundary segregant in alloy 600 and has been shown to segregate by an equilibrium process (Ref 36). The grain-boundary composition versus temperature curves for alloy 600 and type 304 stainless steel are shown in Fig. 23, along with a calculated curve for equilibrium segregation in nickel (Ref 37). It can be seen that grain-boundary phosphorus concentrations to 15 at.% are possible. Grain-boundary segregation of sulfur, boron, nitrogen, and titanium has also been observed in alloy 600; however, a clear connection between the impurity segregation and intergranular SCC in nickel-base alloys has not been observed to date.

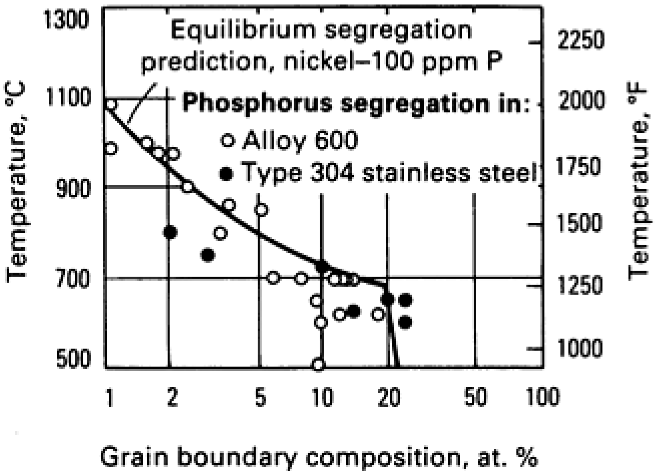

Fig. 23 Grain-boundary segregation measurements in Alloy 600 and type 304 stainless steel. Shown are Auger electron spectroscopy measurements of phosphorus segregation in the two alloys as compared to model prediction for phosphorus segregation in nickel.

In contrast to the high-temperature water results for alloy 600, a clear effect of phosphorus segregation on the intergranular SCC of nickel was observed at oxidizing potentials in acidic solutions at 25 °C (77 °F) (Ref 18), as shown in Fig. 24. Intergranular SCC was observed at anodic potentials ranging from the active-passive transition to transpassive potentials in nickel with phosphorus-enriched grain boundaries but not sulfur-enriched grain boundaries. The role of phosphorus was identified with degradation of the passive film formed on nickel in acidic solutions. This example is a clear case of active-path corrosion; however, the cracking was clearly stress dependent, as evidenced by a threshold stress intensity below which intergranular SCC did not occur and an alignment of cracks with the applied tensile stress. Because there were no grain-boundary carbides or chromium depletion in the nickel, these results illustrate the potential effect of impurities when other grain-boundary processes are absent. Therefore, it appears, as in the case of type 304 stainless steel cited earlier, that impurity segregation may induce intergranular SCC in the absence of carbides and chromium depletion.

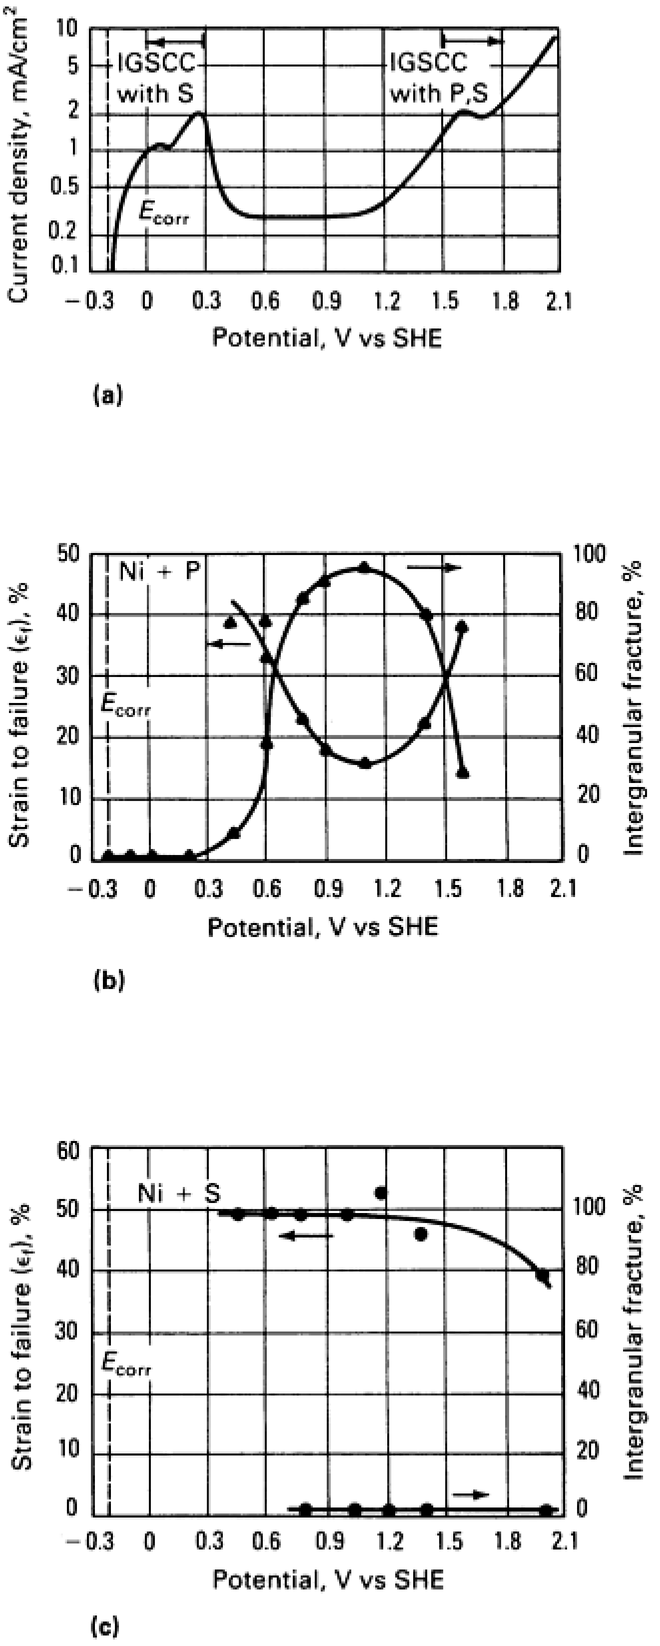

Fig. 24 Stress-corrosion cracking behavior of nickel with phosphorus and sulfur segregation. (a) Polarization curve for nickel in 1 *N* H_2SO_4 at 25 °C (77 °F). (b) Strain to failure and percent intergranular fracture for 26% phosphorus segregation at grain boundaries. (c) Strain to failure and percent intergranular fracture for 40% sulfur segregation at grain boundaries

Like ferritic materials, nickel-base alloys and austenitic stainless steels are susceptible to hydrogen-induced intergranular subcritical crack growth. Impurity segregation is thought to play a key role in this hydrogen-induced fracture, as the results for nickel shown in Fig. 25 illustrate. These results show the combined effect of sulfur segregation and cathodic hydrogen on the amount of intergranular fracture in nickel. For the conditions of these tests, a given amount of intergranular fracture resulted for different combinations of grain-boundary sulfur and hydrogen reduction rate. A decrease in the amount of sulfur could be compensated for by an increased hydrogen activity to give the same amount of intergranular fracture.

Transgranular Stress-Corrosion Cracking. Numerous metallurgical factors affect transgranular SCC, for example, crystal structure, anisotropy, grain size and shape, dislocation density and geometry, yield strength, composition, stacking fault energy, ordering, and phase composition. Some of these factors also affect intergranular SCC, as covered in the discussion "Intergranular Stress-Corrosion Cracking" in this section. Also, some of their effects on transgranular SCC are related to the corrosion behavior of the alloy, which can be understood from potential-pH diagrams or polarization curves. Because these effects are covered elsewhere in this Volume (see the Section "Specific Alloy Systems"), they will not be discussed here. Similarly, yield strength effects will be considered in the discussion "Mechanical Factors" in this section. Metallurgical factors in hydrogen-induced subcritical crack growth, such as crystal structure, hydride stability, and yield strength, are considered in the section "Hydrogen Damage" in this article. The effects of alloy composition on corrosion rate, hydrogen exchange current densities, and hydrogen absorption rates also influence the hydrogen-induced subcritical crack growth of materials in corrosive environments, but these are covered in the articles dealing with specific metals and alloys.

Alloying effects on slip planarity are a key metallurgical factor in transgranular SCC. Planar slip occurs in alloys with low stacking fault energy, alloys containing ordered phases, or alloys exhibiting short- or long-range ordering. The consequences of planar slip on transgranular SCC have been explained by the slip-dissolution model discussed in Ref 39. In this model, the passive film is ruptured by the emergence of a slip step. In high-chloride environments, evidence was presented that preferential corrosion occurred along the high dislocation density plane created by planar slip (Ref 40). A number of crack growth processes were suggested based on the planar slip localized corrosion process--for example, control of crack advance solely by anodic dissolution of the slip plane, brittle fracture of the corrosion product or tarnish

film formed along the localized corrosion path, and the tunneling process by which corrosion along the slip plane branches out into tunnels accompanied by mechanical fracture of the remaining ligaments. The planar slip concept of transgranular SCC appears consistent with a number of observations, such as alloying and strain effects. Details of these mechanisms are presented in the discussion "Crack Propagation Mechanisms" in this section.

A significant difficulty associated with the slip-dissolution mechanism is the nature of the transgranular SCC fracture surfaces, which are generally not on the slip planes and have cleavage-like features. For example, for admiralty brass tested in aqueous ammonia (NH_3) and Al-5.5Zn-2.5Mg tested in aqueous NaCl, the primary fracture facets were (110) planes, while for stable austenitic stainless steel tested in aqueous magnesium chloride ($MgCl_2$) at 155 °C (310 °F), the primary facets were on (100) planes. There is also evidence that crack advance in brass occurs in a discontinuous manner (Ref 24). Several mechanisms for the development of a cleavage crack in ductile face-centered cubic (fcc) alloys have been presented, but a definite correlation has not emerged.

One concept that has received considerable attention is that proposed in Ref 25, in which a rapid crack advance that begins in a brittle film at the crack tip induces cleavage fracture of the ductile material ahead of the crack tip. The brittle films that are regarded as the initiating layers are given in Table 2. These include a dealloyed layer, oxide, nitride, carbide, or hydride. A dealloyed layer acting as a cleavage crack initiator is suggested for brass, copper-gold, and iron-chromium-nickel alloys. If this concept is supported by future research, the relative reactivity of the alloying elements will prove to be a key metallurgical factor in the transgranular SCC of materials. It has also been demonstrated that the dealloying rate of copper-aluminum and copper-zinc as a function of aluminum and zinc, respectively, corresponds to the crack growth rate in ammoniacal solution (Ref 25).

Mechanical Factors

There is more commonality in the mechanical aspects of stress corrosion between intergranular SCC and transgranular SCC and between various materials than there is in environmental and metallurgical aspects. As indicated earlier, many of the environmental or metallurgical factors are specific to a given material/environment combination such that a metallurgical factor may be significant in one environment, but not in another. Threshold stress intensities and stresses, the presence of a stress-independent crack growth regime, and a dependence of crack growth rate on strain rate are features common to a variety of environmentally induced crack growth processes and a variety of materials. Anodic and cathodic controlled processes show many of these common features.

The stress intensity dependence of environmentally induced subcritical crack growth is shown schematically in Fig. 26, along with a relationship for the linear-elastic mode I stress intensity. The applied stress intensity is a function of the uniform stress and the crack length; therefore, for a constant-stress test, the stress intensity increases with increasing crack extension. For low-strength materials that form a significant plastic zone ahead of the crack, nonlinear fracture mechanics relationships must be used to calculate K. The subcritical crack growth behavior of many material/environment combinations is characterized by a threshold and by stages 1, 2, and 3 (see the article "Fracture Mechanics" in *Mechanical Testing,* Volume 8 of *ASM Handbook,* formerly 9th Edition *Metals Handbook,* for a detailed discussion of modes of crack formation).

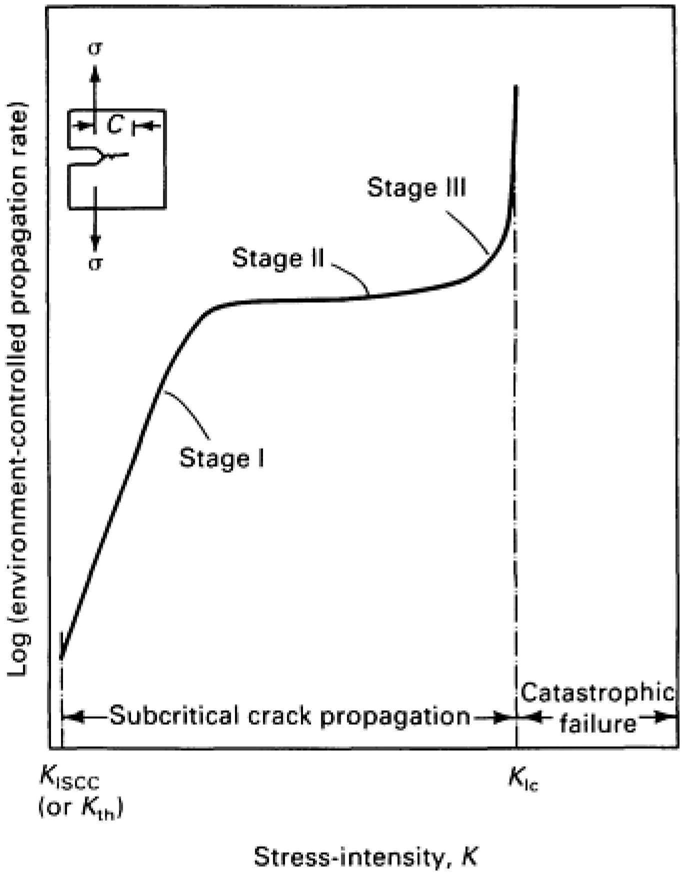

Fig. 26 Typical, subcritical crack propagation rate versus stress intensity relationship. Stress intensity, *K*, is defined as $K = A\sigma\sqrt{\pi C}/B$, where σ is the total tensile stress, *C* is the crack length, and A and B are geometrical constants.

In Fig. 26, the threshold is defined by the minimum detectable or reliably measured crack growth rate, while in some materials, stage 1 has a large *K* dependence such that a lower threshold does not result at lower crack velocities. There are a number of physical processes that can be associated with a threshold stress intensity, including a fracture strain for a passive film rupture mechanism, the critical resolved shear stress for the slip-dissolution mechanism, a fracture stress for a brittle film induced cleavage mechanism, or a critical crack tip opening for transport of species in the crack. The threshold stress intensity is generally associated with the development of a plastic zone at the crack tip; however, calculations of crack tip strains are not very accurate, and experimental correlations between plastic zone development of K_{ISCC} have not been made.

Stage 1 subcritical crack growth is marked by a rapid increase in crack velocity with a small increase in *K*. Dependencies of crack velocity on stress intensity to the fourth power have been reported for a number of material/environment combinations. Changes in crack velocity of two orders of magnitude with small changes in *K* are not uncommon for the stage 1 regime. Few explanations for the *K* dependence of stage 1 have been put forth. One explanation is that in stage 1, the crack tip plastic strain rate is increasing rapidly with *K*, and another explanation is that the transport of species into and out of the crack increases rapidly with increasing crack volume in stage 1.

In metals tested in aqueous solutions, in transport of cations or anions in the crack electrolyte, or in passive film forming materials, the passive film rupture and repassivation rates are thought to be rate-limiting processes. Environmental parameters such as crack tip potential, corrosion rates, and pH also affect the stage 2 crack velocity so that in many systems the limiting velocity is a function of crack tip corrosion rate, strain rate, and transport rate. A steady-state crack transport calculation for intergranular SCC in nickel + phosphorus gave crack growth values within a factor of five of the measured stage 2 values (Ref 16). For transgranular SCC, there is increasing evidence that the crack velocity is a function of the corrosion rate, but that crack advance results from brittle crack jumps that exceed the depth of the corrosion

reaction. In this case, the crack velocity may scale with the corrosion rate, but the crack length exceeds that determined from charge transfer.

Most stress-corrosion data have been obtained by using specimens loaded in a tensile mode in which the stress is perpendicular to the plane of the advancing crack; this condition is defined as mode 1 loading. In practice, a component may have a complex loading mode such that torsion and shear components are present. The effect of mixed loading modes on SCC is therefore an important consideration in component design; however, very few SCC data exist for other than mode 1 loading. Some examples of SCC in modes 1 and 3 for aluminum in 3.5% NaCl and type 304 stainless steel in boiling $MgCl_2$ are shown in Fig. 27, in which it can be seen that mode 1 loading gives the lowest threshold stress or stress intensity. Also shown in Fig. 27(a) is a schematic of the test specimen used to perform mixed-mode SCC tests. In both cases, the researchers concluded that the lower thresholds and higher crack velocities in mode 1 tests of these materials indicate a hydrogen embrittlement component to SCC because hydrogen effects are more prominent under tensile loading conditions (Ref 41, 42). However, anodic stress-corrosion processes are also aided by the crack opening that results from mode 1 loading.

(b) Crack velocity versus stress intensity curves for SCC of type 304 stainless steel in modes 1 and 3 in boiling $MgCl_2$

Stress-corrosion data are frequently given as applied stress versus time to failure, as shown in Fig. 28. These data are obtained with notched or unnotched specimens statically loaded in tension or bending. The threshold stress is sensitive to the environment, alloy composition, and structure and is not strictly a material property. The threshold stress is related to the yield strength of the material, with thresholds generally being greater than one-half the yield strength, and in many cases, the threshold is a significant fraction (about 0.8) of the yield strength of the material. Therefore, most SCC tests performed with this technique are performed at values of about 80% of the yield strength or greater.

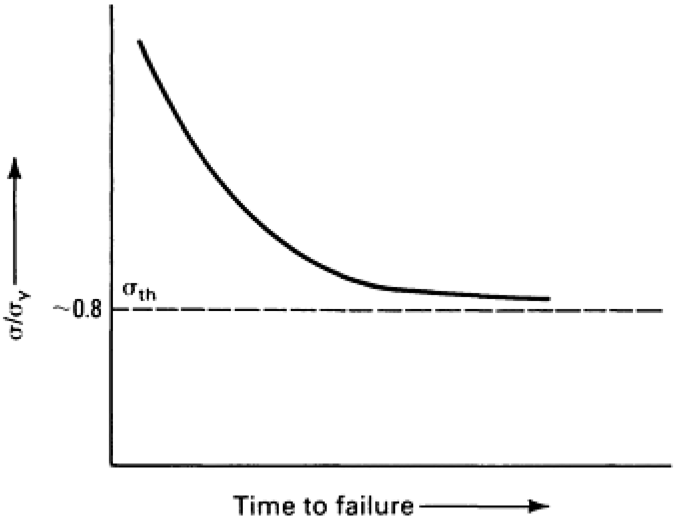

Fig. 28 Schematic diagram of time to failure versus applied stress, σ, normalized to the yield strength σ_y for stress corrosion

The data obtained with this method incorporate the stage 1, 2 and 3 regimes shown in Fig. 26 in addition to a crack initiation stage. Crack growth begins with the development of a pit or intergranular corrosion groove that raises the stress intensity to the K_{ISCC}. Because the stress is constant, the stress intensity increases with increasing crack length as given by the expression in Fig. 26 so that the crack progresses through stage 1 to stage 2 and ultimately to fracture in stage 3. Therefore, the failure time in a constant-stress test is dependent on the initiation rate, the value of the K_{ISCC}, the crack growth rate in stage 2, and the fracture toughness K_{Ic}. These test data are useful because they relate to the sequence that may occur in practice, but it is difficult to relate them to physical processes and rate-controlling steps. Crack growth rates are frequently estimated from constant-load tests based on the crack depth divided by the total test time. Crack velocities obtained in this manner are minimum values because the time for initiation is included so that instantaneous velocities will always be greater.

The threshold stress is perhaps the least complicated value obtained from constant-load tests. For film-forming materials, the threshold can be related to the film formation and rupture rate. Below the threshold stress, the film formation rate is sufficiently high to maintain the surface in a filmed condition; at higher stresses, the film rupture rate exceeds the reformation rate such that a pit or an intergranular corrosion groove can grow. For transgranular SCC initiated by a brittle corrosion film, the threshold stress could be related to the fracture stress of the film; however, this type of relationship has not been established for the brittle film induced cleavage process.

Constant extension rate or slow strain rate tests have essentially replaced the use of the constant-stress test for stress-corrosion testing. This has occurred because of the variability in times of failure with a constant-stress test and the long test times needed to define the stress threshold. Also, the concept that the crack growth rate is a function of the strain rate, as shown in Fig. 29 for intergranular type 304 stainless steel, has led to the use of a constant extension rate test. The CERT specimens will fail within a given period of time, thus eliminating specimens that do not fail because they are loaded to a stress below the threshold. The crack growth rates given in Fig. 29 are minimum values obtained from unnotched specimens, and the strain rate is the average applied rate. Clearly, once a crack develops, the crack tip strain rate will differ from the average applied value. An example of the crack velocity as a function of the crack tip strain rate is given in Fig. 30 for intergranular SCC of a carbon-manganese steel tested in a carbonate solution. A threshold strain rate is evident in these results that is the same as a threshold stress intensity. A second threshold strain rate exists at high strain rates because mechanical fracture occurs before a crack can initiate and propagate to a measurable length. The two strain rate thresholds are illustrated in Fig. 31.

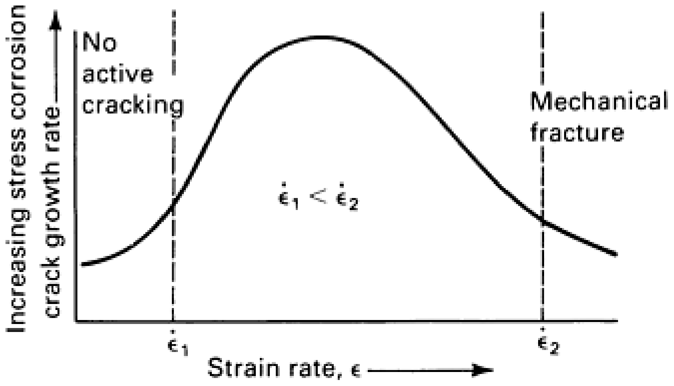

Fig. 31 Stress-corrosion crack growth as a function of the two strain rate thresholds, $\dot{\epsilon}_1$ and $\dot{\epsilon}_2$

It is important to distinguish between static and dynamic effects. For example, a sample could be plastically strained 10% and the load dropped to below the threshold stress before being immersed in a corrosive environment and SCC will not occur. However, a sample can be slowly strained 10% in a corrosive environment with the development of numerous cracks and perhaps even complete failure. Therefore, it is the dynamic strain and creation of fresh surface or dynamic fracture of a brittle film that is crucial to SCC. Corrosion current measurements corroborate these observations; the current density of a prestrained sample is usually very similar to an unstrained sample, while the current density measured during dynamic strain is considerably greater than that in the unstrained sample.

Crack Propagation Mechanisms

As indicated in the previous discussion, it is unlikely that a single mechanism of SCC exists; instead, there are probably two or three different operative mechanisms. Many models have been proposed, but only the more prominent will be discussed. The proposed mechanisms for crack propagation fall into two basic classifications: those based on dissolution as the principal cause of crack propagation and those that involve mechanical fracture in the crack propagation process.

Dissolution Models

According to models of this type, the crack advances by preferential dissolution at the crack tip. A number of models have been proposed to account for this process. For example, preferential dissolution at the crack tip has been attributed to the formation of active paths in the material, stresses at the crack tip, and chemical-mechanical interactions (Ref 43, 44, 45, 46, 47, 48). However, research has essentially eliminated all but one model from serious consideration, and the debate has recently centered on the details of this model.

Film Rupture. The film rupture model, also referred to as the slip-dissolution model, assumes that the stress acts to open the crack and rupture the protective surface film. Two investigators, working independently, first postulated that localized plastic deformation at the crack tip ruptures the passivating film, exposing bare metal at the crack tip (Ref 49, 50). The freshly exposed bare metal then dissolves rapidly, resulting in crack extension. Some investigators (Ref 51, 52, 53) assume that once propagation starts, the crack tip remains bare because the rate of film rupture at the crack tip is greater than the rate of repassivation (Fig. 32a). Others (Ref 54, 55, 56, 57) assume that the crack tip repassivates completely and is periodically ruptured by the emergence of slip steps (Fig. 32b).

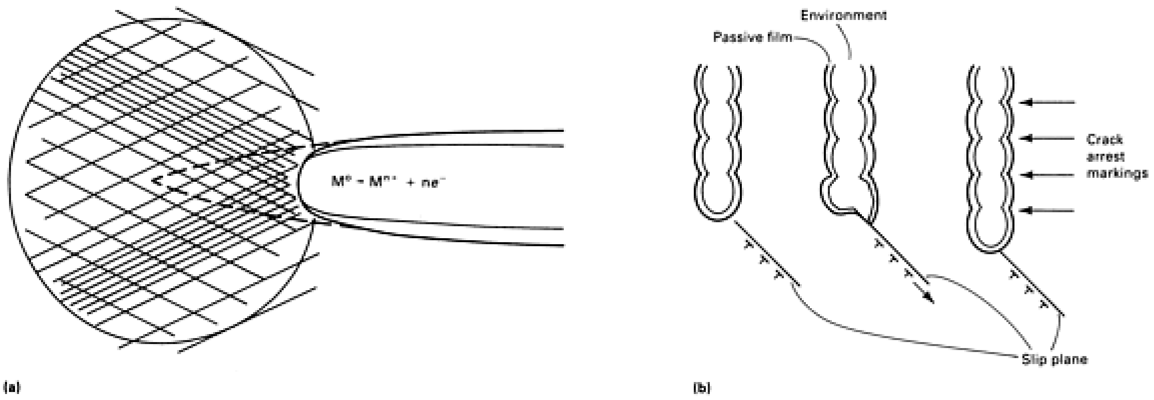

Fig. 32 Schematic representations of crack propagation by the film rupture model. (a) Ref 50. (b) Ref 56 and 57

Considerable evidence has been found to support these mechanistic models, and intergranular corrosion may be considered the low stress limiting case of this mechanism (Ref 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57). However, the observation of discontinuous cracking and crack arrest markings (discussed previously) is an indication that crack propagation can be, and frequently is, discontinuous. Also, transgranular SCC fracture surfaces are flat, crystallographically oriented, and match precisely on opposite sides of the fracture surface (indicating very little dissolution during crack advance). As a result, film rupture and dissolution are accepted as viable mechanisms of intergranular SCC in some systems, but are not generally accepted as mechanisms of transgranular SCC (Ref 58).

Mechanical Fracture Models

Mechanical fracture models originally assumed that stress concentration at the base of corrosion slots or pits increased to the point of ductile deformation and fracture (Ref 48). These early proposals assumed that the crack essentially propagated by dissolution and that the remaining ligaments then failed by mechanical fracture (ductile or brittle). A refinement of this approach has been proposed (Ref 40, 59); it is generally known as the corrosion tunnel model.

The Corrosion Tunnel Model. In this model, it is assumed that a fine array of small corrosion tunnels form at emerging slip steps. These tunnels grow in diameter and length until the stress in the remaining ligaments causes ductile deformation and fracture. The crack thus propagates by alternating tunnel growth and ductile fracture (Fig. 33). Cracks propagating by this mechanism should result in grooved fracture surfaces with evidence of microvoid coalescence on the peaks, as illustrated in Fig. 33(a). This is not consistent with the common fractographic features discussed previously. As a result, it was suggested (Ref 60) that the application of a tensile stress results in a change in the morphology of the corrosion damage from tunnels to thin flat shots, as shown in Fig. 33(b). The formation of slots was observed below the dealloyed sponge layer on the {110} type planes in austenitic stainless steels, and it was found that the formation of these slots required the presence of a tensile stress. The width of the corrosion slots was found to approach atomic dimensions, and as a result, close correspondence of matching fracture surfaces would be expected. It was concluded that transgranular SCC can be explained in terms of the formation and mechanical separation of corrosion slots (Ref 60).

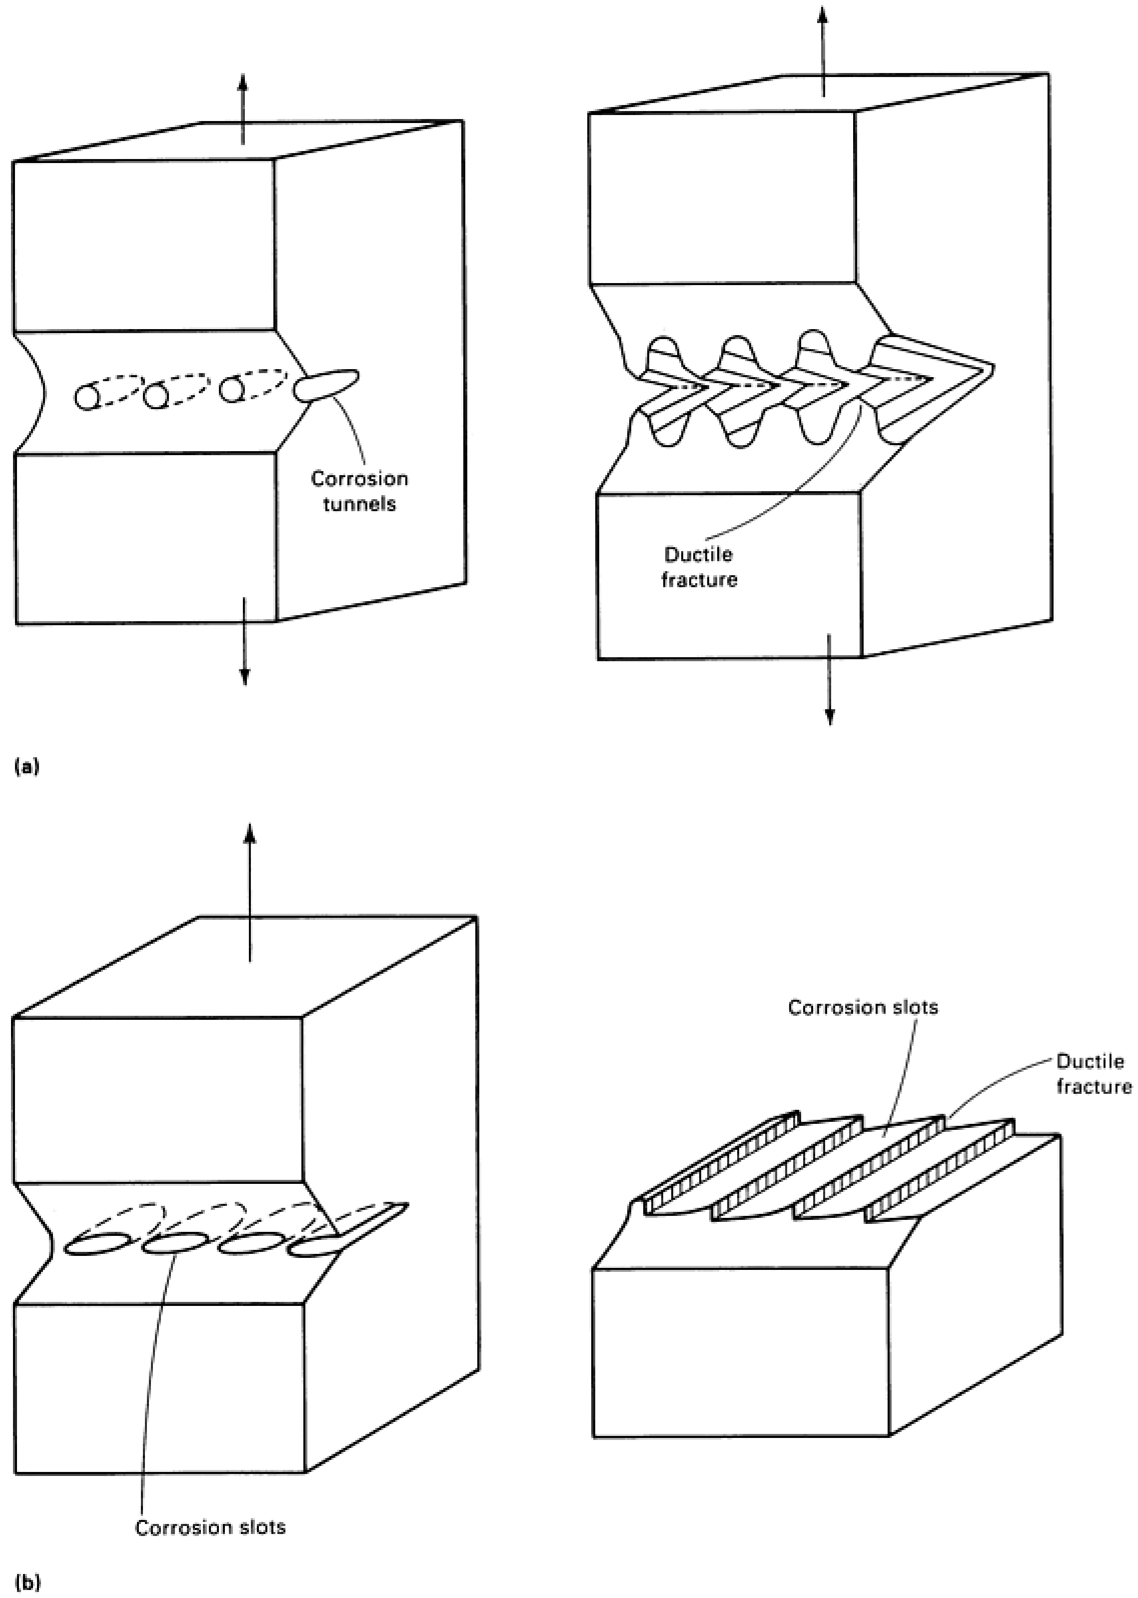

Fig. 33 Corrosion tunnel models. (a) Schematic of tunnel model showing the initiation of a crack by the formation of corrosion tunnels at slip steps and ductile deformation and fracture of the remaining ligaments. (b) Schematic diagram of the tunnel mechanism of SCC and flat slot formation as proposed in Ref 60

Adsorption-Enhanced Plasticity. Studies of liquid-metal embrittlement (LME), hydrogen embrittlement, and SCC have led to the conclusion that similar fracture processes occur in each case (Ref 61, 62, 63). Because chemisorption is common to all three, this process was concluded to be responsible for the environmentally induced crack propagation

(Ref 61). Based on fractographic studies, it was concluded that cleavage fracture is not an atomically brittle process, but occurs by alternate slip at the crack tip in conjunction with formation of very small voids ahead of the crack. It was also proposed that chemisorption of environmental species facilitated the nucleation of dislocations at the crack tip, promoting the shear processes responsible for brittle cleavagelike fracture (Ref 61, 62, 63). The origin of crack arrest markings by this mechanism is, however, uncertain. Nevertheless, this mechanism promises to explain many similarities among SCC, LME, and hydrogen embrittlement. Additional information on adsorption-enhanced plasticity can be found in the section "Liquid-Metal Embrittlement" in this article.

The Tarnish Rupture Model. This model was first proposed (Ref 64) to explain transgranular SCC, but was later modified by other researchers (Ref 65, 66, 67) to explain intergranular SCC. In the original model (Ref 64), a brittle surface film forms on the metal that fractures under the applied stress. Fracture of the film exposes bare metal, which rapidly reacts with the environment to re-form the surface film. The crack propagates by alternating film growth and fracture, as shown in Fig. 34(a). This hypothesis was later modified to explain intergranular SCC based on the assumption that the oxide film penetrates along the grain boundary ahead of the crack tip, as shown in Fig. 34(b). Again, crack propagation consists of alternating periods of film growth and brittle film fracture. Film growth requires transport of species across the film and, as a result, the thickness of the film is limited in the absence of stress (Ref 67). This model predicts crack arrest markings on intergranular fracture surfaces and discontinuous acoustic emission during crack propagation that are not always observed during intergranular SCC. Also, it assumed penetration of the film into the grain boundary ahead of the crack tip, which may not be the case for all systems (Ref 68). At present, experimental results are insufficient to confirm or refute this model (Ref 66, 67).

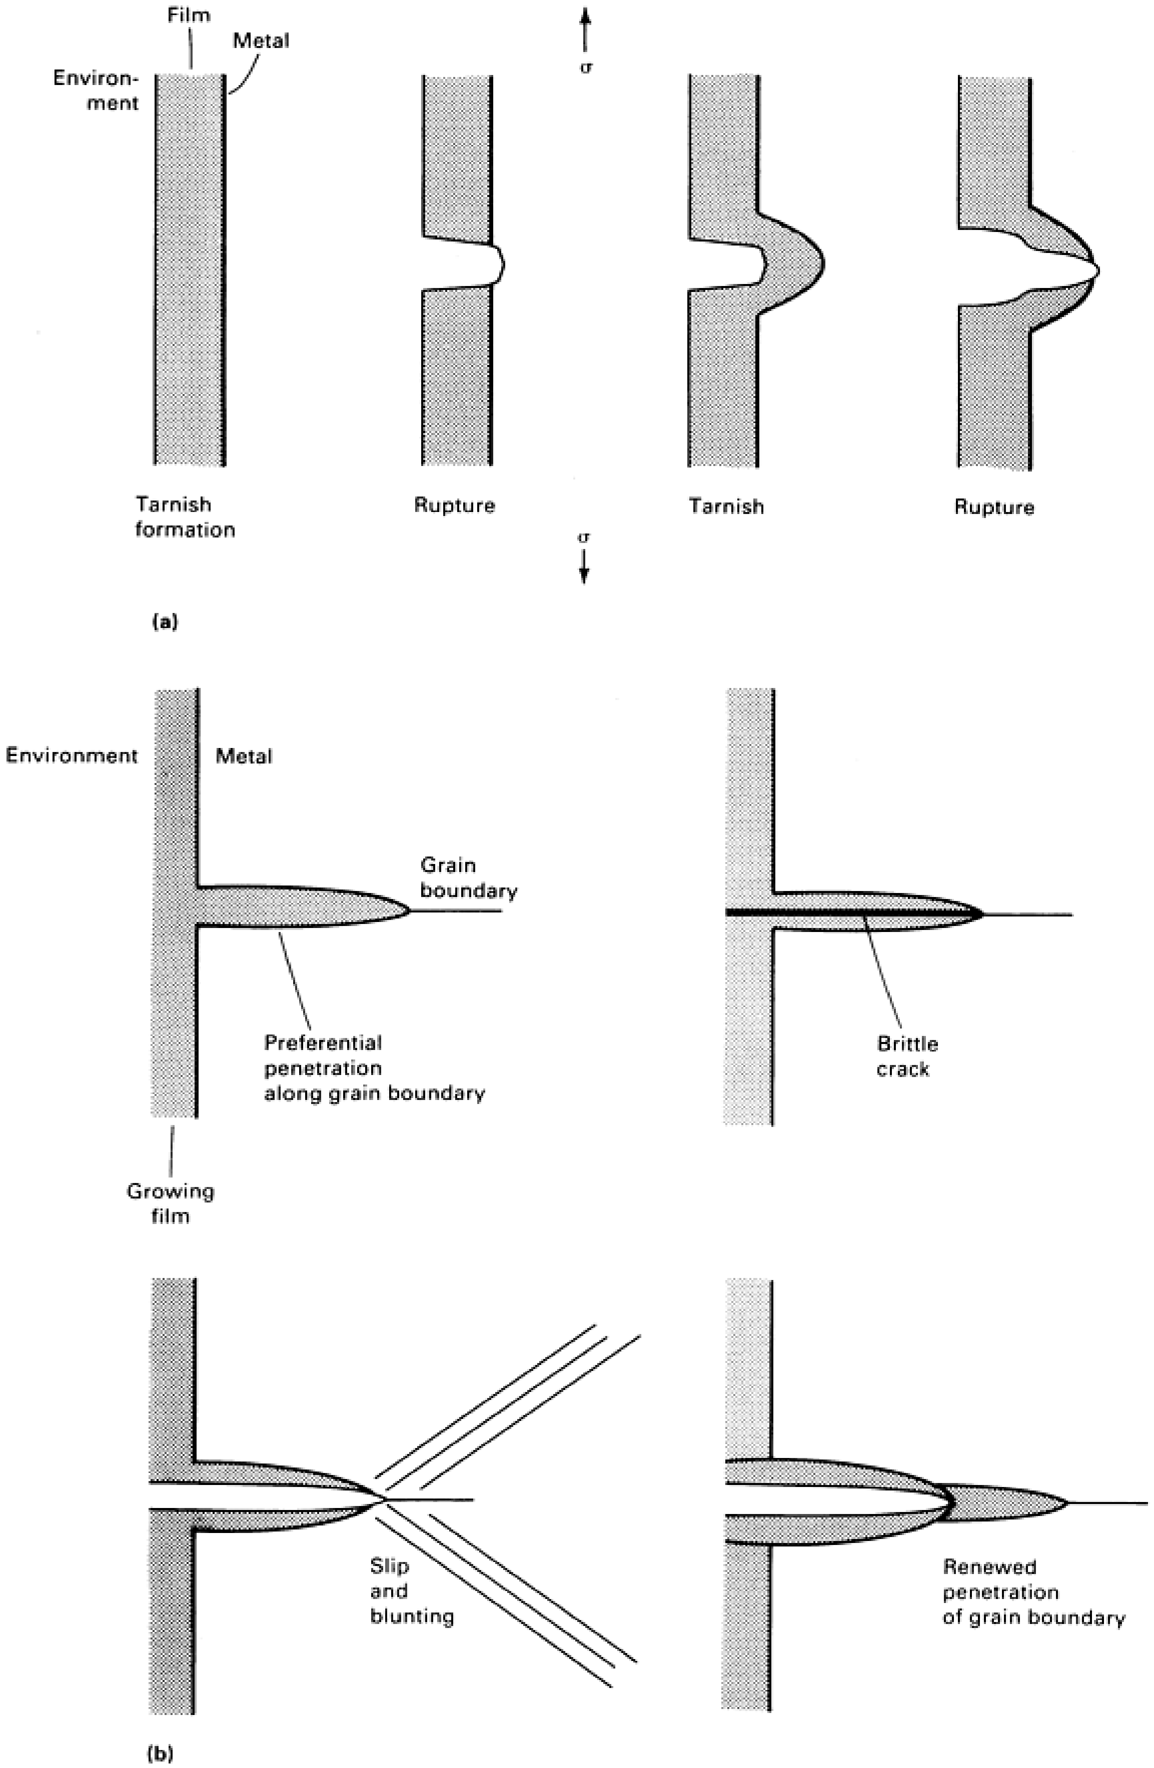

Fig. 34 Tarnish rupture models. (a) Schematic of the tarnish rupture model for SCC as proposed in Ref 64. (b) Modified tarnish rupture model of SCC for systems with intergranular oxide film penetration (Ref 66, 67)

The Film-Induced Cleavage Model. In 1959, the hypothesis was presented that dealloying and/or vacancy injection could induce brittle fracture (Ref 69). However, the exact nature of the interactions and how they could induce the observed crack propagation was not thoroughly evaluated. More recently, a model was developed based on the hypothesis that a surface film could induce cleavage fracture (Ref 70). This model assumes that:

- A thin surface film or layer forms on the surface
- A brittle crack initiates in this layer
- The brittle crack crosses the film/matrix interface with little loss in velocity
- Once in the ductile matrix, the brittle crack will continue to propagate
- This crack will eventually blunt and arrest, after which this process repeats itself

This model has the unique ability to explain the crack arrest markings, the cleavagelike facets on the fracture surface, and the discontinuous nature of crack propagation.

The hypothesis that a brittle crack will continue to propagate after it has entered the normally ductile matrix is a critical point. This allows a thin surface layer to induce brittle crack propagation over distances much greater than the film thickness. A critical examination of this hypothesis concluded that a brittle crack can propagate in a ductile matrix if the crack is sharp and is propagating at high velocities before entering the ductile matrix (Ref 71). A computer model was developed for this process, and it was concluded that a surface layer can initiate brittle fracture even if the layer is ductile (depending on lattice mismatch, and so on) (Ref 72). More research into surface films and brittle fracture is required before this model can be thoroughly evaluated.

Adsorption-Induced Brittle Fracture. This model, which was initially presented in Ref 46, is based on the hypothesis that adsorption of environmental species lowers the interatomic bond strength and the stress required for cleavage fracture. This model is frequently referred to as the stress-sorption model, and similar mechanisms have been proposed for hydrogen embrittlement and LME (Ref 73). This model predicts that cracks should propagate in a continuous manner at a rate determined by the arrival of the embrittling species at the crack tip. This model does not explain how the crack maintains an atomically sharp tip in a normally ductile material, because it does not include a provision for limiting deformation in the plastic zone. Also, the discontinuous nature of crack propagation is not explained by this model.

Hydrogen Embrittlement. Stress-corrosion cracking in some material/environment combinations can be a form of hydrogen-induced subcritical crack growth. Because the anodic reaction must have a corresponding cathodic reaction and because the reduction of hydrogen is frequently the cathodic reaction, hydrogen-induced subcritical crack growth can be the dominant stress-corrosion crack growth process in some materials. Many features of hydrogen-induced subcritical crack growth from cathodic hydrogen are very similar to those produced by gaseous or internal hydrogen. The mechanisms of hydrogen damage are discussed in the following section of this article. However, a few features of hydrogen embrittlement from cathodic hydrogen that are different from other forms of hydrogen embrittlement will be summarized.

Once hydrogen has been absorbed by a material, its effect, whether from a gaseous or cathodic source, is the same. This has been shown for a number of materials and a variety of properties. There are three primary differences between gaseous and cathodic hydrogen absorption processes, as follows. First, cathodic hydrogen adsorbs on the surface as atomic hydrogen (as reduced), while gaseous hydrogen adsorbs in the molecular form and must dissociate to form atomic hydrogen. Desorption of loosely bound molecular hydrogen is relatively easy, while the dissociation step can in some cases be the rate-determining step. Therefore, the desorption and absorption rates of gaseous and cathodic hydrogen may be substantially different for equal hydrogen activities. Second, the hydrogen activities produced by cathodic hydrogen can be quite large (thousands of psi) and are dependent on the anodic reaction rate, while gaseous hydrogen pressures are generally much lower. Lastly, the surface of the material at a crack tip may be substantially different under electrochemical corrosion conditions from that in the presence of gaseous hydrogen containing substantial quantities of other gases, such a O_2 and CO_2.

Hydrogen-induced crack growth as the dominant stress-corrosion mechanism has been suggested for ferritic steels, nickel-base alloys, titanium alloys, and aluminum alloys, although ferritic steels show the most evidence of this mechanism. The effects of such factors as yield strength, impurity segregation, and temperature on the crack growth behavior of ferritic materials in aqueous environments all follow the trends of gaseous hydrogen embrittlement. For example, the crack growth rate of a 3% Ni steel as a function of temperature in water is shown in Fig. 35(a), while the

crack growth rate of 4340 steel in gaseous hydrogen is shown in Fig. 35(b). The maximum crack growth rate occurs at about 20 °C (70 °F), with similar decreases at both higher and lower temperatures. However, anodic stress-corrosion processes become active at temperatures above 100 °C (212 °F) for the steel tested in water. Similar trends have been shown for impurity segregation effects on hydrogen-induced crack growth of materials where cathodic and gaseous hydrogen produce essentially similar results. Some of these results have been presented in the discussion "Material Chemistry and Microstructure" in this section.

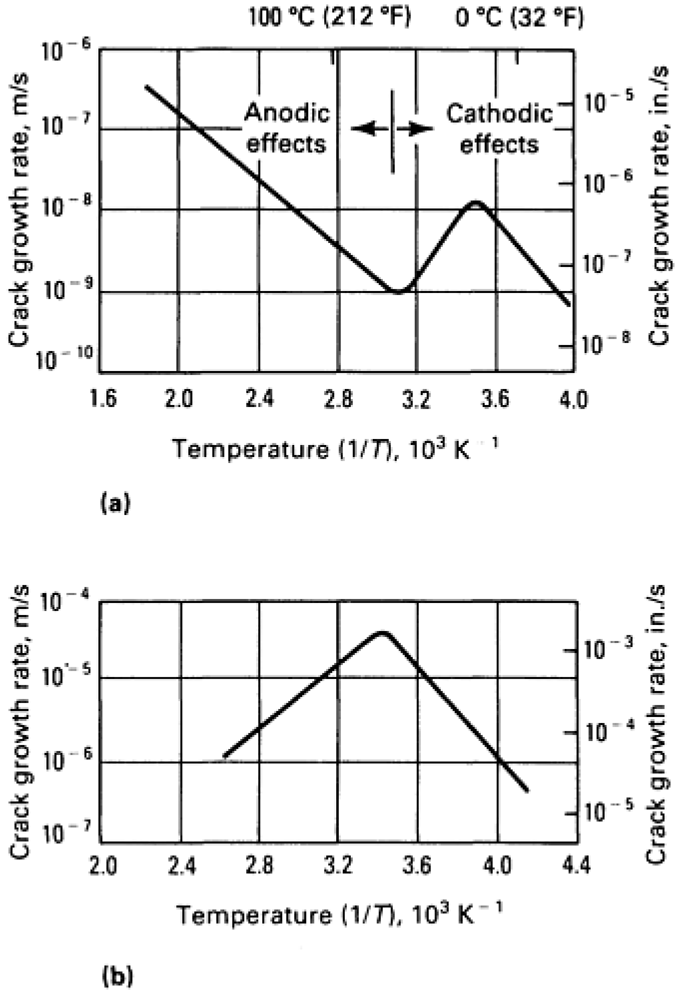

Fig. 35 Schematic of crack growth rate versus temperature for (a) 3% Ni steel in water (Ref 74) and (b) 4340 steel in gaseous hydrogen (Ref 75)

Specific mechanisms of cathodic hydrogen induced subcritical crack growth have not been developed, because it has generally been sufficient merely to identify hydrogen as the cause for cracking. However, a mechanism was presented in which grain-boundary impurities act as hydrogen recombinant poisons and enhance the uptake of cathodic hydrogen (Ref 76). A schematic of this process is shown in Fig. 36, in which the tin and antimony that segregated to the grain boundaries of nickel enhance the hydrogen uptake kinetics. This mechanism does not propose a new mechanism by which hydrogen can cause cracking, but merely proposes a mechanism by which impurity segregation can enhance hydrogen uptake. There may be circumstances in which such a mechanism could tip the balance between an anodically driven process and a cathodically driven process or could accelerate cracking to a value that is measurable or of practical significance. However, a review of the combined effects of impurity segregation and hydrogen embrittlement concluded that grain-boundary impurities behave the same with cathodic and gaseous hydrogen in that they enhance crack growth by a combined grain-boundary embrittlement processes but not by enhanced hydrogen uptake (Ref 77). It should be noted, however, that a material with impurities such as sulfur, phosphorus, antimony, and tin segregated to their grain boundaries are more susceptible to all forms of hydrogen--cathodic, gaseous, or internal.

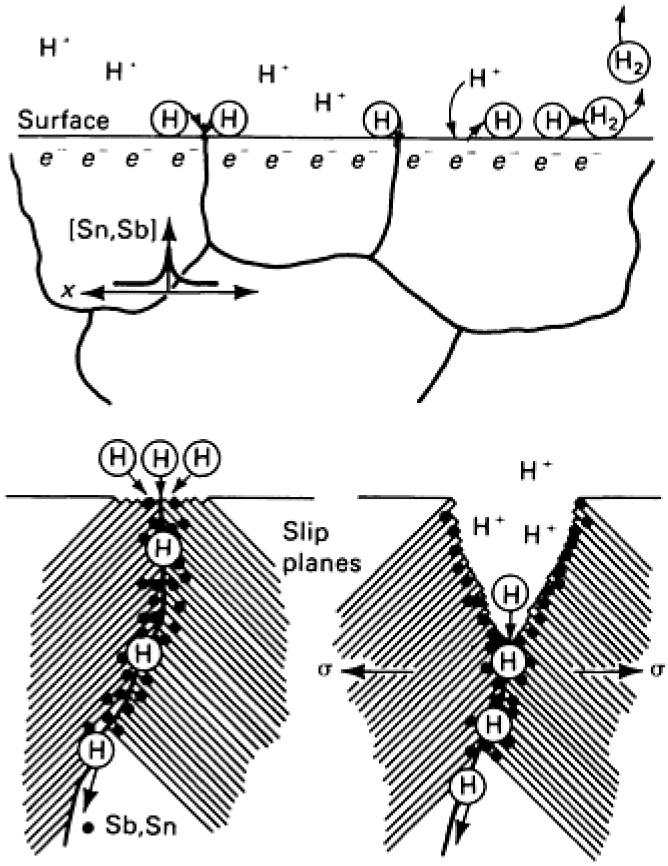

Fig. 36 Schematic showing effect of some impurities on mechanism by which intergranular embrittlement of nickel is presumed to occur at cathodic potentials

Summary

Stress-corrosion cracking is a phenomenon in which time-dependent crack growth occurs when the necessary electrochemical, mechanical, and metallurgical conditions exist. Corrosion fatigue is a related process in which the load is cyclic in corrosion fatigue rather than static as in stress corrosion. When hydrogen is generated as a product of the corrosion reaction, crack growth can occur by a hydrogen embrittlement process in much the same way as if hydrogen were in the gaseous form. A common feature of each of these processes is the subcritical crack growth in which cracks grow from existing flaws or initiation sites and grow to a size at which catastrophic failure occurs. Catastrophic failure occurs because the combination of crack length and applied stress increases the stress intensity to the fracture toughness of the material. A second common feature of stress corrosion, corrosion fatigue, and hydrogen-induced crack growth is that these mechanisms do not require the entire component to become embrittled; the effect is localized to the crack tip region.

This section was intended to familiarize the reader with the phenomenological and mechanistic aspects of stress corrosion in order to enhance the use of other discussions in this Handbook on stress-corrosion evaluation and occurrence in specific industries and environments. The phenomenological description of crack initiation and propagation describes well-established experimental evidence and observations of stress corrosion, while the discussions on mechanisms describe the physical process involved in crack initiation and propagation. The physical processes involved in crack growth have received more evaluation and are better understood than the processes responsible for crack initiation. There is some phenomenological understanding of stress-corrosion crack initiation, but the detailed mechanistic information is not well known.

Stress-corrosion cracking occurs when certain critical conditions are achieved. These conditions include electrochemical, mechanical, and metallurgical factors that must exist simultaneously. A change in any one of these three factors is adequate for eliminating SCC; therefore, a clear knowledge of these critical factors is important in system design. The

important electrochemical parameters include oxidizing potential, pH, impurity concentration, and temperature. The important mechanical parameters include stress, stress intensity, and strain rate. The important metallurgical factors include localized micro-chemistry (such as the depletion of passive film forming elements or the enrichment of active corroding elements), bulk composition, deformation character, and yield strength.

There are a number of plausible mechanisms or physical processes that account for SCC. No single mechanism is adequate to describe stress corrosion in the variety of materials in which it has been observed. Stress-corrosion crack propagation mechanisms can be subdivided into dissolution and mechanical fracture models, with the mechanical fracture models further divided into ductile and brittle crack extension processes. Dissolution models include film-rupture and active-path processes, while ductile mechanical models include corrosion tunneling and adsorption-enhanced plasticity models. Brittle mechanical models include the tarnish rupture and film-induced cleavage models.

Hydrogen Damage

Bruce Craig, Metallurgical Consultants, Inc.

Hydrogen damage is a form of environmentally assisted failure that results most often from the combined action of hydrogen and residual or applied tensile stress. Hydrogen damage to specific alloys or groups of alloys manifests itself in many ways, such as cracking, blistering, hydride formation, and loss in tensile ductility. For many years, these failures have been collectively termed hydrogen embrittlement; this term persists even though it is improperly used to describe a multitude of failure modes involving hydrogen, several of which do not demonstrate the classical features of embrittlement (that is, reduced load carrying capability or fracture below the yield strength). This section will classify the various forms of hydrogen damage, summarize the various theories that seek to explain hydrogen damage, and review hydrogen degradation in specific ferrous and nonferrous alloys. Information on the effect of hydrogen on fracture characteristics is available in the article "Modes of Fracture" in *Fractography,* Volume 12 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Classification of Hydrogen Processes

The specific types of hydrogen damage have been categorized in order to enhance the understanding of the factors that affect this behavior in alloys and to provide a basis for development and analysis of theories regarding different hydrogen damage mechanisms (Ref 78). Table 3 presents one of these classifications schemes, describing the materials that are susceptible to the various forms of damage, the source of hydrogen, typical conditions for the occurrence of failure, and the initiation site. The mechanisms for each of these failure modes will also be described briefly. The first three classes are grouped together and designated hydrogen embrittlement because these are the failure modes that typically exemplify classical hydrogen embrittlement.

Table 3 Classifications of processes of hydrogen degradation of metals

	Hydrogen embrittlement			**Hydrogen attack**	**Blistering**	**Shatter cracks, flakes, fisheyes**	**Micro-perforation**	**Degradation in flow properties**	**Metal hydride formation**
	Hydrogen environment embrittlement	**Hydrogen stress cracking**	**Loss in tensile ductility**						
Typical materials	Steels, nickel-base alloys, metastable stainless steel, titanium alloys	Carbon and low-alloy steels	Steels, nickel-base alloys, Be-Cu bronze, aluminum alloys	Carbon and low-alloy steels	Steels, copper, aluminum	Steels (forgings and castings)	Steels (compressors)	Iron, steels, nickel-base alloys	V, Nb, Ta, Ti, Zr, U
Usual source of hydrogen (not exclusive)	Gaseous H_2	Thermal processing, electrolysis, corrosion	Gaseous hydrogen, internal hydrogen from electrochemical charging	Gaseous	Hydrogen sulfide corrosion, electrolytic charging, gaseous	Water vapor reacting with molten steel	Gaseous hydrogen	Gaseous or internal hydrogen	Internal hydrogen from melt; corrosion, electrolytic charging, welding
Typical conditions	10^{-6} to 10^{8} N/m^2 (10^{-10} to 10^{4} psi) gas pressure	0.1 to 10 ppm total hydrogen content	0.1 to 10 ppm total hydrogen content range of gas pressure exposure	Up to 10^{8} N/m^2 (15 ksi) at 200-595 °C (400-1100 °F)	Hydrogen activity equivalent to 0.2 to 1 × 10^{8} N/m^2 (3-15 ksi) at 0-150 °C (30-300 °F)	Precipitation of dissolved ingot cooling	2 to 8 × 10^{8} N/m^2 (30-125 ksi) at 20-100 °C (70-200 °F)	1-10 ppm hydrogen content (iron at 20 °C, or 70 °F) up to 10^{8} N/m^2 (15 ksi) gaseous hydrogen (various metals, *T* >0.5 melting point)	10^{5} to 10^{8} N/m^2 (15-15,000 psi) gas pressure hydrogen activity must exceed solubility limit near 20 °C (70 °F)
	Observed at -100 to 700 °C (-150 to 1290 °F); most severe near 20 °C (70 °F)	Observed at -100 to 100 °C (-150 to 212 °F); most severe near 20 °C (70 °F)	Observed at -100 to 700 °C (-150 to 1290 °F)	. . .	. . .	. . .	. . .	. . .	. . .
	Strain rate important; embrittlement more severe at low strain	Strain rate important; embrittlement more severe at	Occurs in absence of effect on yield stress; strain rate	. . .	. . .	. . .	. . .	. . .	. . .

	rate; generally more severe in notched or precracked specimens	low strain rate; always more severe in notched or precracked specimens	important						
Failure initiation	Surface or internal initiation; incubation period not observed	Internal crack initiation	Surface and/or internal effect	Surface (decarburization); internal carbide interfaces (methane bubble formation)	Internal defect	Internal defect	Unknown	. . .	Internal defect
Mechanisms	Surface or subsurface processes	Internal diffusion to stress concentration	Surface or subsurface processes	Carbon diffusion (decarburization); hydrogen diffusion; nucleation and growth (bubble formation)	Hydrogen diffusion; nucleation and growth of bubble; steam formation	Hydrogen diffusion to voids	Unknown	Adsorption to dislocations; solid-solution effects	Hydride precipitation

Source: Ref 78

Hydrogen environment embrittlement occurs during the plastic deformation of alloys in contact with hydrogen-bearing gases or a corrosion reaction and is therefore strain rate dependent. The degradation of the mechanical properties of ferritic steels, nickel-base alloys, titanium alloys, and metastable austenitic stainless steels is greatest when the strain rate is low and the hydrogen pressure and purity are high.

Hydrogen stress cracking, often referred to as hydrogen-induced cracking or static fatigue, is characterized by the brittle fracture of a normally ductile alloy under sustained load in the presence of hydrogen. Most often, fracture occurs at sustained loads below the yield strength of the material. This cracking mechanism depends on the hydrogen fugacity, strength level of the material, heat treatment/microstructure, applied stress, and temperature. For many steels, a threshold stress exists below which hydrogen stress cracking does not occur. This threshold is a function of the strength level of the steel and the specific hydrogen-bearing environment. Therefore, threshold stress or stress intensity for hydrogen stress cracking is not considered a material property. Generally, the threshold stress decreases as the yield strength and tensile strength of an alloy increase. Hydrogen stress cracking is associated with absorption of hydrogen and a delayed time to failure (incubation time) during which hydrogen diffuses into regions of high triaxial stress. Hydrogen stress cracking may promote one mode of fracture in an alloy rather than another form normally observed in benign environments. Thus, all modes of cracking have been observed in most commercial alloy systems; however, hydrogen stress cracking usually produces sharp singular cracks in contrast to the extensive branching observed for SCC. The catastrophic cracking of steels in hydrogen sulfide (H_2S) environments referred to as sulfide stress cracking is a special case of hydrogen stress cracking.

Loss in tensile ductility was one of the earliest recognized forms of hydrogen damage. Significant decreases in elongation and reduction in area are observed for steels, stainless steels, nickel-base alloys, aluminum alloys, and titanium alloys exposed to hydrogen. This mode of failure is most often observed in lower-strength alloys, and the extent of loss in tensile ductility is a function of hydrogen content of the material. Loss in tensile ductility behavior is strain rate sensitive and becomes more pronounced as the strain rate decreases.

Hydrogen attack is a high-temperature form of hydrogen damage that occurs in carbon and low-alloy steels exposed to high-pressure hydrogen at high temperatures for extended time. Hydrogen enters the steel and reacts with carbon either in solution or as carbides to form methane gas; this may result in the formation of cracks and fissures or may simply decarburize the steel, resulting in a loss in strength of the alloy. This form of damage is temperature dependent, with a threshold temperature of approximately 200 °C (400 °F).

Blistering occurs predominantly in low-strength alloys when atomic hydrogen diffuses to internal defects, such as laminations or nonmetallic inclusions, and then precipitates as molecular hydrogen (H_2). The pressure of molecular hydrogen can attain such high values that localized plastic deformation of the alloy occurs, forming a blister that often ruptures. Blisters are frequently found in low-strength steels that have been exposed to aggressive corrosive environments (such as H_2S) or cleaned by pickling.

Shatter cracks, flakes, and fish eyes are features common to hydrogen damage in forgings, weldments, and castings. They are attributed to hydrogen pickup during melting operations when the melt has a higher solubility for hydrogen than the solid alloy. During cooling from the melt, hydrogen diffuses to and precipitates in voids and discontinuities, producing the features that result from the decreased solubility of hydrogen in the solid metal. In many aspects, these features are comparable to blistering, and this could be considered a special case of that class.

Microperforation by high-pressure hydrogen occurs at extremely high pressures of hydrogen near room temperature. Microperforation occurs predominately in steels. This form of hydrogen damage manifests itself as a network of small fissures that allow permeation of the alloy by gases and liquids.

Degradation in flow properties in hydrogen environments has been found at ambient temperatures for iron and steel and at elevated temperature for several alloy systems. The steady-state creep rate under constant load has been observed to increase in the presence of hydrogen for some nickel-base alloys.

Hydride formation produces embrittlement in magnesium, tantalum, niobium, vanadium, uranium, thorium, zirconium, titanium, and their alloys, as well as many other less common metals and alloys. The degradation of mechanical properties and the cracking of these metals and their alloys are attributable to the precipitation of metal hydride phases. Hydrogen pickup often results from welding, heat treating, charging from corrosion processes, or during melting of the alloy. Hydride formation is enhanced for some metal-hydrogen systems by the application of stress--the so-called stress-induced hydride formation. Alloy systems that form hydrides are generally ductile at high (>300 K) and low

(<100 K) temperatures at which they fracture by ductile rupture. This temperature dependence is comparable to that observed for the hydrogen embrittlement of ferrous and nickel alloys. Some of these alloys are also susceptible to failure in hydrogen by mechanisms other than hydriding. Some evidence exists that nickel and aluminum alloys may also form a highly unstable hydride that could contribute to hydrogen damage of these alloys; however, this possibility has not been confirmed.

Theories for Hydrogen Damage

As may be appreciated from the numerous classes of hydrogen damage, there are many explanations or theories for these various forms of degradation. The preeminent theories for hydrogen damage are based on pressure, surface adsorption, decohesion, enhanced plastic flow, hydrogen attack, and hydride formation. Although many other theories have been presented, most are variations on these basic models.

The pressure theory of hydrogen damage, or more specifically, hydrogen embrittlement, is one of the oldest models for hydrogen damage (Ref 79). This theory attributes hydrogen embrittlement to the diffusion of atomic hydrogen into the metal and its eventual accumulation at voids or other internal surfaces in the alloy. As the concentration of hydrogen increases at these microstructural discontinuities, a high internal pressure is created that enhances void growth or initiates cracking. This model, although apparently reasonable for blistering and possibly appropriate for some aspects of loss in tensile ductility, does not explain many of the factors observed for classes of failure such as hydrogen stress cracking. However, it is a well-recognized phenomenon that charging hydrogen into steel or nickel alloys at high fugacity, either with high-pressure hydrogen gas or under extreme electro-chemical charging, can create a significant density of voids and irreversible damage to the alloy consistent with a pressure-dependent model.

The surface adsorption theory suggests that hydrogen adsorbs on the free surfaces created adjacent to the crack tip, decreasing the surface free energy and thus the work of fracture (Ref 80). Reduction in the work of fracture would thus enhance crack propagation at stress levels below those typically experienced for a particular alloy in a benign environment. There are many arguments against this model. The principal criticism is that it greatly underestimates the work of fracture and does not account for the discontinuous crack growth that has been observed for hydrogen cracking.

Decohesion describes the effect of hydrogen on the cohesive force between atoms of the alloy matrix (Ref 81, 82). Sufficiently high hydrogen concentrations that accumulate ahead of a crack tip are assumed to lower the maximum cohesive force between metal atoms such that the local maximum tensile stress perpendicular to the plane of the crack then becomes equivalent to or greater than the lattice cohesive force and fracture results.

Enhanced plastic flow is associated with hydrogen dislocation interactions and is primarily based on fractographic observations (Ref 83). This approach proposes that atomic hydrogen enhances dislocation motion, generally screw dislocations, and the creation of dislocations at surfaces and/or crack tips, leading to softening of the material on a localized scale. Although this behavior has been observed in certain steels, hardening by hydrogen has also been found. Careful high-resolution electron microscopy of what appears to be brittle cleavage or intergranular fracture surfaces has revealed evidence of crack tip plasticity in support of this mechanism.

Hydride formation is the degradation of Group Vb metals (niobium, vanadium, and tantalum) and zirconium, titanium, and magnesium in hydrogen environments by the formation of a brittle metal hydride at the crack tip. When sufficient hydrogen is available in the alloy, a metal hydride precipitates. Cracking of the hydride occurs, followed by crack arrest in the more ductile matrix or continued crack growth between hydrides by ductile rupture. Because hydride formation is enhanced by the application of stress, the stress field ahead of the crack tip may induce precipitation of additional hydrides that cleave. Thus, in some alloys, brittle crack propagation occurs by repeated precipitation of hydrides ahead of the crack tip, cleavage of these hydrides, and precipitation of new hydrides and so on until fracture is complete (Ref 84).

Hydrogen attack is one of the better understood mechanisms of hydrogen damage, but is specific to a single class of damage by hydrogen at high temperature (Ref 85). Hydrogen attack may take two forms of damage: surface decarburization or internal decarburization. However, the mechanism is the same for both forms. At elevated temperatures, hydrogen diffuses into the steel or reacts at the surface with carbon in solid solution or that which has dissociated from carbides to form a hydrocarbon--typically methane. This chemical reaction is easily described thermodynamically, which sets this form of damage apart for the more complex forms of hydrogen damage. As expected, damage is dependent on temperature and hydrogen partial pressure. Surface decarburization occurs at temperatures above 540 °C (1000 °F) and internal decarburization at temperatures from 200 °C (400 °F) upward.

Hydrogen Trapping. Although numerous models exist, none adequately explains the behavior exhibited by alloys in different hydrogen-bearing systems. Until a universal theory is developed, one must rely on the phenomenological behavior between the more prominent alloy systems to understand hydrogen damage. One of the principal factors that determines the hydrogen damage susceptibility of ferrous alloys is a phenomenon referred to as trapping (Ref 86). Diffusion studies of iron and steels have shown an initial retardation in diffusion rate or lag time for hydrogen diffusion through these alloys before a steady-state diffusivity compatible with that expected theoretically is achieved. This lag time is generally considered to be related to the filling of traps by hydrogen. In fact, the apparent diffusivity of hydrogen in steels shows a precipitous decrease with increasing concentration of particles (traps), as shown in Fig. 37.

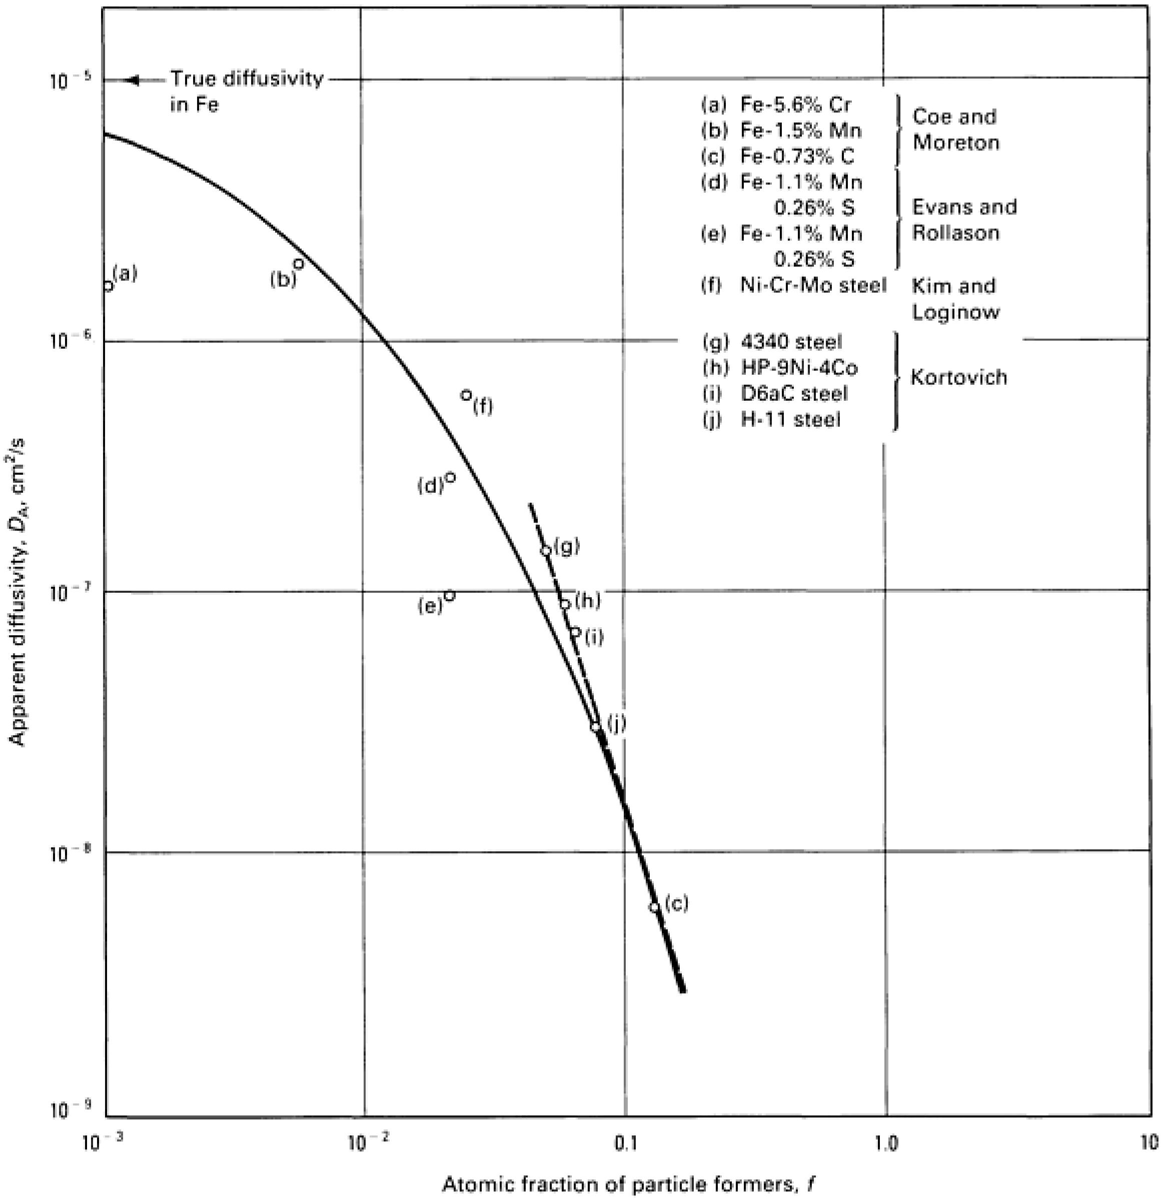

Fig. 37 Decrease in apparent hydrogen diffusivity with increased fraction of precipitate particles. Source: Ref 87

Hydrogen trapping may be considered the binding of hydrogen atoms to impurities, structural defects, or microstructural constituents in the alloy. Binding may be attributed to local electric fields and stress fields, temperature gradients, chemical potential gradients, or physical trapping. These hydrogen traps may be mobile (dislocations, stacking faults) or stationary (grain boundaries, carbide particles, individual solute atoms). They may also be reversible or irreversible traps. Short-duration trapping of hydrogen in which the occupancy time is limited is referred to as reversible. A long residency time for hydrogen characterized by a high binding energy is termed irreversible trapping. Table 4 presents a classification

of hydrogen traps in steel. The concept and investigation of trapping have been developed primarily for steels; however, it may not be restricted to this system. Face-centered cubic alloys show a similar trapping behavior, although at a somewhat reduced efficiency for trapping compared to steels.

Table 4 Classification of hydrogen traps in steels according to size

Trap class	**Example of trap**		**Interaction energy[a], eV**	**Character if known**	Influence diameter, D_i
	Elements at the left of iron	**Elements with a negative ϵ_H^i [b]**			
Point	. . .	Ni	(0.083)	Most probably reversible	**A few interatomic spacings**
	Mn	Mn	(0.09)		
	Cr	Cr	(0.10)		
	V	V	(0.16)		
	. . .	Ce	(0.16)		
	. . .	Nb	(0.16)	Reversible	
	Ti	Ti (vacancy)	0.27		
	Sc	O	(0.71)	Getting more irreversible	
	Ca	Ta	(0.98)		
	K	Ia	(0.98)		
	. . .	Nd	(1.34)		
Linear	Dislocations		0.31	Reversible	**3 nm for an edge dislocation**
			0.25 (average values)	Reversible	
	Intersection of three grain boundaries		. . .	Depends on coherency	. . .
Planar or bimensional	Particle/matrix interfaces				

bimensional	TIC (incoherent)	0.98	Irreversible, gets more reversible as the particle is more coherent	**Diameter of the particle, or a little more as coherency increases**
	Fe_3C MnS	0.8-0.98		
	Grain boundaries	0.27	Reversible	**Same as dislocation**
		Average value 0.55-0.61 (high angle)	Reversible or irreversible	
	Twins	. . .	Reversible	**A few interatomic spacings**
	Internal surfaces (voids)	. . .	. . .	**. . .**
Volume	Voids	>0.22	. . .	**Dimension of the defect**

(a) Values of interaction energies are either experimental or are calculated (when between parentheses) at room temperature.

(b) ϵ_H^i is the interaction coefficient. A negative ϵ_H^i means hydrogen is attracted.

Hydrogen Damage in Iron-Base Alloys

Pure Irons. Hydrogen damage may occur in relatively pure irons, such as Ferrovac, Plastiron, and Armco Iron, producing either transgranular or intergranular fracture, depending on the presence of impurities and solutes (carbon, oxygen, and nitrogen) at the grain boundaries and the heat treatment. Hydrogen can also lower the yield strength and flow stress of high-purity iron around room temperature or lead to hardening. Although the yield strength is reduced for impure iron, the flow stress may be increased under conditions of low hydrogen fugacity.

Ferrous Alloys. Many factors affect the behavior of ferrous alloys in hydrogen-bearing environments. Hydrogen concentration, temperature, heat treatment/microstructure, stress level (applied and yield stress), solution composition, and environment are the primary factors involved in determining susceptibility to hydrogen embrittlement. Figure 38 shows the effect of hydrogen concentration on the time to failure for a high-strength steel. The longer the baking time, the lower the residual hydrogen in the steel matrix. In general, increasing the concentration of hydrogen in an alloy will reduce time to failure and the stress level at which failure will occur.

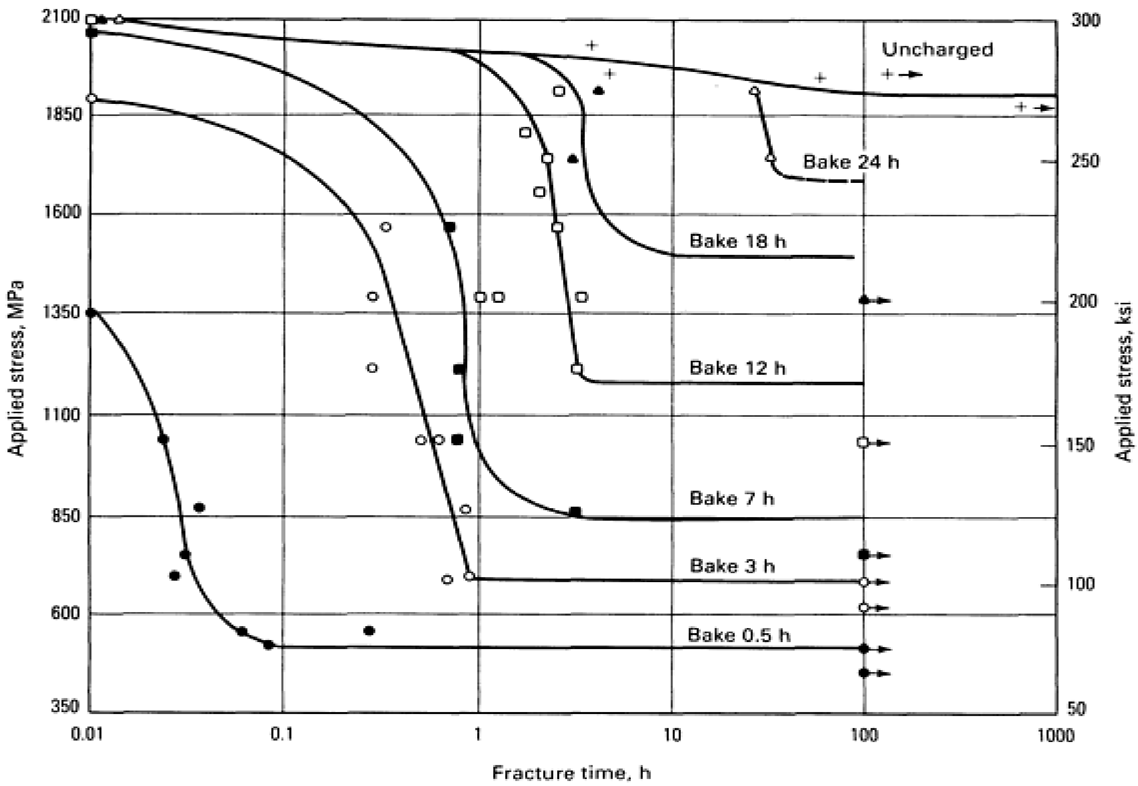

Fig. 38 Static fatigue curves for various hydrogen concentrations obtained by different baking times at 570 °C (300 °F). Sharp-notch high-strength steel specimens; normal notch strength: 2070 MPa (300 ksi). Source: Ref 81

Hydrogen concentration in the alloy is a function of the fugacity or the approximate concentration of hydrogen at the surface exposed to the environment. Therefore, hydrogen embrittlement will be controlled by the hydrogen gas pressure or pH of the environment as well as constituents within the environment that may accelerate or inhibit the entry of hydrogen into the alloy. Elements such as sulfur, phosphorus, antimony, tin, and arsenic and their compounds have been found to inhibit the hydrogen recombination reaction in aqueous solutions, thus increasing the charging of atomic hydrogen into the alloy. In contrast, small amounts of oxygen in gaseous hydrogen environments have demonstrated an inhibitive effect on crack growth of high-strength steels subject to hydrogen cracking.

Figure 39 shows the dependence of both the threshold stress intensity and the crack growth rate of high-strength AISI 4130 steel on hydrogen pressure. Increasing the hydrogen pressure reduces the threshold stress intensity for crack initiation and increases the crack growth rate for a specific stress intensity value.

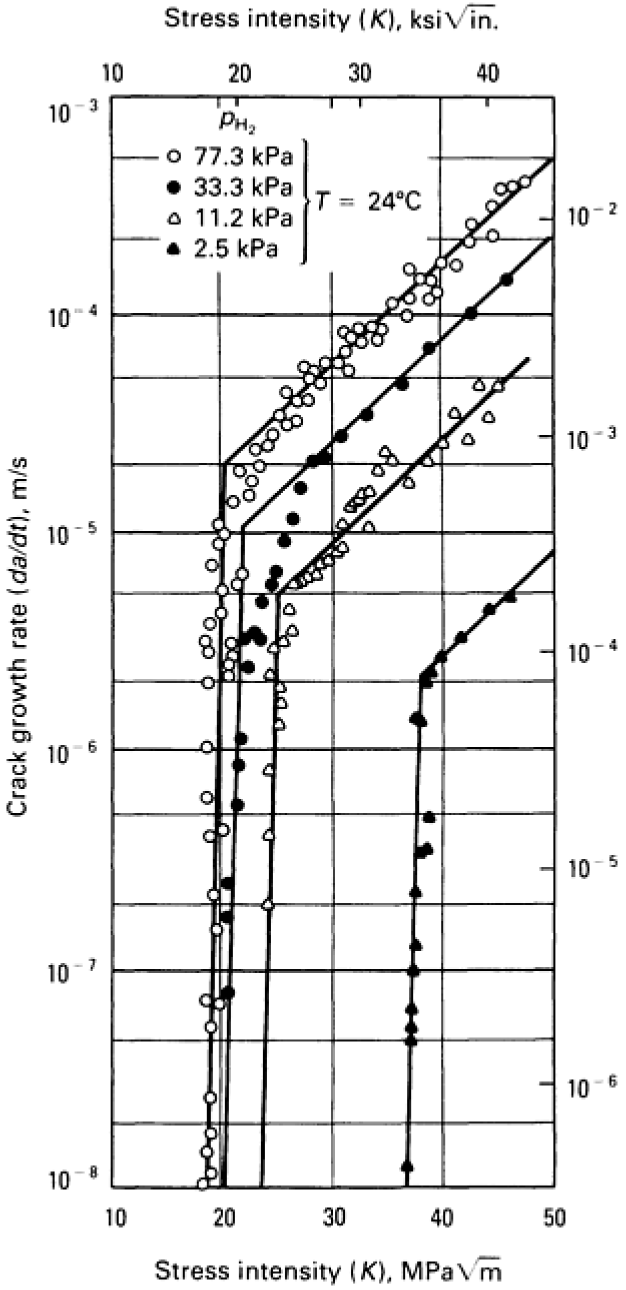

Fig. 39 The *K* dependence of *da/dt* at various hydrogen pressures at 24 °C (75 °F) for AISI 4340 steel. Source: Ref 89

Temperature also plays an important role in the hydrogen embrittlement of ferrous alloys. Embrittlement is most severe near room temperature (Ref 90) and becomes less severe or nonexistent at higher or lower temperatures (Fig. 40). At lower temperatures, the diffusivity of hydrogen is too sluggish to fill sufficient traps, but at high temperatures, hydrogen mobility is enhanced and trapping is diminished. As can be seen in Fig. 40, embrittlement is also strongly strain rate dependent. At high strain rates, fracture may proceed without the assistance of hydrogen because the mobility of hydrogen is not sufficient to maintain a hydrogen atmosphere around moving dislocations.

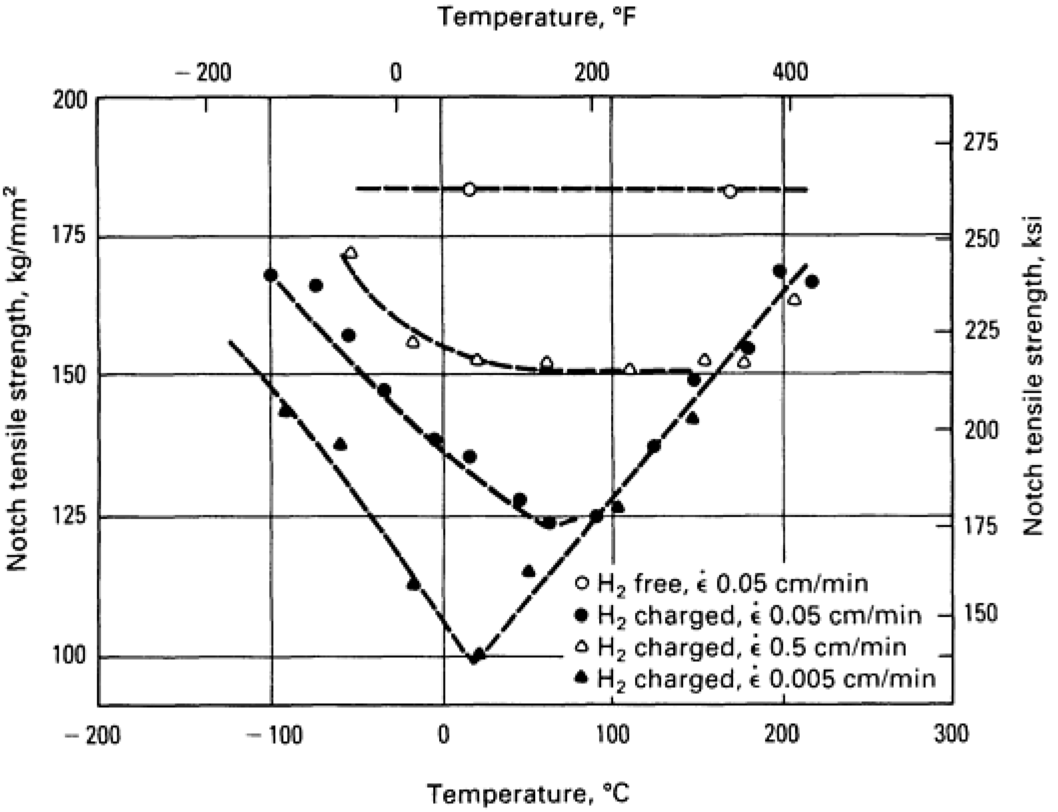

Fig. 40 Notch tensile strength of high-strength steel plotted against testing temperature for three strain rates (crosshead speeds). Source: Ref 90

Figure 41 shows threshold stress intensity as a function of yield strength of AISI 4340 steel in aqueous and gaseous hydrogen. It can be seen that the threshold stress intensity for crack growth generally decreases with increasing yield strength, regardless of environment, and that very high-strength steels are not usable in hydrogen environments. Threshold stress intensities and crack growth rates are a function of the specific hydrogen environments, with H_2S being one of the most severe environments (Fig. 42). At lower yield strengths, the mechanism for hydrogen-assisted failure apparently changes, and blistering becomes the more common feature of failure. The threshold stress intensities for high-strength steels subjected to hydrogen environments are significantly less than those thresholds measured under benign conditions. These lower thresholds lead to subcritical crack growth when compared to critical values expected from fracture mechanics. Therefore, it is common to designate these thresholds as K_{ISCC} or K_{IH}.

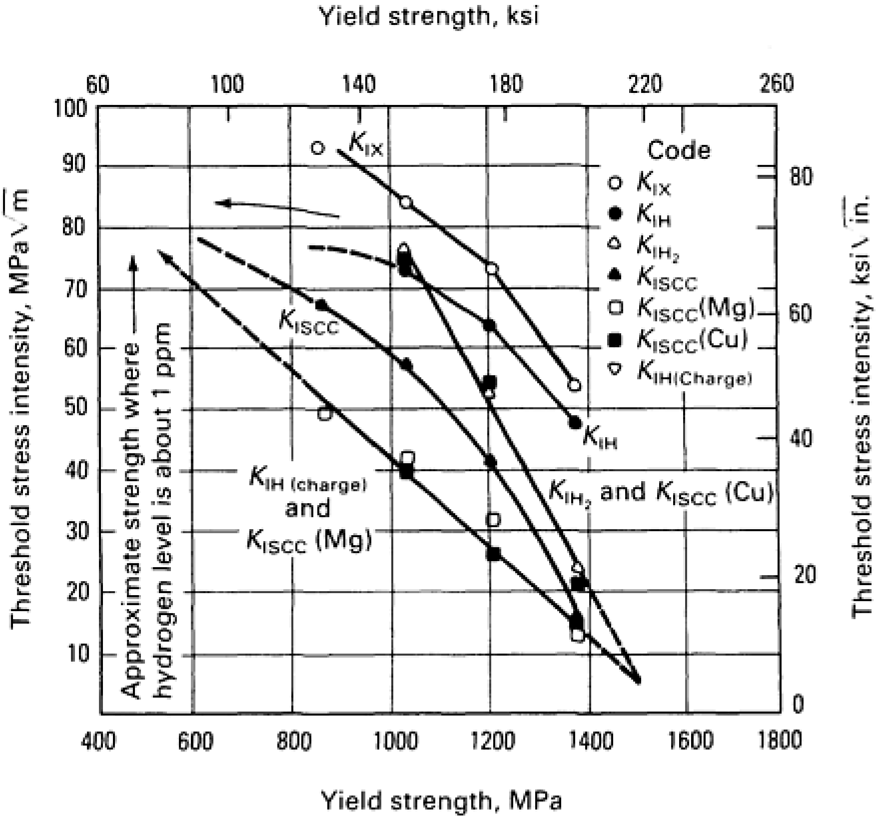

Fig. 41 Effect of yield strength on some threshold stress intensity parameters for crack growth in a commercial AISI 4340 plate. K_{IX} = threshold stress intensity as a function of the yield strength in air; K_{IH} is similar to K_{IX} but slowly loaded; K_{ISCC} (Mg) and K_{ISCC} (Cu) represent specimen coupled to magnesium and copper, respectively. Source: Ref 91

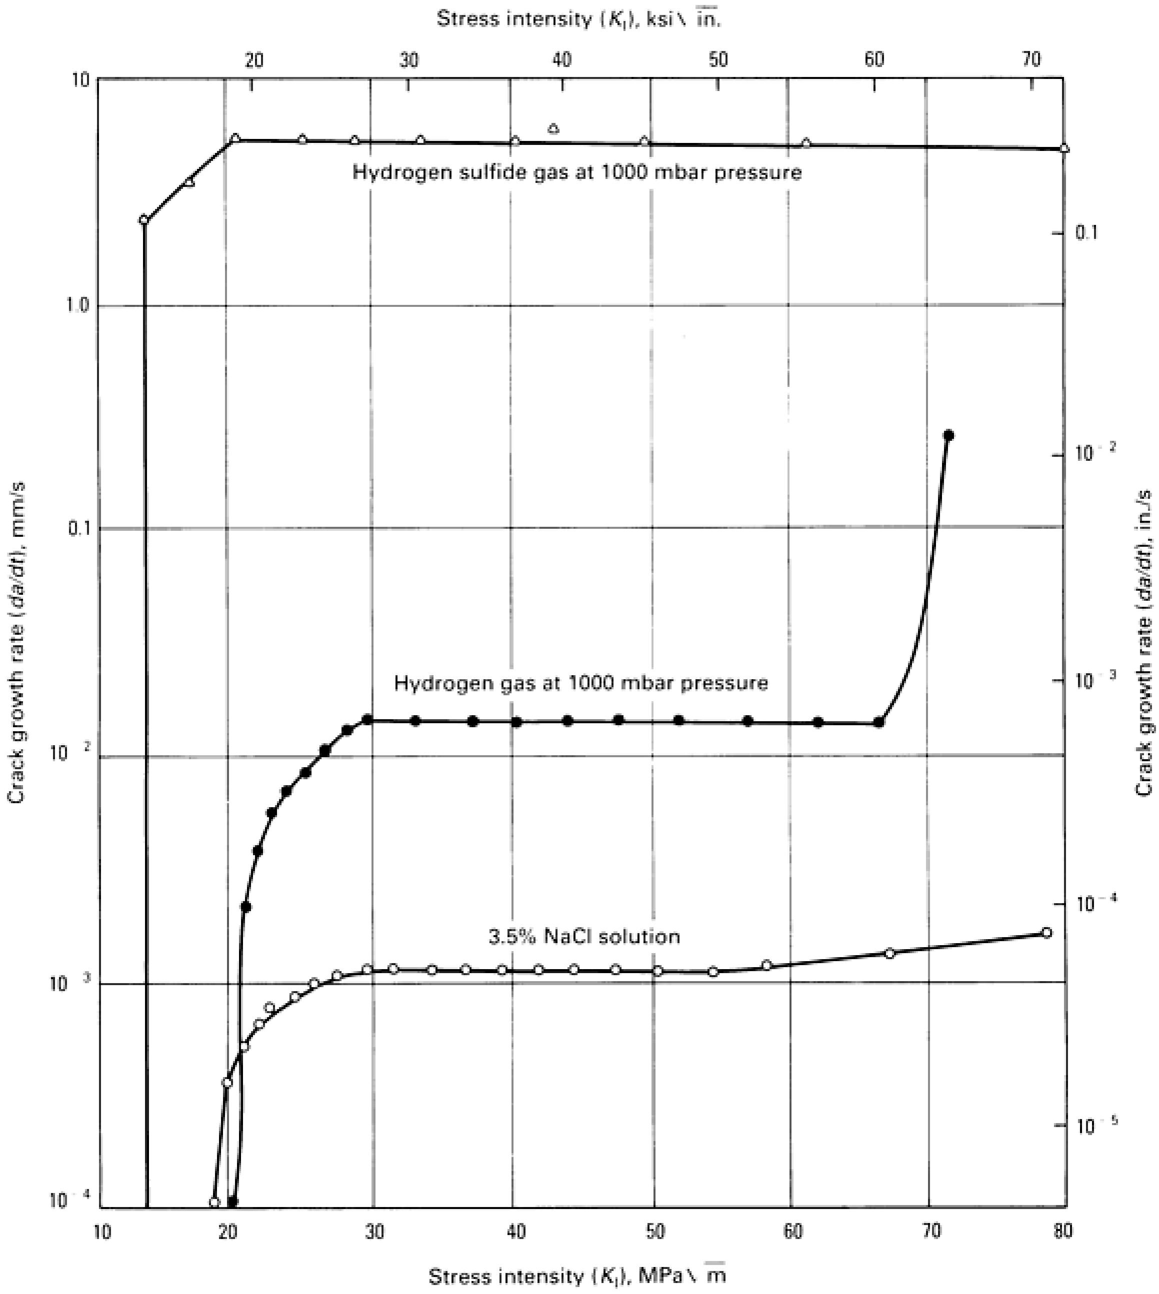

Fig. 42 Crack velocity as a function of stress intensity for a chromium-molybdenum-vanadium steel at 291 K (18 °C, or 64 °F). Source: Ref 92

In low-strength steels (700-MPa, or 100-ksi, yield or less), hydrogen damage occurs predominately by loss in tensile ductility or blistering. For loss in tensile ductility, hydrogen promotes the formation and/or growth of voids by enhancing the decohesion of the matrix at carbide particle and inclusion interfaces.

At higher hydrogen fugacities and often in the absence of stress, blistering or a form of cracking also associated with inclusions--referred to as stepwise, or blister cracking--can occur. Stepwise cracking has been observed frequently in low-strength steels subjected to H_2S-containing environments in the absence of stress (Fig. 43).

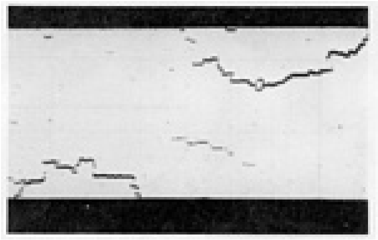

Fig. 43 Stepwise cracking of a low-strength pipeline steel exposed to H_2S. 6×

Fracture of low-strength steels in hydrogen environments may be characterized by ductile dimple-rupture, tearing, cleavage, quasi-cleavage, and, less frequently under certain conditions, intergranular cracking. The article "Modes of Fracture" in *Fractography,* Volume 12 of *ASM Handbook,* formerly 9th Edition *Metals Handbook,* contains fractographs illustrating the effects of hydrogen on the fracture appearance of steels.

High-strength steels (>700-MPa, or 100-ksi, yield) are prone to fracture either in an intergranular fashion or by quasi-cleavage, depending on the stress intensity. These steels commonly display an incubation time before fracture initiates under sustained loading, usually in association with regions of high-stress triaxiality. Because triaxial stresses are created at notch roots or under plane strain, fracture initiates internally in the steel. Intergranular fracture is promoted by the presence of impurity elements at prior-austenite or ferrite grain boundaries. Elements such as phosphorus, sulfur, tin, antimony, and arsenic have been found to enhance the intergranular fracture of high-strength steels in hydrogen, and as expected, temper-embrittled steels are even more susceptible to hydrogen stress cracking than steels that are not embrittled.

Metallurgical structure can have a profound effect on the resistance of steels to hydrogen embrittlement. When compared at equivalent strength levels, a quenched-and-tempered fine-grain microstructure is more resistant to cracking than a normalized or bainitic steel. However, this is also dependent to large extent on the strength level at which this comparison is made. In general, the most resistant microstructure is a highly tempered martensitic structure with equiaxed ferrite grains and spheroidized carbides evenly distributed throughout the matrix. Because microstructure is dependent on heat treatment and composition, these factors are not easily separated and must be considered together. There is also a grain size effect that produces enhanced resistance to hydrogen with decreasing prior-austenite grain size (Fig. 44). However, if the grain size is significantly larger than the plastic zone size, the reverse may be true.

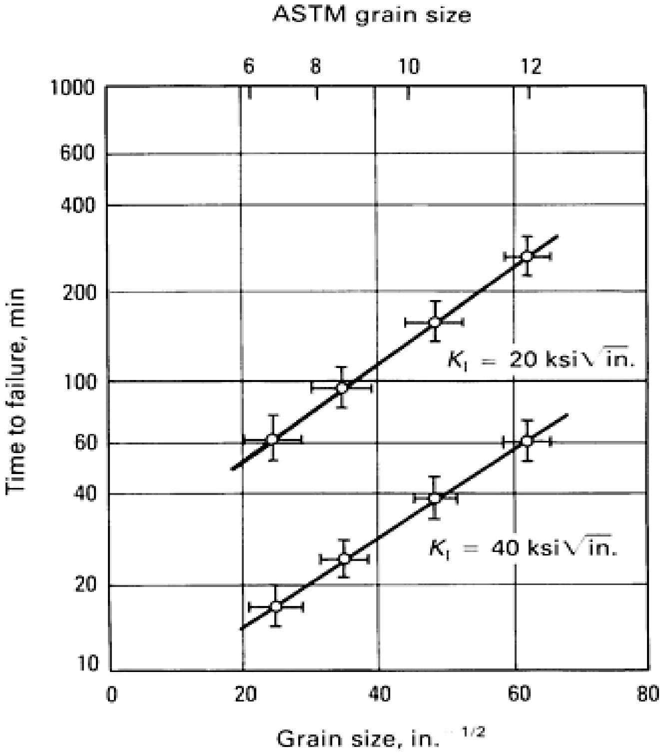

Fig. 44 Illustration of how a refinement in grain size improves resistance to hydrogen failure as measured by the time to failure of two strengths of AISI 4340 steels. Source: Ref 93

The role of alloying elements is quite complex and not easily distinguished from the effects of heat treatment, microstructure, and strength level. Depending on the microstructure and strength level, a specific alloying element may or may not contribute to the hydrogen embrittlement resistance of an alloy or may even increase susceptibility to cracking. The concentration of the alloying element is also a factor in the behavior of alloys in hydrogen. Molybdenum, for example, is beneficial in reducing susceptibility to sulfide stress cracking, a form of hydrogen stress cracking, in AISI 4130 steels up to approximately 0.75 wt%. However, beyond this concentration, a separate Mo_2C phase precipitates in the alloy after tempering at above 500 °C (930 °F), significantly reducing resistance to sulfide stress cracking.

In general, elements such as carbon, phosphorus, sulfur, manganese, and chromium impart greater susceptibility to hydrogen embrittlement in low-alloy steels. However, large increases in such elements as chromium, nickel, and molybdenum in order to produce stainless steels alter the crystal structure, microstructure, and subsequently the heat treatment requirements and therefore the hydrogen embrittlement behavior of this group of ferrous alloys.

The response of stainless steels to hydrogen-bearing environments is basically related to their strength level. Ferritic stainless steels have excellent resistance to hydrogen embrittlement because of their low strength and enhanced ductility. However, if the ferritic stainless steels are cold worked, they may become susceptible to cracking in hydrogen environments. Similarly, austenitic stainless steels are highly resistant to hydrogen cracking in the annealed or lightly cold-worked condition, but can become quite susceptible when heavily cold worked. This increased susceptibility to hydrogen cracking due to increasing yield strength from cold working is similar to the dependence of carbon and low-alloy steel on strength. Decreased resistance to hydrogen for highly cold-worked austenitic stainless steels is largely attributed to the deformation-induced formation of martensite. For those austenitic stainless steels having a very stable austenite phase and high yield strength (such as 21Cr-6Ni-9Mn) susceptibility is considered to be solely a function of yield strength similar to the body-centered cubic (bcc) low-alloy steel behavior.

Other factors that may affect the susceptibility of austenitic stainless steels to hydrogen damage are the possible formation of metastable hydride phase that would produce a hydride-based fracture path and the interaction of hydrogen with stacking faults to reduce stacking fault energy in the austenite, leading to planar slip and brittle fracture. The degree of participation of any of these factors has not been established.

Just as a similarity exists between austenitic stainless steels and low-alloy steels at the high-strength end of the spectrum, the lower-strength austenitics behave in the same manner as the low-alloy steels in hydrogen by a reduction in ductility. Figure 45 shows the loss in reduction in area for several austenitic stainless steels in high-pressure hydrogen. It is apparent that a wide variation in hydrogen damage exists between these various austenitic alloys. Type 304L is the most susceptible to loss in tensile ductility, and the stable austenitic alloys, such as 15Cr-25Ni, are almost unaffected. As observed in carbon and low-alloy steels, there is a temperature effect (~0 °C, or 32 °F) involved with the ductility loss in austenitic stainless steels, although it is somewhat lower than the room-temperature dependence observed for low-alloy steels.

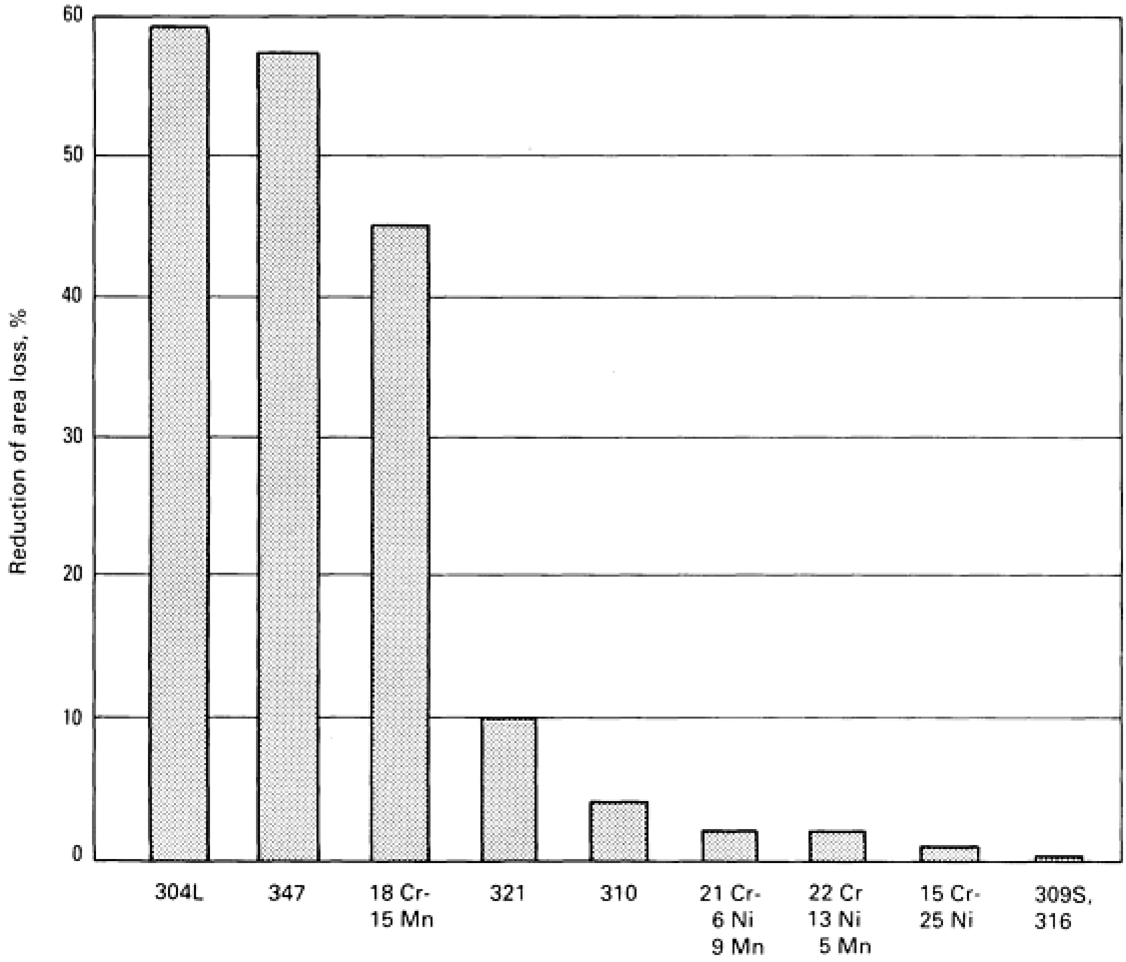

Fig. 45 Ductility loss for several austenitic stainless steels in high-pressure hydrogen. Source: Ref 94

It is apparent that there are many similarities in behavior between stainless steels and carbon and low-alloy steels in hydrogen. Similarly, the martensitic and precipitation-hardening stainless steels exhibit the same dependence on strength level and microstructure as observed in low-alloy steels. Martensitic and precipitation-hardening stainless steels are extremely susceptible to hydrogen embrittlement with increasing yield strength. Figure 46 compares several grades of precipitation-hardening stainless steel with type 410 martensitic stainless steel tested in an aqueous environment saturated with H_2S. The numbers adjacent to each data point represent the tempering or aging treatment. Generally, the same trend of decreasing time to failure with increasing yield strength is observed as for low-alloy steels. The poor performance of the type 410 martensitic stainless compared to precipitation-hardening stainless steels is typical of the behavior of most martensitic stainless steels, which also compare poorly with low-alloy steels at the same strength level.

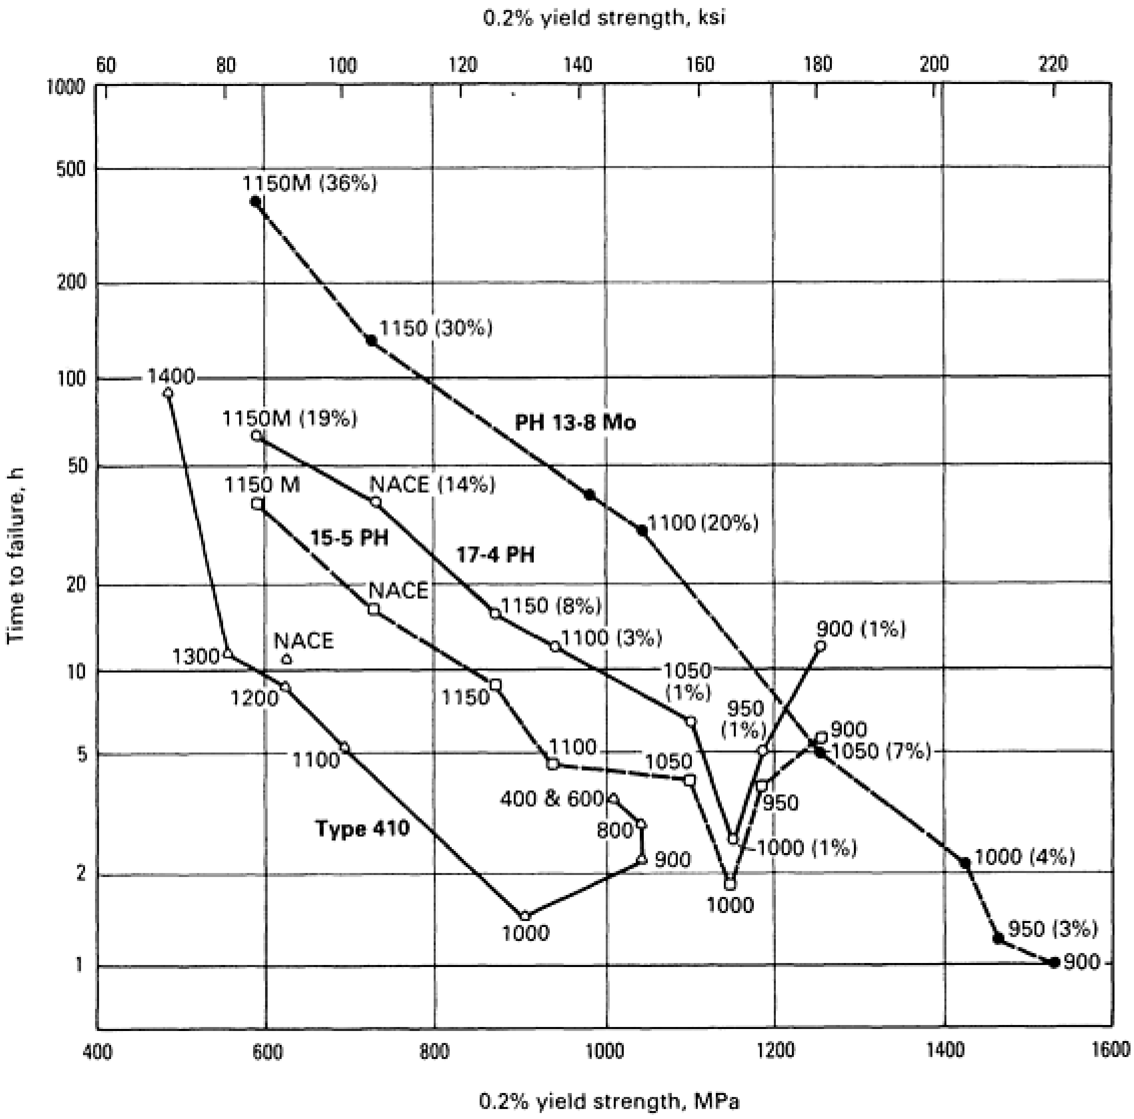

Fig. 46 Time to failure of various alloys as a function of yield strength when tested under 345 MPa (50 ksi) of applied stress in saturated H_2S. Numbers adjacent to data points represent tempering or aging treatment; parenthetical values indicate approximate amounts of austenite. Source: Ref 95

Ultrahigh-strength (>1400 MPa, or 200 ksi) martensitic stainless steels, low-alloy steels, and maraging steels are extremely susceptible to cracking in hydrogen environments, including aqueous solutions containing NaCl. Although chlorides are the primary cause of SCC in many alloy systems, it is generally accepted that the mechanism of cracking in ultrahigh-strength steels is related to hydrogen embrittlement.

Figure 47 compares the crack growth rate of AISI 4340 in several environments against grade 250 maraging steel. The maraging steel has much better resistance to crack propagation in 3.5% NaCl than 4340 and displays a high threshold stress intensity for crack propagation. For maraging steels, there is evidence that peak-aged condition or slight overaging may improve resistance to hydrogen embrittlement, but underaging is detrimental to resistance.

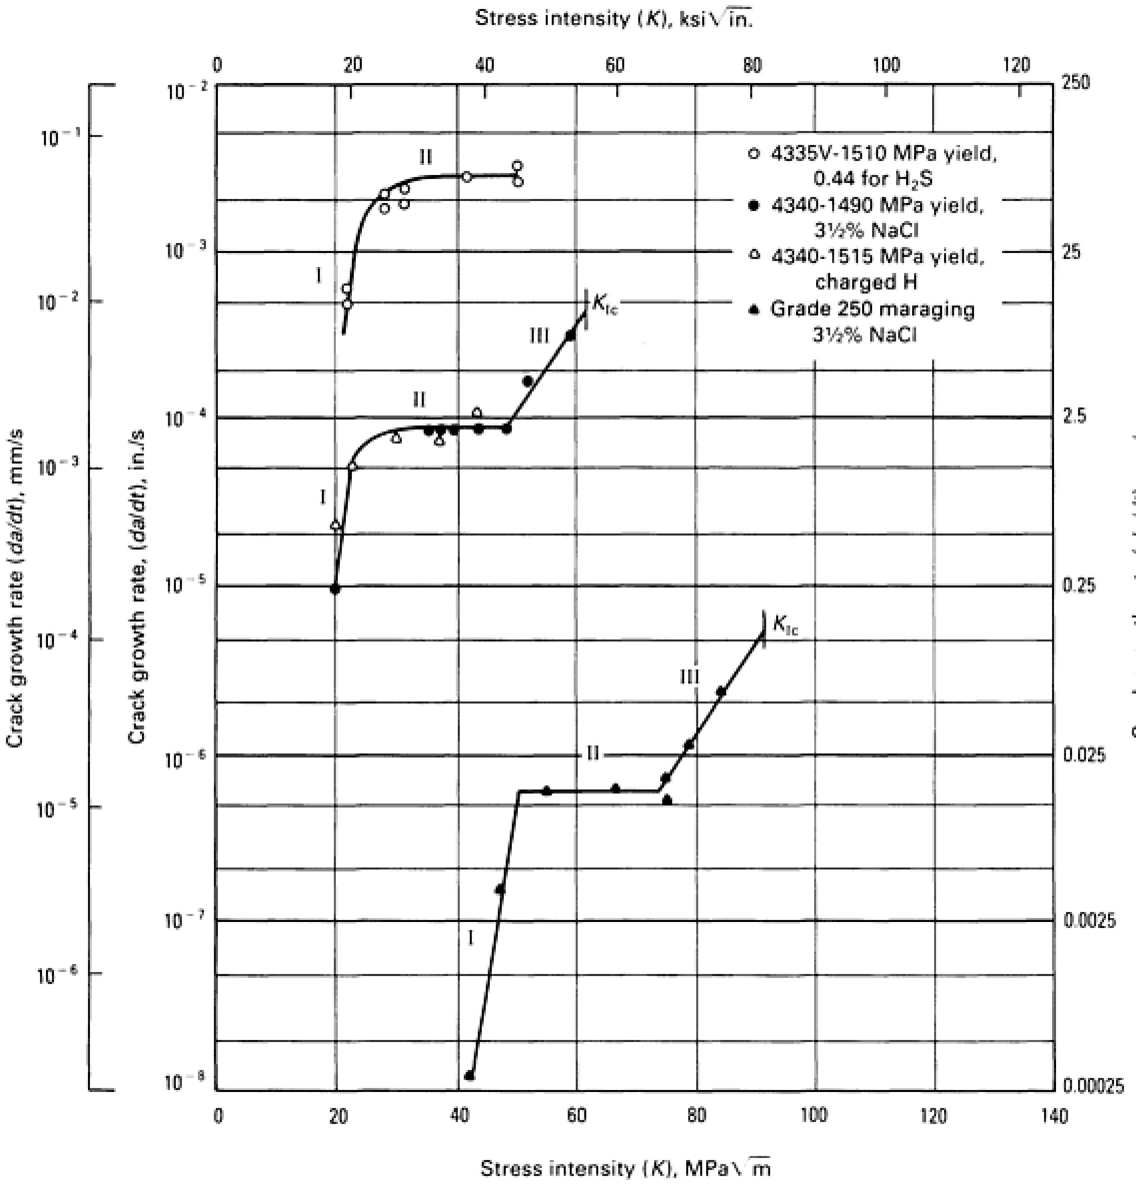

Fig. 47 Effect of material, environment, and stress intensity level on crack growth. Source: Ref 87

Hydrogen attack is strictly a high-temperature form of hydrogen damage that primarily affects ferritic steels. Hydrogen attack is dependent on time, temperature, and hydrogen pressure. After a certain incubation time, a diminution of properties occurs with the onset of decarburization and cracking (Fig. 48). Resistance of steels to hydrogen attack is related to the stability of the carbides, and as such, the addition of carbide-stabilizing elements such as vanadium, titanium, niobium, and molybdenum enhance the resistance to this form of hydrogen damage.

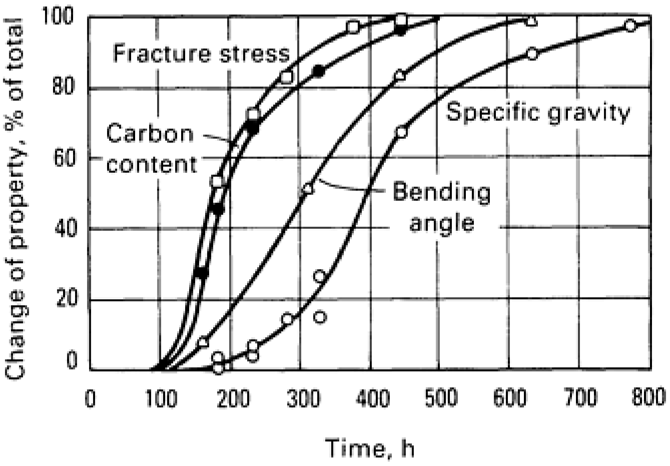

Fig. 48 Relative change of properties of an SAE 1020 steel as a function of time of exposure to hydrogen at 427 °C (800 °F) and 6.2 MPa (900 psi) partial pressure. Source: Ref 85

Chromium-molybdenum steels have been found to be the most resistant to hydrogen attack for the cost involved; therefore, a great deal of industrial experience has been gained with these alloys. Much of this experience has been compiled and plotted to provide a guideline for steel selection as a function of temperature and hydrogen partial pressure and is presented as a series of curves often referred to as a Nelson diagram (Ref 96). As more experience is gathered on the use of these steels in hydrogen, this series of curves is periodically updated by the American Petroleum Institute.

Nickel Alloys

Nickel and its alloys are susceptible to hydrogen damage in both aqueous and gaseous hydrogen environments. The same factors that affect hydrogen embrittlement susceptibility in ferrous alloys are also prevalent in nickel alloys, although to a lesser degree. In general, fcc metals, because of their greater ease of slip and reduced solute diffusivities as compared to bcc materials, are less susceptible to hydrogen damage. As with ferrous alloys, hydrogen in nickel and its alloys may introduce intergranular, transgranular, or quasi-cleavage cracking, and although the macroscopic features appear to be brittle, on a microscopic scale there is a high degree of local plasticity, suggesting that hydrogen enhances flow at the crack tip. Figure 49 shows the reduction in ductility associated with hydrogen charging a 72Ni-28Fe alloy as a function of strain rate. Almost identical behavior was observed for unalloyed nickel.

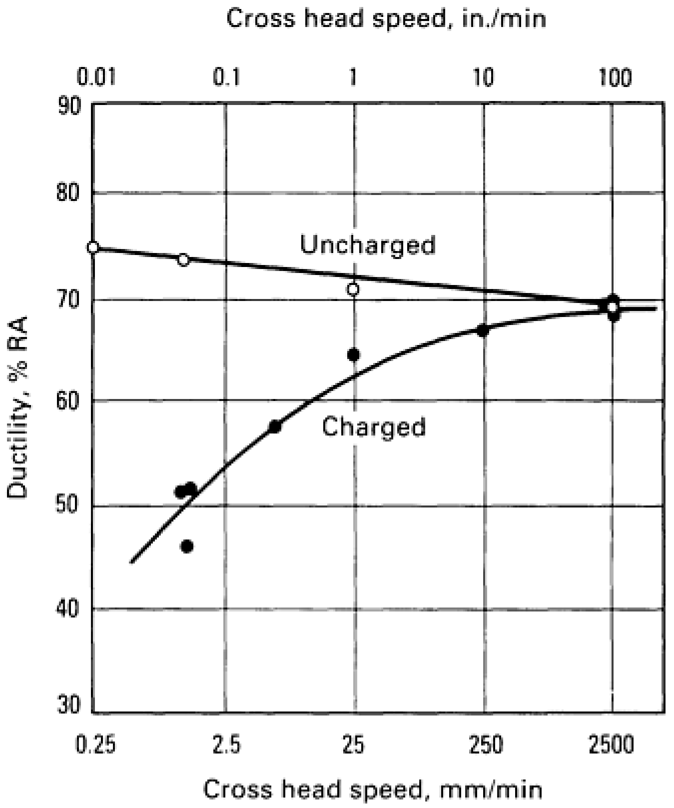

Fig. 49 Ductility at fracture as a function of strain rate in a hydrogen-charged and uncharged 72Ni-28Fe alloy. Source: Ref 81

Alloys based on the ternary Fe-Ni-Cr system (Incoloy) and Inconel alloys show reductions in ductility when charged with hydrogen, depending on the specific thermomechanical treatments performed on the alloy. Generally, these alloys are more resistant to hydrogen stress cracking in the cold-worked and unaged condition as compared to the cold-worked and aged condition. Age-hardenable alloys show the least resistance to hydrogen when aged to their peak or near-peak strength. Stabilization treatments, followed by aging, reduce the resistance of these alloys as compared to direct aging. Increased cold work also produces a loss in tensile ductility. Hydrogen stress cracking of these alloys may also occur, rather than a loss in tensile ductility, when they possess high yield strengths or are under high hydrogen fugacity. The nickel-copper alloys (Monels) have also been found to be susceptible to hydrogen embrittlement, with increasing strength obtained by cold working or aging.

Several nickel-base alloys are resistant to hydrogen-stress cracking when cold worked to yield strengths in excess of 1240 MPa (180 ksi). However, when these alloys (Hastelloy alloy C-276, Hastelloy alloy C-4, and Inconel alloy 625) are aged at low temperature, their resistance to hydrogen cracking is considerably diminished. This behavior is attributed to the segregation of phosphorus and sulfur to grain boundaries, which provide low-energy fracture paths (much the same as occurs in high-strength steels), or to an ordering reaction of the form $Ni_2(Cr, Mo)$. Figure 50 presents data that relate the reduction in area loss to ordering for the ordering alloy Ni_2Cr charged with hydrogen.

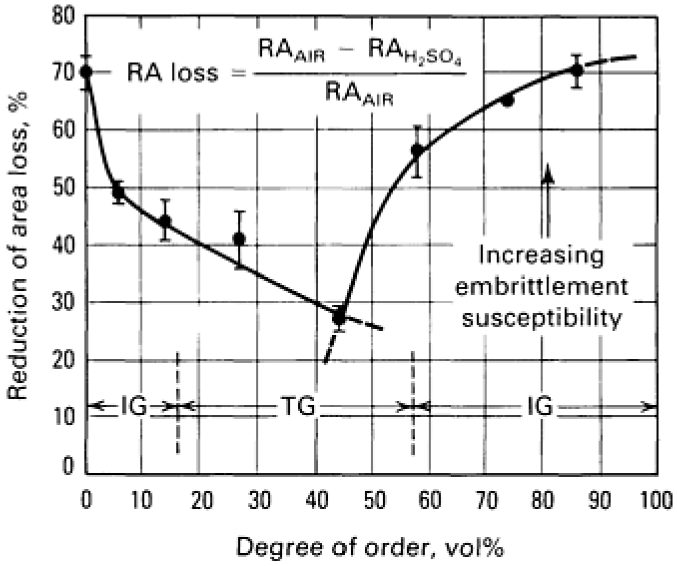

Fig. 50 Effect of the degree of order on the embrittlement susceptibility of Ni_2Cr. Regions of intergranular (IG) and ductile transgranular fracture (TG) are shown. Source: Ref 97

Aluminum Alloys

Only recently has it been determined that hydrogen embrittles aluminum. For many years, all environmental cracking of aluminum and its alloys was represented as SCC; however, testing in specific hydrogen environments has revealed the susceptibility of aluminum to hydrogen damage. Hydrogen damage in aluminum alloys may take the form of intergranular or transgranular cracking or blistering. Blistering is most often associated with the melting or heat treatment of aluminum where reaction with water vapor produces hydrogen. Blistering due to hydrogen is frequently associated with grain-boundary precipitates or the formation of small voids. Blister formation in aluminum is different from that in ferrous alloys in that it is more common to form a multitude of near-surface voids that coalesce to produce a large blister.

In a manner similar to the mechanism in iron-base alloys, hydrogen diffuses into the aluminum lattice and collects at internal defects. This occurs most frequently during annealing or solution treating in air furnaces prior to age hardening.

Dry hydrogen gas is not detrimental to aluminum alloys; however, with the addition of water vapor, subcritical crack growth increases dramatically (Fig. 51). The threshold stress intensity for cracking of aluminum also decreases significantly in the presence of humid hydrogen gas at ambient temperature (Fig. 52).

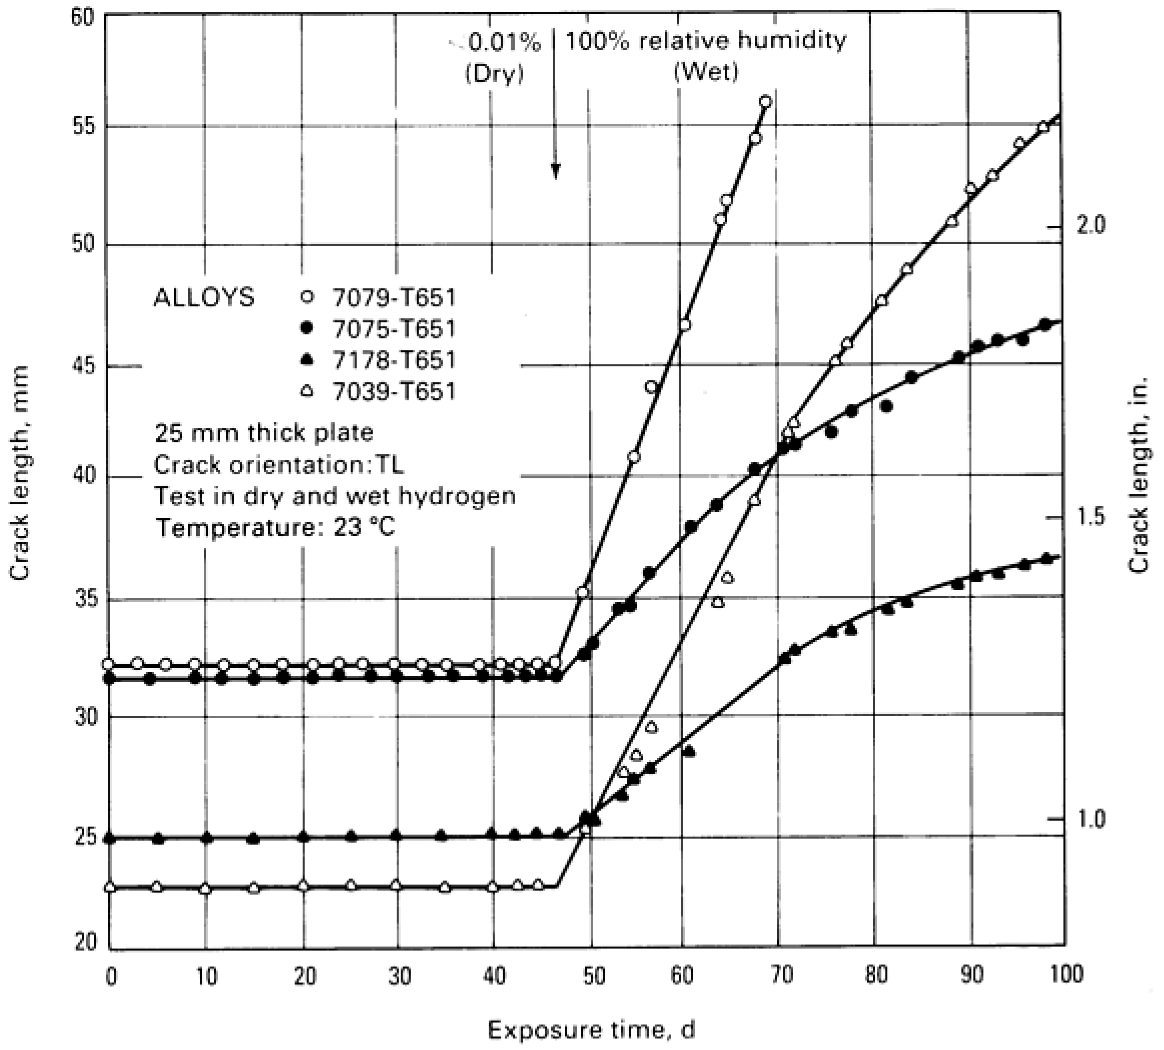

Fig. 51 Effect of humidity on subcritical crack growth of high-strength aluminum alloys in hydrogen gas. Source: Ref 98

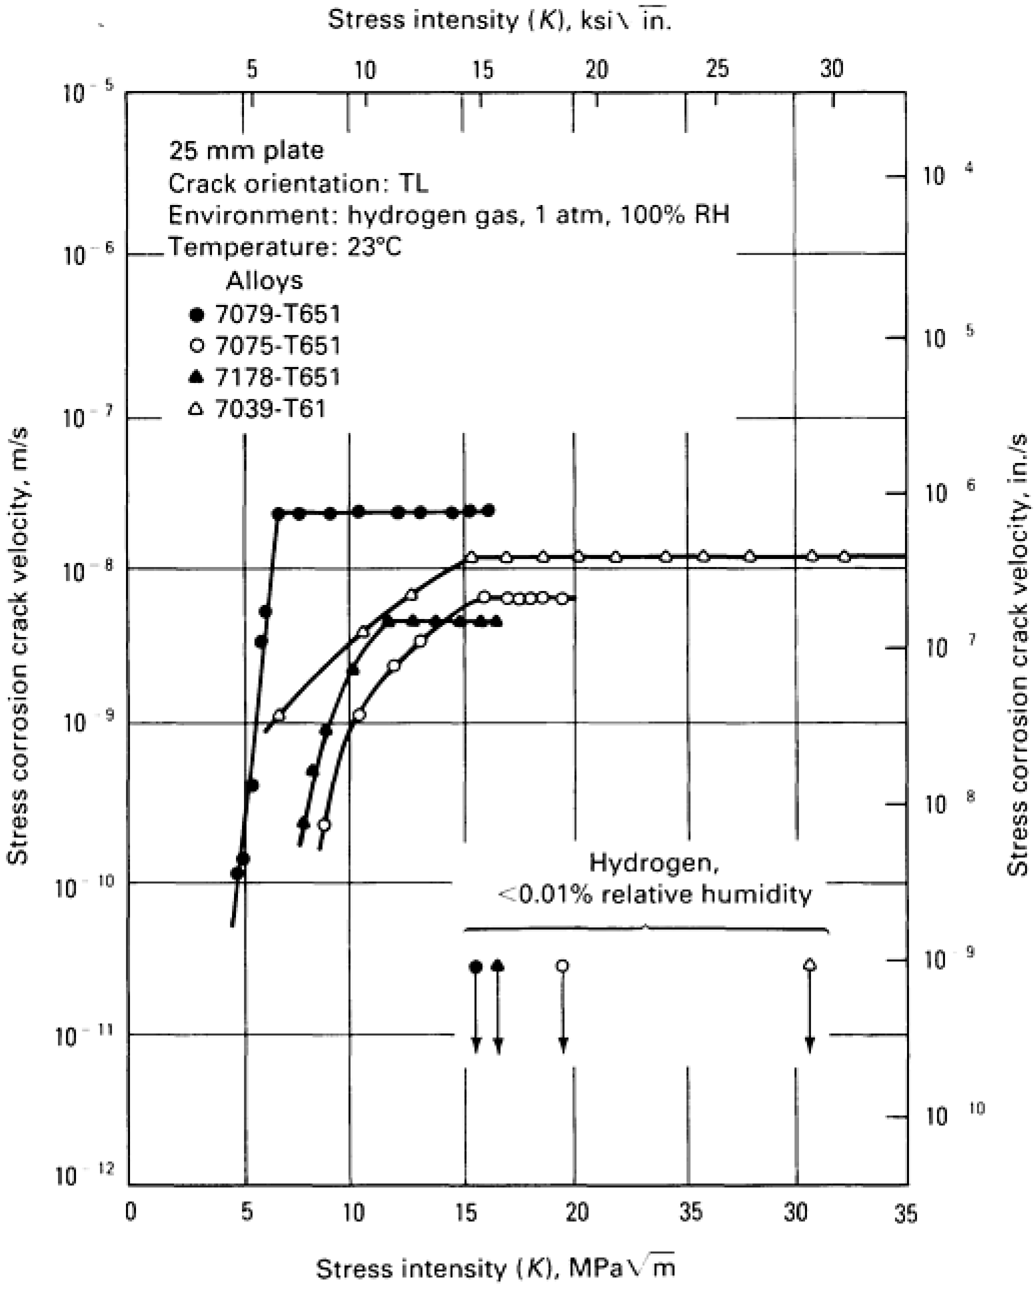

Fig. 52 Crack velocity of four high-strength aluminum alloys plotted as a function of crack-tip stress intensity in moist and dry hydrogen gas. Source: Ref 98

Crack growth in aluminum in hydrogen is also a function of hydrogen permeability, as in the iron- and nickel-base alloys. Hydrogen permeation and the crack growth rate are a function of potential, increasing with more negative potentials, as expected for hydrogen embrittlement behavior. Similarly, the ductility of aluminum alloys in hydrogen is temperature dependent, displaying a minimum in reduction in area below 0 °C; this is similar to other fcc alloys (Ref 98).

Most of the work on hydrogen embrittlement of aluminum alloys has been on the 7000 series (Al-Zn-Mg); therefore, the full extent of hydrogen damage in aluminum alloys has not been determined or the mechanisms established. Some evidence for a metastable aluminum hydride has been found that would explain the brittle intergranular fracture of aluminum-zinc-magnesium alloys in water vapor. However, the instability of the hydride is such that is has been difficult to evaluate. Another explanation for intergranular fracture of these alloys is preferential decohesion of grain boundaries containing segregated magnesium. Overaging of these alloys increases their resistance to hydrogen embrittlement in much the same way as for highly tempered martensitic steels.

Copper Alloys

A common form of hydrogen damage in copper has been known for years as steam embrittlement and is observed only when copper contains oxygen. Hydrogen entering the metal reacts with oxygen either is solid solution or at oxide inclusions to form water. At temperatures above the critical temperature for water, steam forms, and the pressure generated is sufficient to produce microcavity formation and cracking. The equation for reaction with cuprous oxide particles is:

$$Cu_2O + 2H = 2Cu + H_2O(g)$$

The circumstances under which this form of hydrogen damage occurs are typically related to the annealing of copper in a hydrogen atmosphere. At lower temperatures, steam is not generated and therefore does not create the problem. Although the use of oxygen-free copper essentially eliminates susceptibility to steam embrittlement, the heavy cold working of oxygen-free copper can result in grain-boundary void formation when hydrogen is introduced.

Compared to the ferrous and nickel alloys, relatively little work has been performed specific to the hydrogen embrittlement of copper-base alloys. There is some indication that age-hardenable alloys such as beryllium copper are susceptible to embrittlement under severe charging conditions, producing a loss in tensile ductility. A systematic study of these alloys remains to be performed.

Titanium Alloys

Titanium and its alloys suffer hydrogen damage primarily by hydride-phase formation. Pure α-titanium is relatively unaffected by small concentrations (<200 ppm) of hydrogen; however, above this content, the impact toughness is impaired. The purity of the α-titanium is important to its behavior in hydrogen. Commercially pure titanium is much more sensitive to hydrogen than pure titanium is. The amount of hydrogen necessary to induce ductile-to-brittle transition behavior in commercially pure titanium is one-half the amount needed in pure titanium.

Loss in impact toughness also occurs in α/β-titanium and β-titanium alloys and is sometimes referred to as impact embrittlement. This hydrogen damage at high strain rates is the result of hydrides that precipitate after the high-temperature exposure of titanium to hydrogen.

Another mode of failure for titanium alloys in hydrogen predominates under slow strain rate loading. Figure 53 shows the strain rate behavior for an α/β alloy. As the strain rate increases, the effect of hydrogen is lost. As in steels, the reduction in area and the elongation of titanium alloys are diminished in hydrogen.

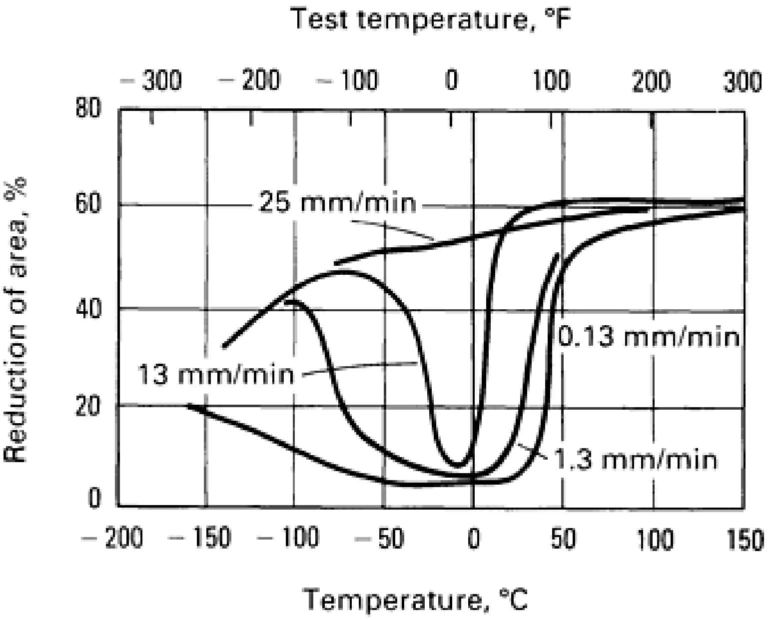

Fig. 53 Effects of hydrogen content (375 ppm), strain rate, and temperature on the tensile ductility of typical α/β titanium alloy unnotched tensile specimens. Source: Ref 99

Both types of failure for titanium alloys in hydrogen are attributed to hydride-phrase precipitation. The low strain rate embrittlement is related to hydride formation caused by strain-enhanced precipitation, but embrittlement under impact is caused by hydride-phase formation after fabrication or heat treatment. Unlike many hydride-forming systems, titanium forms a stable hydride, but the kinetics of precipitation are slow compared to the Group Vb metals. Therefore, embrittlement is more prone to occur at low strain rates at which precipitation can proceed at a rate that is sufficient to provide a brittle crack path.

Because hydrogen solubility increases with temperature for these alloys, hydride embrittlement typically decreases as the temperature increases. Additionally, at higher temperatures, the hydride many become more ductile, reducing brittle crack initiation. As expected, the threshold stress intensity for crack propagation is also a function of the hydrogen content decreasing with increasing hydrogen.

The role of microstructure in the hydrogen damage of titanium is quite complex and is not fully understood. However, it has been determined that under slow strain rates the α/β alloys fail by intergranular separation along boundaries but that completely α alloys fracture by transgranular cleavage. Embrittlement is not a severe in α/β alloys with a continuous equiaxed α matrix as for those alloys with a continuous acicular β matrix (Ref 100). However, this behavior is a function of hydrogen pressure and may be reversed at lower pressures (Ref 101).

Zirconium Alloys

Zirconium and its alloys suffer hydrogen damage by hydride precipitation, especially in the presence of notches or at low temperatures in smooth specimens. Failure occurs by cracking of the brittle, precipitated hydride phase during straining. These fractured hydrides may then accelerate fracture by ductile microvoid formation and coalescence, primarily enhancing the latter. Similarly to titanium, zirconium alloys precipitate stable hydrides. Depending on the hydrogen content of the alloy, one of two stable or one metastable hydride may precipitate. The two stable zirconium hydrides are δ-hydride (fcc) and ε-hydride (face-centered tetragonal, fct). The metastable γ-hydride also has an fct structure (Ref 102).

As in other alloy systems, the tensile ductility generally diminishes with increasing hydrogen content (Fig. 54). Similarly, the hydrogen embrittlement of these alloys is dependent on stress state, becoming more pronounced as the stress state moves from uniaxial to biaxial to triaxial tension. For example, the local stress state ahead of a sharp notch can produce a region of biaxial or triaxial stress, thus increasing the susceptibility to hydrogen embrittlement.

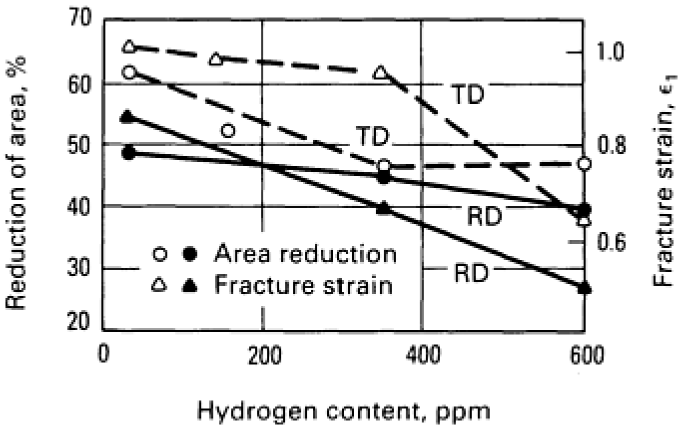

Fig. 54 Influence of hydrogen on the reduction of area at fracture and the true strain at fracture for Zircaloy-2. TD transverse direction; RD, rolling direction. Source: Ref 103

The embrittlement by zirconium hydride formation is a strong function of temperature, because increasing the temperature will reduce the volume fraction of hydride due to the increased solid solubility of hydrogen with temperature. Ductile-to-brittle transition behavior has been observed in hydrided zirconium alloys, and the transition temperature has been found to be a function of hydrogen content, increasing with hydrogen concentration (Fig. 55).

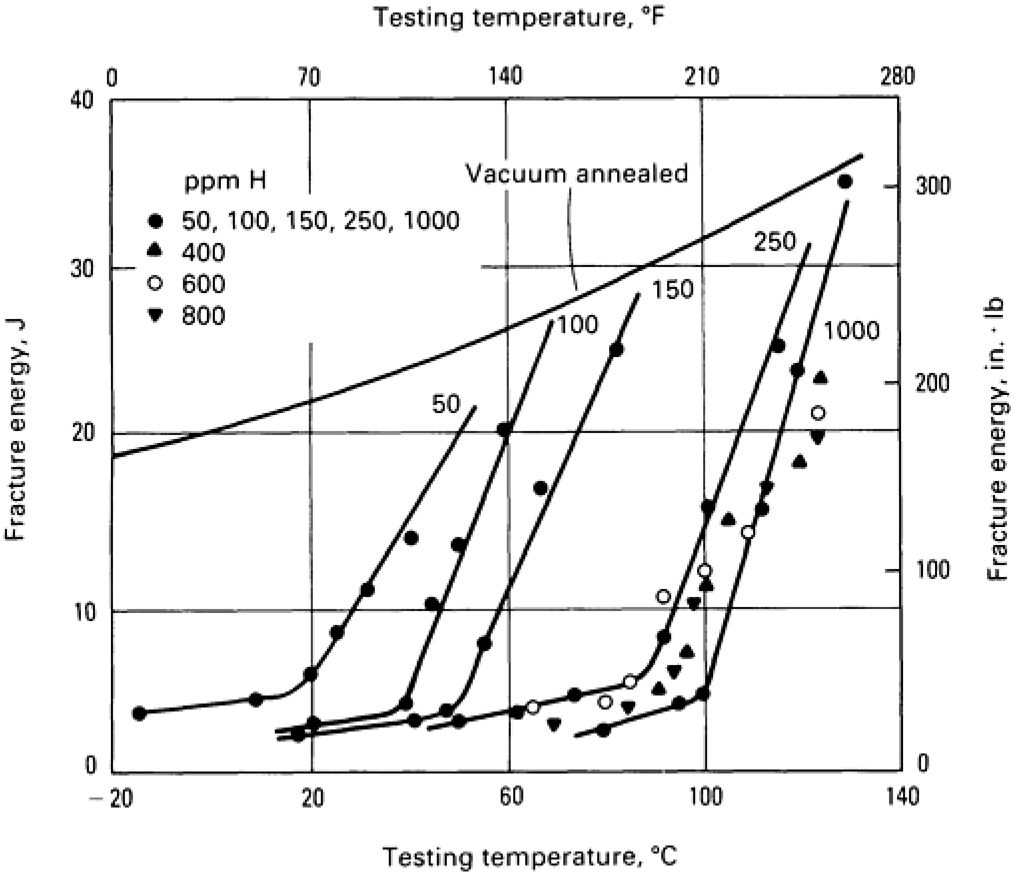

Fig. 55 Ductile-to-brittle transitions in hydrided zirconium. Source: Ref 104

Hydride distribution and morphology are other important factors in the extent of hydrogen damage in zirconium alloys. Because the brittle hydride phase provides an easy crack path for fracture, the distribution and morphology of this phase in relation to the sense of the applied tensile stress determine the degree of embrittlement. The shape and distribution of the hydrides are dependent on heat treatment prior to precipitation and cooling rate during precipitation. Rapid cooling produces a more uniform dispersion of hydrides, while slow cooling enhances the grain-boundary precipitation of the hydride platelets. Toughness is not as dramatically affected in the former case as in the latter.

Vanadium, Niobium, Tantalum, and Their Alloys

These metals and alloys are all embrittled by hydrogen--primarily by hydride-phase formation; however, unlike titanium and zirconium alloys, these systems do not form a stable hydride. The introduction of hydrogen into unalloyed vanadium, niobium, and tantalum increases the yield strength of these metals and creates ductile-to-brittle transition behavior (Fig. 56).

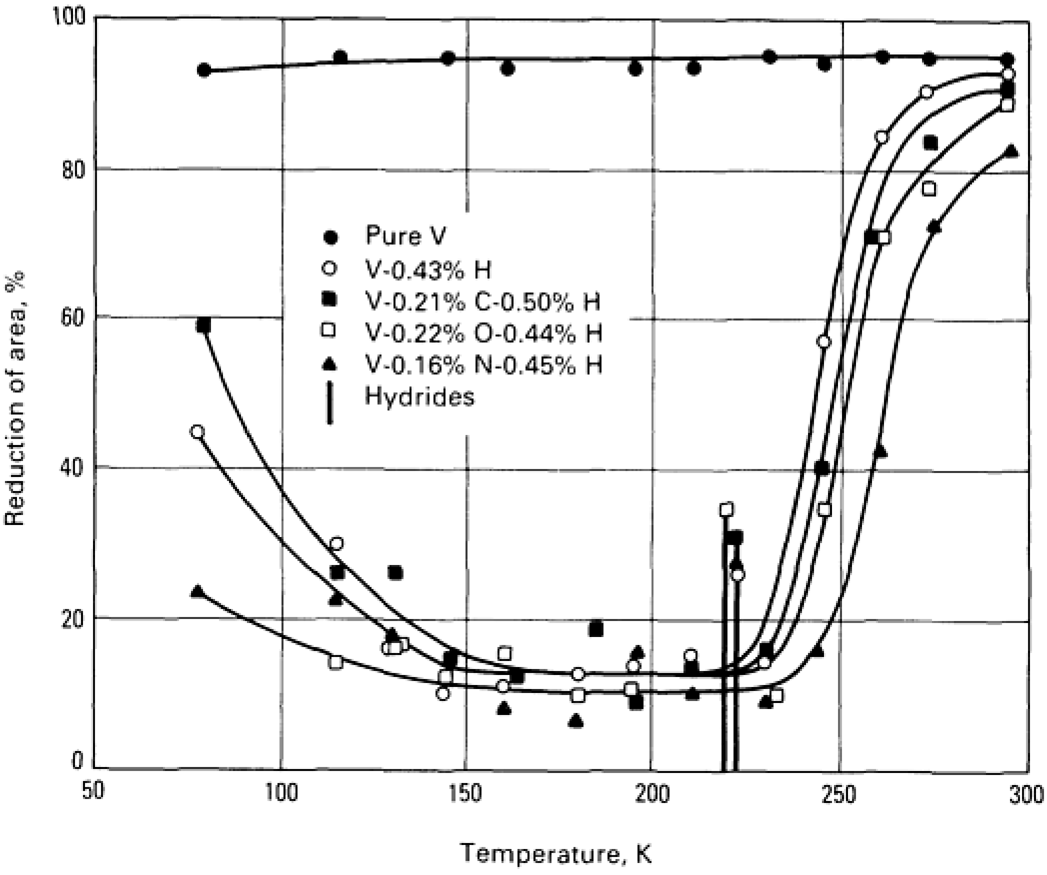

Fig. 56 Effect of hydrogen and combined carbon, nitrogen, or oxygen and hydrogen on the temperature dependence of ductility in vanadium. Source: Ref 105

Many of these alloy systems display ductile-to-brittle transition behavior in the presence of hydrogen in much the same manner as that described for zirconium and titanium. However, these alloys have been found to exhibit grain-boundary cracking when low levels of hydrogen are present in solid solution below the terminal solid-solubility limit. In fact, all of the hydride-forming systems exhibit hydrogen damage from solute hydrogen at low concentrations of hydrogen at which hydrides are not expected to precipitate. Although fracture transition is correlated with hydride formation in vanadium, other systems, such a niobium, zirconium, titanium, and tantalum, display more classical hydrogen embrittlement without a corresponding hydride-phase precipitation (Ref 102, 105).

Once the hydrogen content exceeds terminal solid solubility, damage may proceed by hydride precipitate formation. Below this solubility limit, the relative resistance to cracking or loss in tensile ductility is largely a function of the hydrogen concentration and alloying elements (Fig. 57). However, the terminal solid solubility for a particular metal-hydrogen system that forms hydrides is an extremely strong function of stress so that reference to stress-free equilibrium phase diagrams for predicting hydride phase behavior may be inaccurate (Ref 107).

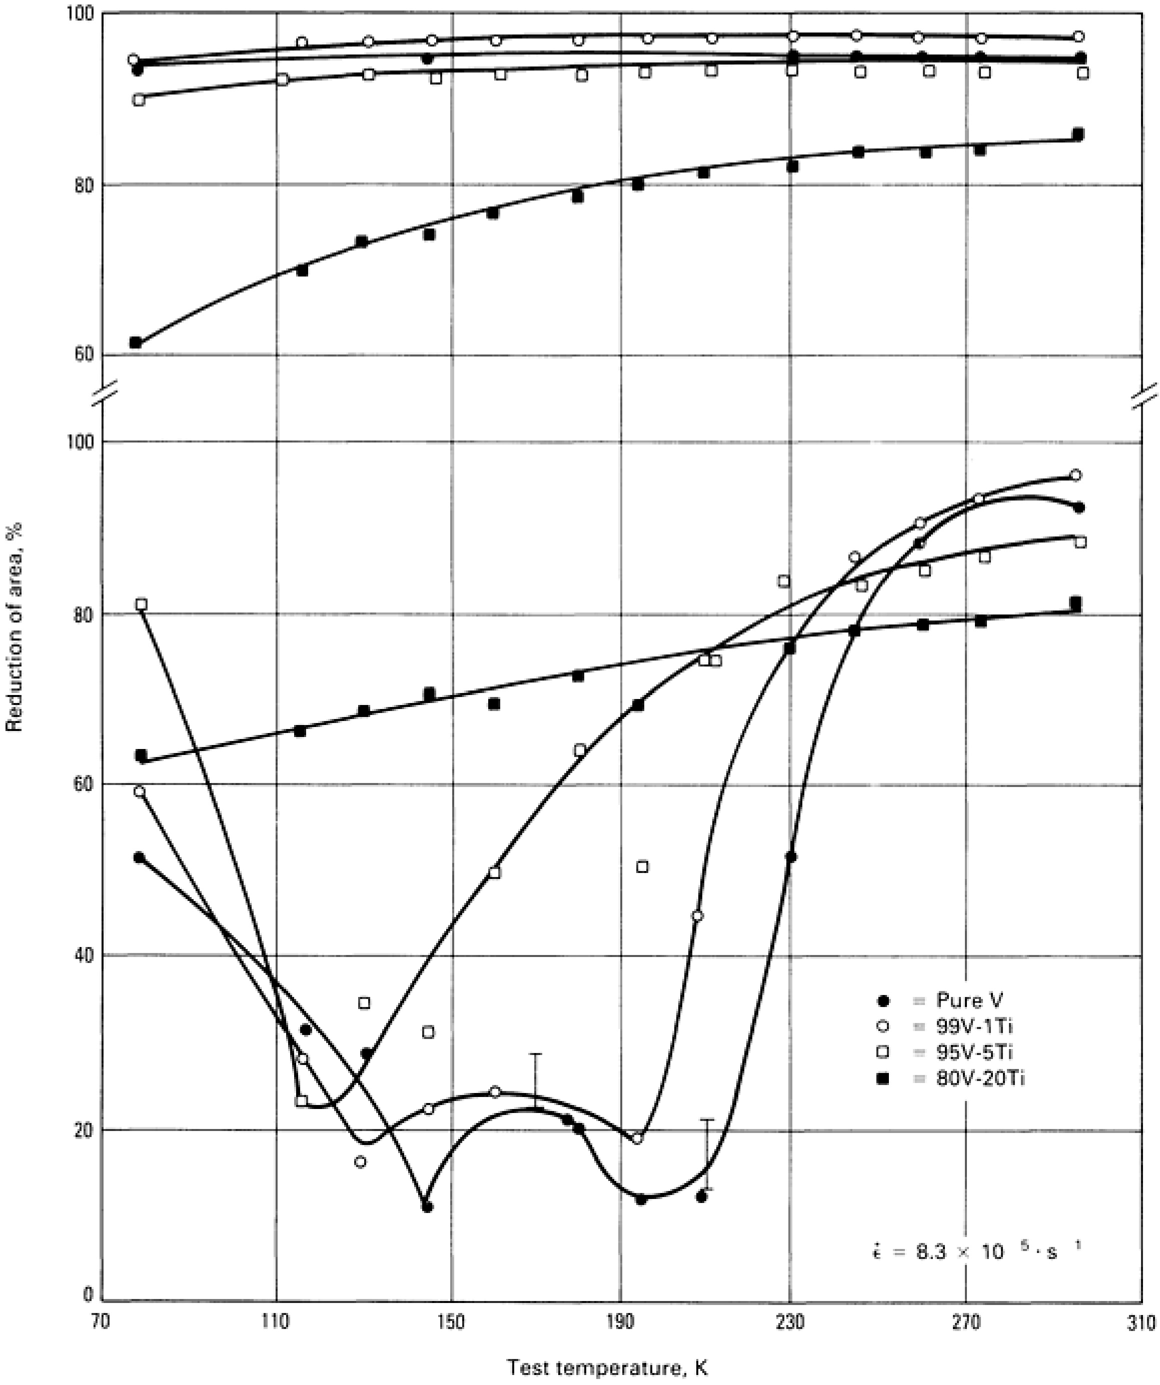

Fig. 57 Temperature dependence of reduction of area for selected hydrogen-charged (bottom) and uncharged (top) vanadium-titanium alloys. Source: Ref 106

There are many other metals and alloys that form hydrides (for example, thorium, uranium, and beryllium), but far less is known about these systems. Therefore, a great deal of investigation into the metal/hydrogen interactions in many alloy systems remains to be done, especially considering the trend in new materials for advanced technologies.

Liquid-Metal Embrittlement

M.H. Kamdar, Benet Weapons Laboratory, U.S. Army Armament Research, Development, and Engineering Center

Liquid-metal embrittlement is the catastrophic brittle failure of a normally ductile metal when coated with a thin film of a liquid metal and subsequently stressed in tension. The fracture mode changes from a ductile to a brittle intergranular or brittle transgranular (cleavage) mode; however, there is no change in the yield and flow behavior of the solid metal. As shown in Fig. 58, embrittlement manifests itself as a reduction in fracture stress, strain, or both. Fracture can occur well below the yield stress of the solid. The stress needed to propagate a sharp crack or a flaw in liquid is significantly lower than that necessary to initiate a crack in the liquid-metal environment. In most cases, the initiation or the propagation of cracks appears to occur instantaneously, with the fracture propagating through the entire test specimen. The velocity of crack or fracture propagation has been estimated to be 10 to 100 cm/s (4 to 40 in./s).

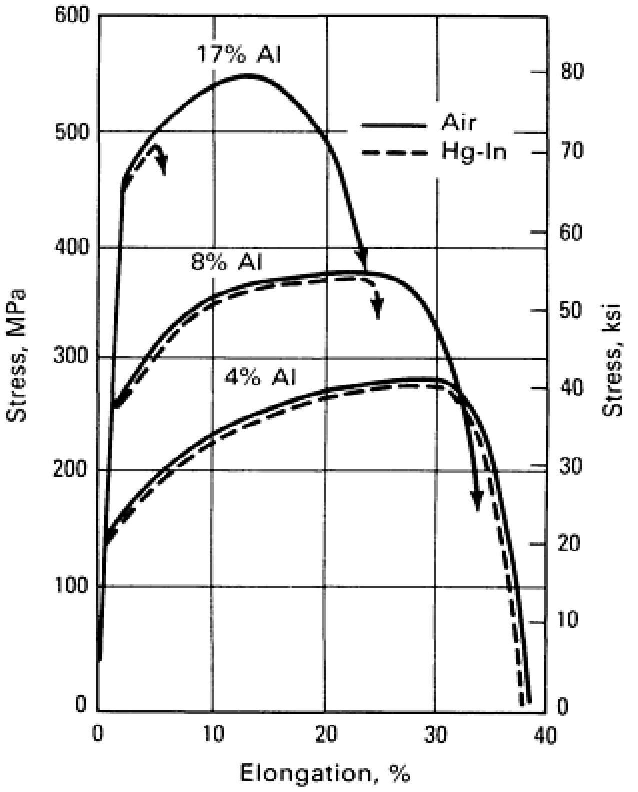

Fig. 58 Effects of environment on the yield stress and strain-hardening rate on various iron-aluminum alloys tested in air and mercury-indium solutions

Examination of LME fracture surfaces shows complete coverage by the liquid metal. Liquid metal is in intimate contact with the solid and is usually difficult to remove. The fracture mode becomes apparent when special techniques are used to remove the liquid. It should be emphasized that gross amounts of liquid are not necessary; even micrograms of liquid lead can cause LME in 75-mm (3-in.) thick steel tubes (Fig. 59). The fracture is usually brittle intergranular, with little indication of crack branching or striation to indicate slow crack propagation.

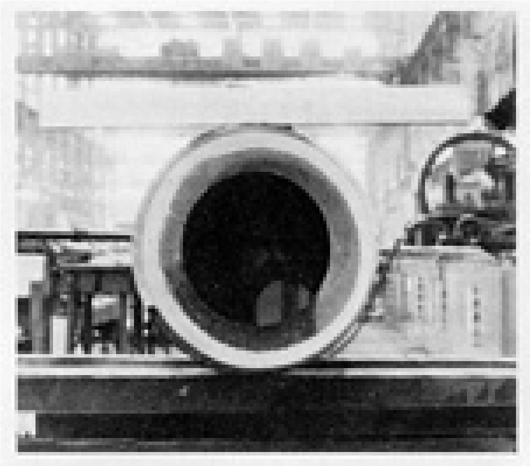

Fig. 59 Liquid lead induced brittle fracture of a 75-mm (3-in.) section of a 4340 steel pressure vessel tube

The presence of liquid at the moving crack tip appears necessary for fast fracture. However, in high-strength brittle metals, a crack initiated in the liquid may propagate in a brittle manner in the absence of liquid. In low-strength metals, a transition may occur from brittle-to-ductile failure under similar circumstances, Although far less frequent than brittle fracture, embrittlement can also occur by a ductile dimpled rupture mode in certain steels, copper alloys, and aluminum alloys. The embrittlement then manifests itself as the degradation of the mechanical properties in the solid metal. Fracture is not limited to polycrystalline metals and the presence of grain boundaries. Single crystals of zinc and cadmium are also embrittled by liquid metal and result in fracture by a brittle cleavage mode (Fig. 60). These are but a few of the manifestations of LME.

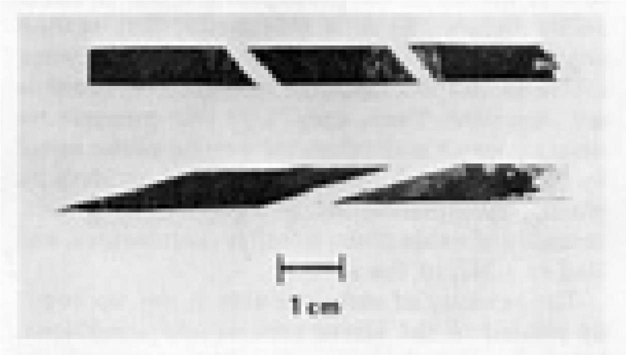

Fig. 60 Cleavage fracture of cadmium monocrystals at 25 °C (75 °F) following a coating with Hg-60In (at.%) solution

Embrittlement is not a corrosion, dissolution, or diffusion-controlled intergranular penetration process, but is considered to be a special case of brittle fracture that occurs in the absence of an inert environment and at low temperatures. Time- and temperature-dependent processes are not considered to be responsible for the occurrence of LME. Also, in most cases of LME, little or no penetration of liquid metal into the solid metal is observed. The embrittlement of the solid metal coated with liquid metal or immersed in the liquid does not depend on the time of exposure to the liquid metal before testing (Fig. 61) or on whether the liquid is pure or presaturated with the solid. Usually, one of the prerequisites is that the solid has little or no solubility in the liquid and forms no intermetallic compound to constitute an embrittlement couple. However, exceptions to this empirical rule have been noted.

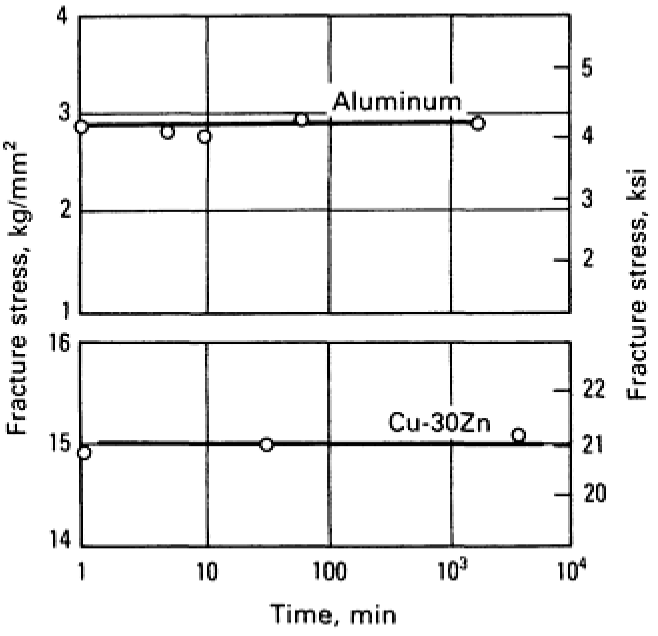

Fig. 61 Fracture stress of polycrystalline aluminum and Cu-30Zn brass as a function of exposure to liquid mercury before testing in this environment

An increase in test temperature decreases embrittlement, which leads to a brittle-to-ductile transition. Severe embrittlement occurs near the freezing temperature of the liquid. In fact, in iron-lead, iron-indium (Fig. 62), and many other metallic couples, embrittlement occurs below the melting temperature of the liquid. This new phenomenon is called solid metal induced embrittlement (SMIE) of metals and is described in the following section of this article.

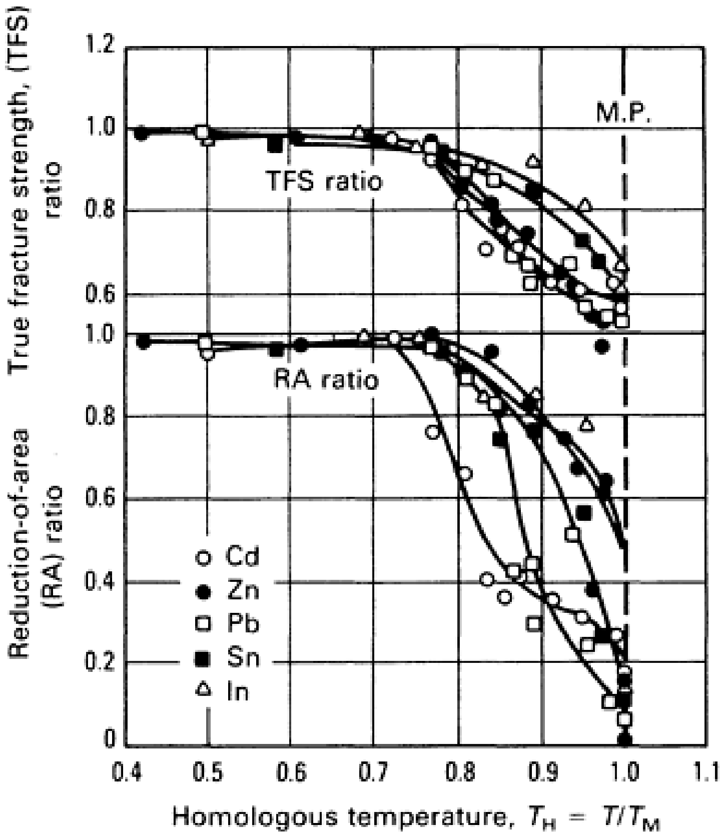

Fig. 62 Embrittlement of 4140 steel by various liquid metals below their melting point. Comparison of normalized true fracture strength (TFS) ratio and the reduction-of-area (RA) ratio as a function of homologous temperature T_H where T and T_M are the test and the melting temperature of the liquid metal, respectively, M.P., melting point

The occurrence of LME is not a laboratory curiosity. Such failures have been observed in metals and alloys in the following industrial applications and processes:

- Small amounts of alloying elements, such as lead and tellurium, added to steel to improve machinability may lead to embrittlement (Fig. 63). Internally leaded steels have cracked at lead inclusions. For example, leaded steel gears have cracked during induction-hardening heat treatments, and warm punching of leaded steel shafts has resulted in unexpected fracture during the forming operation
- Cadmium-plated titanium and steels are embrittled during high-temperature service by molten cadmium
- Indium, used as a high-vacuum seal in steel chambers, has caused cracking during bakeout operations
- Zircaloy tubes used in nuclear reactors have been cracked by both solid and liquid cadmium
- Although infrequent, LME also occurs in petrochemical plants and in the steel industry during heat treatment, hot rolling, brazing, soldering, and welding operations
- Embrittlement of steel occurs by electroplated or dipped cadmium, zinc, or tin--all of which provide corrosion resistance
- In liquid metal cooled reactors, liquid lithium can cause both corrosion and LME in metals and alloys

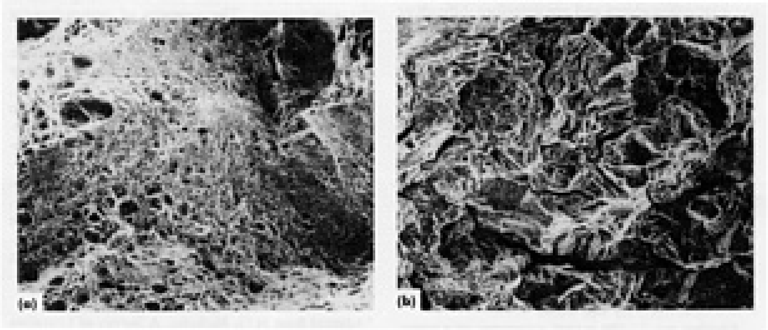

Fig. 63 Influence of lead on the fracture morphology of a 4340 steel. (a) Ductile failure after testing in argon at 370 °C (700 °F). (b) The same steel tested in liquid lead at 370 °C (700 °F) showing brittle intergranular fracture

The distinctive features of embrittlement and of the resultant fracture surfaces are a significant loss in mechanical properties and usually a brittle fracture mode, although ductile fracture morphologies have been reported. The fracture surfaces are easily distinguished from those due to SCC, which are similar to fracture due to hydrogen or temper embrittlement. The embrittlement is severe, and the propagation of fracture is very fast in the case of LME as compared to that in SCC. Thus, the predominant occurrence of brittle fracture surfaces, fast or catastrophic fracture, significant loss in ductility and strength, and the presence of liquid at the tip of the propagating crack are some of the characteristics that may be used to distinguish LME from other environmentally induced failures. Detailed information on the mechanisms of LME and the susceptibility of specific metals and alloys to liquid metal induced failures can be found in the Selected References provided at the end of this article.

Mechanisms of Embrittlement

Several mechanisms have been proposed to explain LME, including stress-assisted dissolution of the solid at the crack tip and reduction in the surface energy of the solid by the liquid metal. It has been suggested that embrittlement is associated with liquid-metal adsorption induced localized reduction in the strength of the atomic bonds at the crack tip or at the surface of the solid metal at sites of stress concentrations.

With this possibility in mind, consider the crack shown in Fig. 64. Crack propagation will occur by the breaking of $A\text{-}A_0$ bonds at the crack tip and, subsequently, the breaking of similar bonds at the propagating crack tip by the chemisorbed liquid-metal atom B (a vapor phase from a solid in a solid-solid metal embrittlement couple or an elemental gas, such as hydrogen, may also provide the embrittling atom B). Next, assume that liquid-metal atom B at the crack tip reduces the cohesive strength of $A\text{-}A_0$ bonds. The chemisorption process presumably occurs spontaneously or only after the $A\text{-}A_0$ bonds have been strained to some critical value. In any event, electronic rearrangement occurs because of adsorption, which weakens the bonds at the crack tip. When the applied stress is increased so that it exceeds the reduced breaking strength of $A\text{-}A_0$ bonds, then the crack propagates. The liquid-metal atom becomes stably chemisorbed on the freshly created surfaces. The surface diffusion of the liquid-metal atoms over the chemisorbed liquid-metal atoms feeds the advancing crack tip, thus propagating the crack at reduced stress and causing complete failure of the specimen.

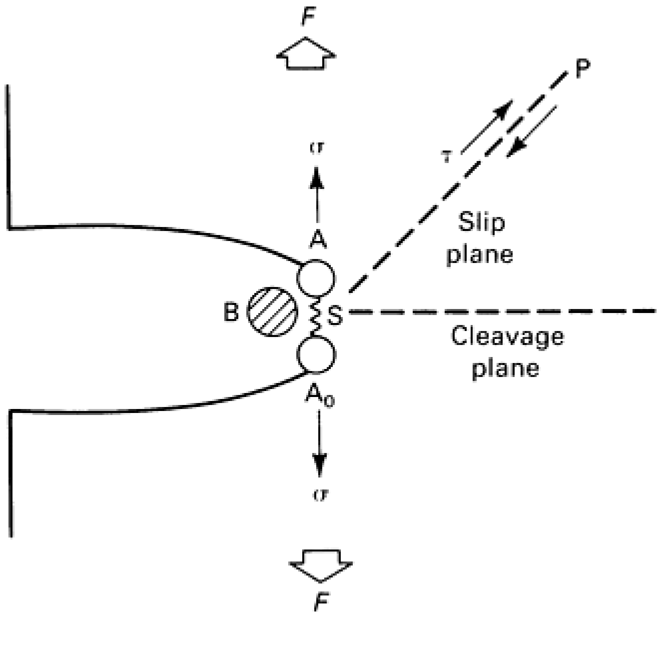

Fig. 64 Schematic illustrating displacement of atoms at the crack tip. The bond A-A_0 constitutes the crack tip, and B is the liquid-metal atom.

In the above mechanism, it is assumed that reduction in the tensile cohesion is predominantly responsible for the occurrence of embrittlement, although both tensile as well as shear cohesion are reduced. Embrittlement can also occur by the adsorption-induced reductions in the shear strength of the atomic bonds at the crack tip. The reduced shear strength facilitates nucleation of dislocations or slip at low stresses at or near the crack tip. This localized increase in plasticity produces a plastic zone with sufficiently large strains such that a void is nucleated ahead of the crack tip at precipitates, inclusions, or at subboundaries in a single crystal. The void will grow, and crack growth will occur. The fracture occurs by the ductile rupture mode, with the appearance of dimples on the fracture surfaces. The localized increased plasticity results in an overall reduction in the strain at failure as compared to that in the absence of liquid metal, thus causing embrittlement. For embrittlement due to reduced shear cohesion, lower strain at failure or subcritical crack growth by linkage of voids is the measure of LME.

A schematic representation of the above process is given in Fig. 65, and supporting fractographic evidence is given for high-strength steel (Fig. 66a) and beryllium-copper alloys (Fig. 66b) broken in liquid-metal environments. Conversely, Fig. 66(c) to (e) and Fig. 67 provide strong support for the reduced tensile cohesion mechanism.

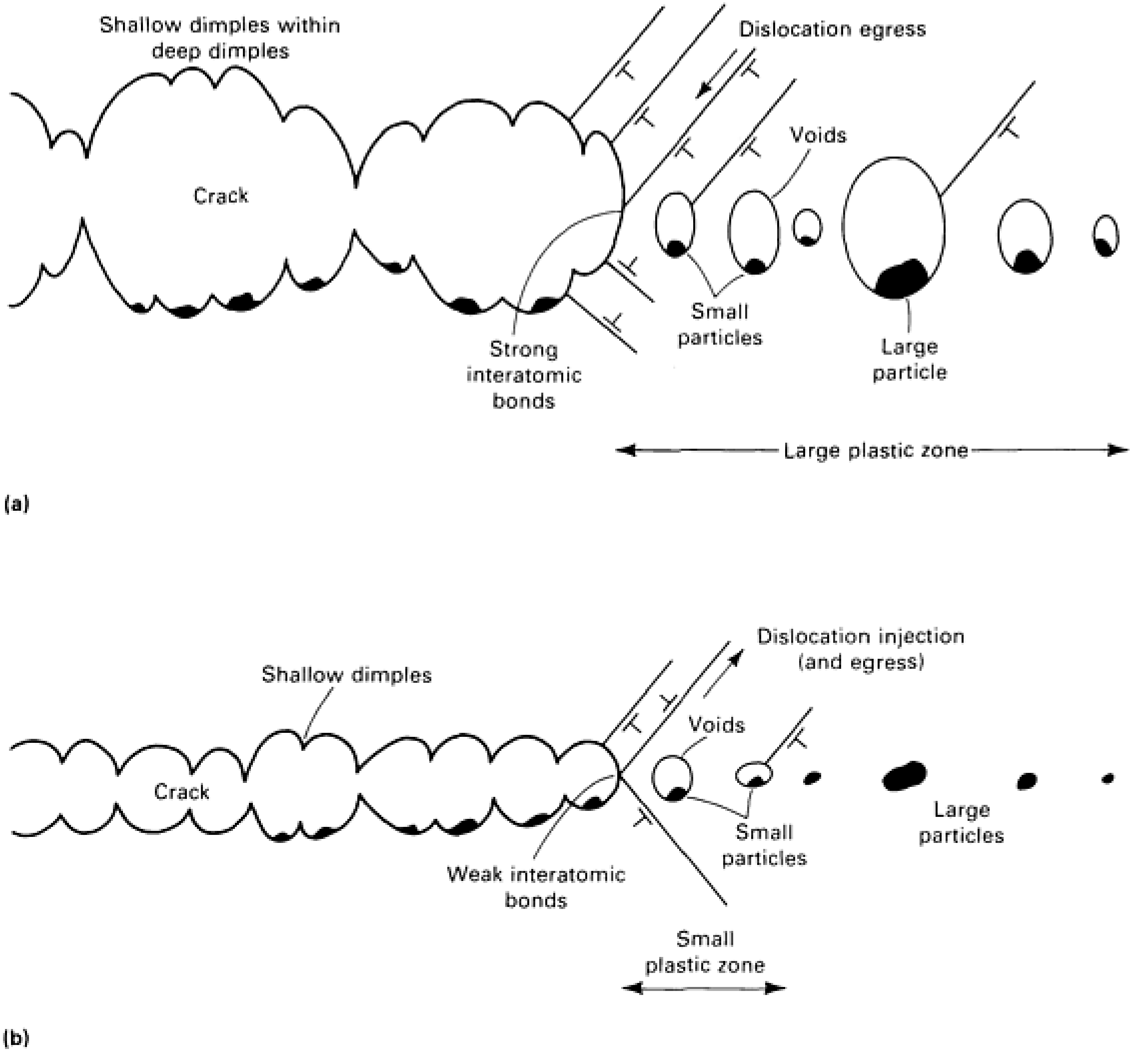

Fig. 65 Schematic illustrating the mechanisms of crack growth by microvoid coalescence. (a) Inert environment. (b) Embrittling liquid-metal environment

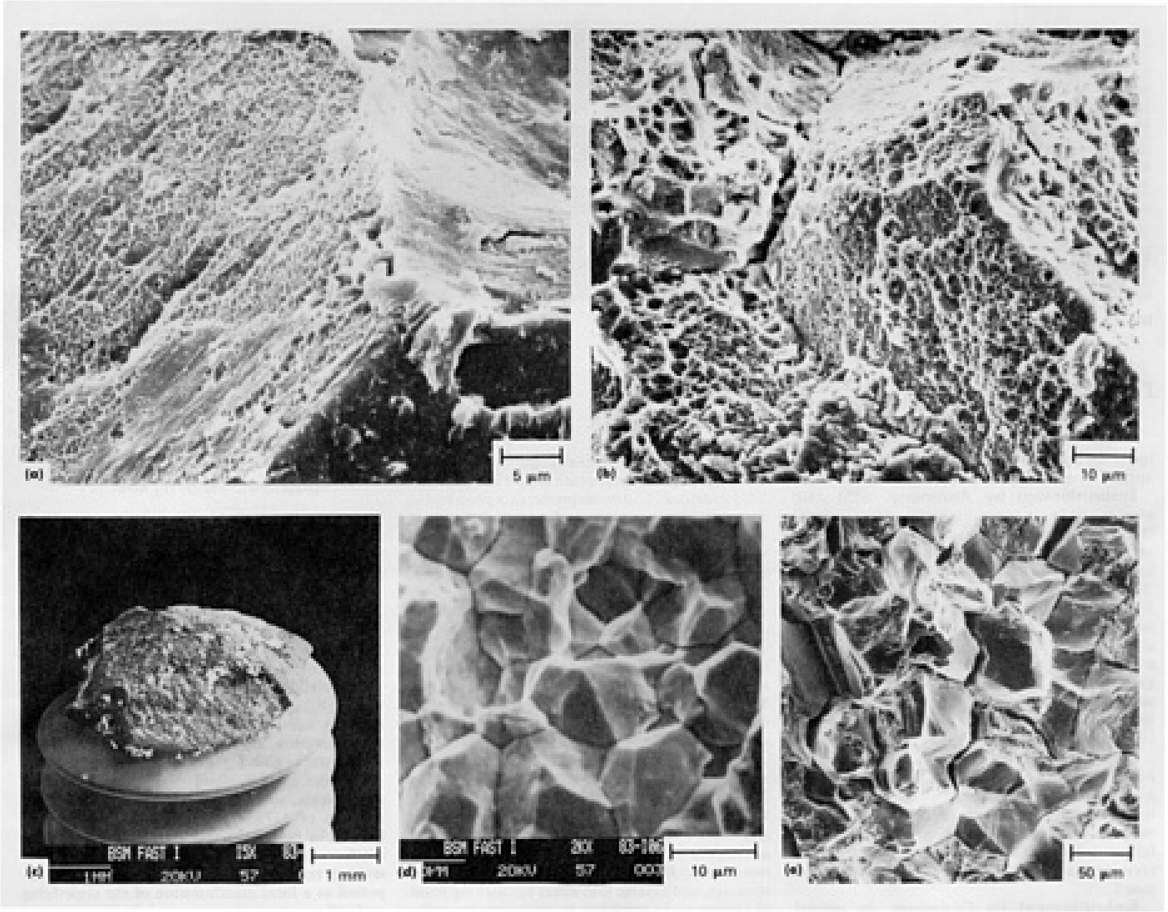

Fig. 66 Ductile and brittle fracture morphologies resulting from LME. (a) Fracture surface produced by subcritical cracking in D-6ac steel (tempered at 650 °C, or 1200 °F) in liquid mercury showing predominantly dimpled intercrystalline fracture along prior-austenite grain boundaries. (b) Fracture surface produced by rapid subcritical crack growth (~1 mm/s, or 0.4 in./s) in a Cu-1.9Be alloy in liquid mercury at 20 °C (70 °F) showing predominantly dimpled intercrystalline fracture. (c) Macrograph of a cadmium-plated fastener made from 1040 steel. Aerodynamic heating during descent of the solid fuel rocket engine resulted in brittle intergranular fracture. (d) Scanning electron micrograph of the failed machine screw shown in (c). (e) Fracture surface of a Monel specimen that failed in liquid mercury. The fracture is predominantly intergranular with some transgranular contribution.

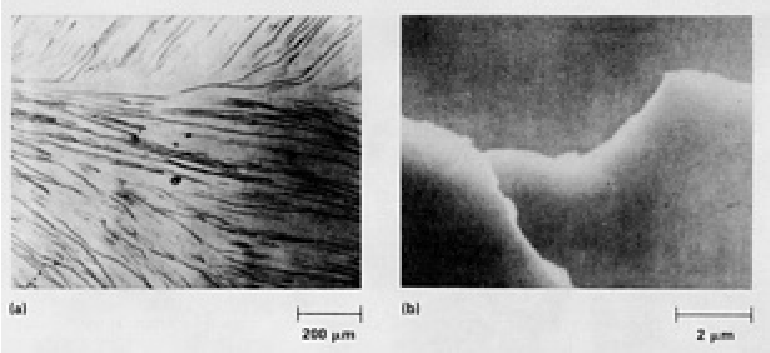

Fig. 67 Optical micrograph (a) and scanning electron micrograph (b) showing cleavage fracture surface produced by cracking zinc single crystal in liquid mercury

Most often, LME induces a brittle intergranular or cleavage fracture mode at reduced tensile stresses and thus supports the tensile decohesion mode. However, the dimpled ductile failure mechanism of LME should be considered an embrittling

process in a failure analysis in which the reduction in the mechanical parameters at fracture is the measure of embrittlement. AlthoughLME can occur by either a brittle or a ductile fracture mode, both degrade the mechanical properties of the solid metal.

Role of Liquid in Crack Propagation

In the mechanism of embrittlement described above, it was implied that once a crack is nucleated subsequent crack propagation occurs mechanically with liquid absent at the crack tip or occurs by the continuous presence of the liquid-metal atoms at the propagating crack tip caused by the surface diffusion of liquid-metal atoms over chemisorbed liquid-metal atoms. The role of liquid in embrittlement should be investigated by measuring the crack growth rate as a function of temperature and stress intensity. The velocity of crack propagation, or crack growth rate, in SCC has been extensively investigated. However, such investigations in liquid metal have been reported only recently for brass (Fig. 68) and aluminum in liquid mercury. The velocity of crack growth in brass in liquid mercury was at least two orders of magnitude higher than that in an inert environment. The crack propagation activation energy for brass in liquid mercury is only 3 to 5 kcal/mol (Fig. 69). This corresponds to diffusion of liquid mercury over mercury adsorbed on brass. The very high velocities of crack propagation and very low activation energies are considered to be distinguishing features from similar investigations in SCC environments in the same metals. Such characteristics can be used to differentiate liquid metal induced crack propagation from stress-corrosion or hydrogen damage.

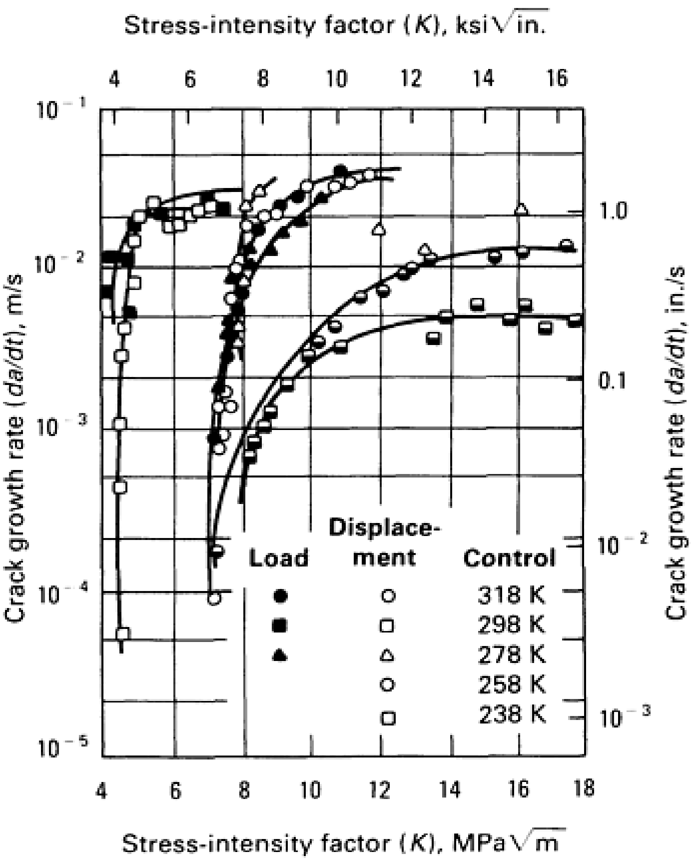

Fig. 68 Crack growth rate versus stress intensity factor for brass in liquid mercury at various temperatures under load and displacement control conditions

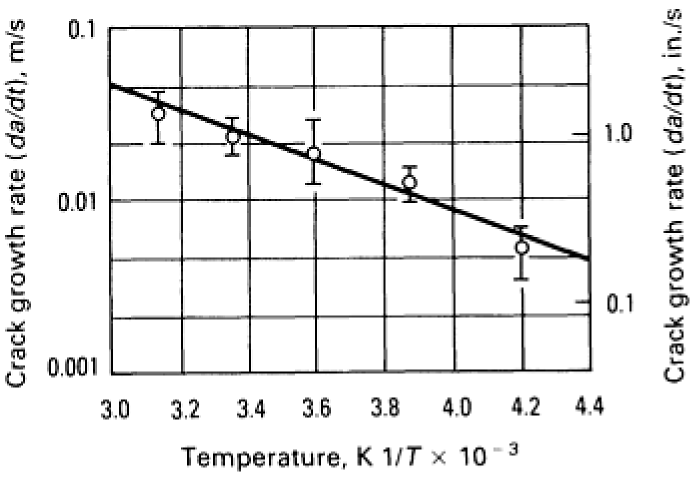

Fig. 69 Crack growth rate versus reciprocal of temperature for brass in liquid mercury. The activation energy, *Q*, is 4 cal/mol.

Occurrence of LME

Susceptibility to LME is unique to specific metals. For example, liquid gallium embrittles aluminum but not magnesium, and liquid mercury embrittles zinc but not cadmium. The equilibrium phase diagrams of most embrittlement couples show that they form simple binary systems with little or no solid solubility. Also, they form immiscible liquids in the liquid state, and they usually do not form intermetallic compounds. This is an empirical observation, and exceptions have been reported, although it is valid for many embrittlement couples.

The most critical and mandatory condition for LME is that the liquid should be in intimate contact with the surface of the solid to initiate embrittlement and should subsequently be present at the tip of the propagating crack to cause brittle failure. Even a thin oxide film several angstroms thick may prevent interaction between the solid and the liquid so that embrittlement is not observed. Thus, conditions that promote intimate contact and enhanced wetting of the liquid by the solid, such as freshly created surfaces by plastic deformation in a liquid environment, breaking of oxide films, or other such factors, will lead to LME of the solid.

The severity of embrittlement is not necessarily related to the above criteria and conditions, but it is related to the chemical nature of the embrittling species. For example, zinc is more severely embrittled by liquid gallium than by mercury. In addition, the severity of embrittlement is related to the properties of the solid and depends on such factors as strength, alloying elements, grain size, and strain rate. The severity or occurrence or nonoccurrence of embrittlement depends on the type of test and whether the solid contains stress concentrators, such as preexisting cracks or flaws, or is smooth and free of stress raisers. By increasing the possibilities of maintaining high stress concentrations, the susceptibility of the solid to LME is also increased. For example, smooth specimens of low-alloy low-strength steel are not embrittled by liquid lead, but the same steel containing a fatigue precrack is severely embrittled by liquid lead.

Certain other prerequisites must be fulfilled before fracture can initiate in a solid. For a ductile nonprecracked metal, these are an applied tensile stress, plastic deformation, and the presence of a stable obstacle to slip serving as a stress concentrator. This obstacle can be preexisting (for example, a grain boundary) or can be created during deformation (for example, a twin or kink band).

In addition, there should be an adequate supply of liquid metal to adsorb at the obstacle and subsequently at the propagating crack tip (only a few atomic monolayers of liquid-metal atoms are necessary for LME.) Plastic deformation or yielding may mean localized deformation in few grains rather than general yielding of the solid metal. If a specimen contains a preexisting crack, then adsorption of the liquid at the crack tip and some tensile stress are necessary to propagate a crack. If the solid is notch brittle, LME will occur at reduced stress. However, a crack, once initiated, may propagate in a brittle manner in the absence of the liquid at the tip. Thus, it may not be necessary for the liquid to be

present at the propagating crack tip. The occurrence of LME in an embrittlement couple requires good wetting of the surface of the solid by the liquid, the presence of sufficient stress concentration to initiate or propagate a crack in liquid, and possible concurrence with the empirical observations mentioned above.

Effects of Metallurgical, Mechanical, and Physical Factors

It has been shown that the prerequisites for liquid metal induced brittle fracture are the same as those for brittle fracture in an inert environment at low temperatures, that is, the need for plastic flow. A barrier for crack nucleation, sufficient tensile stress, and adsorption of liquid metal are necessary to initiate and/or propagate a crack. From the investigations reported for many embrittlement couples, including classic zinc-mercury couples, it has been concluded that adsorption-induced embrittlement can be regarded as a special case of brittle fracture that normally occurs in brittle materials at low temperatures in an inert environment (ductile fracture can also result by the adsorption-induced reductions in the shear strength of the atomic bonds at the crack tip). Thus, the effects of yield stress, grain size, strain rate, temperature, and so on, in a liquid-metal environment follow trends similar to those noted for metals tested in an inert environment.

Effects of Grain Size. The grain size dependence of fracture stress has been investigated for zinc-mercury, cadmium-gallium, brass and copper alloys in mercury, and low-carbon steel in lithium. In these and other instances, the fracture stress varied linearly with the reciprocal of the square root of grain size and followed the well-known Cottrell-Petch relationship of grain size dependence on fracture stress. For the zinc-mercury couple shown in Fig. 70, fracture is nucleation controlled in region I, whereas in region II it is propagation controlled.

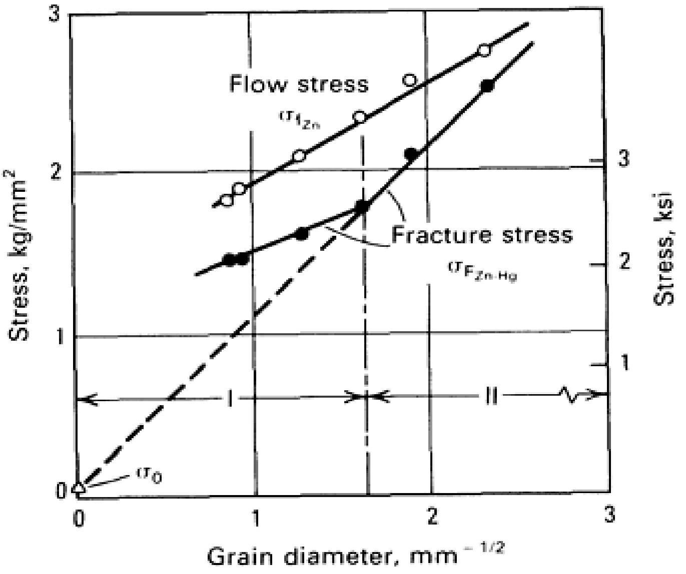

Fig. 70 Effect of grain size on LME. Variation of the flow stress of amalgamated zinc polycrystalline specimens, σf_{Zn}, and fracture stress of amalgamated zinc specimens, $\sigma^{F}{}_{Zn-Hg}$, as a function of grain size at 298 K

Nucleation-controlled embrittlement means that once a crack is initiated it propagates to failure in the presence or absence of the liquid metal at the crack tip. In propagation-controlled failure, microcracks are formed at some low stress in a liquid-metal environment, but the microcracks propagate to failure only when a higher stress is reached. Thus, in propagation-controlled failure, unpropagated microcracks may be found beside the main fracture, and complete fracture of the specimen occurs only in the presence of liquid metal. The reverse is observed when fracture is initiation controlled.

Effects of Temperature and Strain Rate. Liquid-metal embrittlement occurs at the melting point of liquid metal (there are quite a few instances in which embrittlement occurs below the melting point of liquid by SMIE). In most cases, the susceptibility to embrittlement may remain essentially unchanged with temperature. At a sufficiently high test temperature, a brittle-to-ductile transition occurs when embrittlement ceases and ductility is restored to the solid. Such transitions do not occur at a sharply defined temperature and are not predictable on a theoretical basis or in terms of

diffusion, dissolution, or other such embrittlement processes. It is generally accepted that a significant increase in ductility with temperature counteracts the inherent propensity for fracture in the embrittling liquid-metal environment.

In smooth steel specimens tested in liquid lead, brittle-to-ductile transition occurs at approximately 510 °C (950 °F), some 335 °C (600 °F) above the melting point of lead. In similar steel fracture mechanics type test specimens containing sharp notches tested in liquid lead, the transition occurs at approximately 650 °C (1200 °F), some 140 °C (250 °F) higher than that for smooth specimens. Transition temperature in this case depends on the presence or absence of a stress raiser in the specimen and on the type of test method used. Such brittle-to-ductile transitions have been reported for zinc-mercury, aluminum-mercury, brass-mercury, titanium-cadmium, steel-lead, and steel-lead-antimony solution embrittlement couples.

Transition temperature also varies with strain rate and grain size in a manner observed for metals tested in an inert environment. Thus, an increase in strain rate and a decrease in grain size increase the transition temperature. The effects of grain size on transition temperature have been reported for aluminum in Hg-3Sn solutions and brass-mercury embrittlement couples. The effects of strain rate on transition temperature have been reported for cadmium-gallium, zinc-mercury, aluminum-mercury, zinc-indium, brass-mercury, and titanium-cadmium embrittlement couples. Changes in the strain rate by orders of magnitude are usually required to change the transition temperature by 50 to 100 °C (90 to 180 °F). For example, in the titanium-cadmium couple, a change of approximately 60 °C (110 °F) occurs with a change of one to two orders of magnitude in the strain rate and corresponds to a comparable increase in yield stress with the strain rate. The effects of strain rate appear to be related to the increase in the yield stress. This corresponds to an increase in the embrittlement susceptibility and a decrease in the brittle-to-ductile transition temperature.

Effects of Stress. Static fatigue or delayed-failure tests are conducted to study the effects of time-dependent processes, such as diffusion penetration of the grain boundary, as the cause of embrittlement. Also, such tests are performed because they simulate service conditions of constant stress in an embrittling environment as a function of time and assist in the failure analysis. Delayed failure has been reported for notchinsensitive aluminum-copper and beryllium-copper alloys in liquid mercury. Penetration of mercury did not occur, and embrittlement was independent of time to failure; but failure time increased with an increased stress level of the tests. In notch-sensitive zinc tested in mercury, the time to failure was very sensitive to the stress level, with complete failure occurring instantly at a stress slightly higher than a threshold stress. Penetration of mercury was not observed.

These tests indicate that time-dependent diffusion penetration or dissolution processes are not the cause of LME. In isolated instances, grain-boundary penetration by the liquid has been the cause of embrittlement. For example, unstressed aluminum or commercial aluminum alloys disintegrate into individual grains when contacted with liquid gallium. Liquid antimony embrittles steel, and embrittlement increases with temperature; thus, diffusional processes cause antimony to embrittle steel. Liquid copper and liquid lithium embrittle steel in a similar manner (Fig. 71). However, in these cases, both diffusional and classic LME have been observed. Such behavior can be differentiated by the temperature dependence, by the susceptibility to embrittlement, or by embrittlement occurring in solid-metal environments.

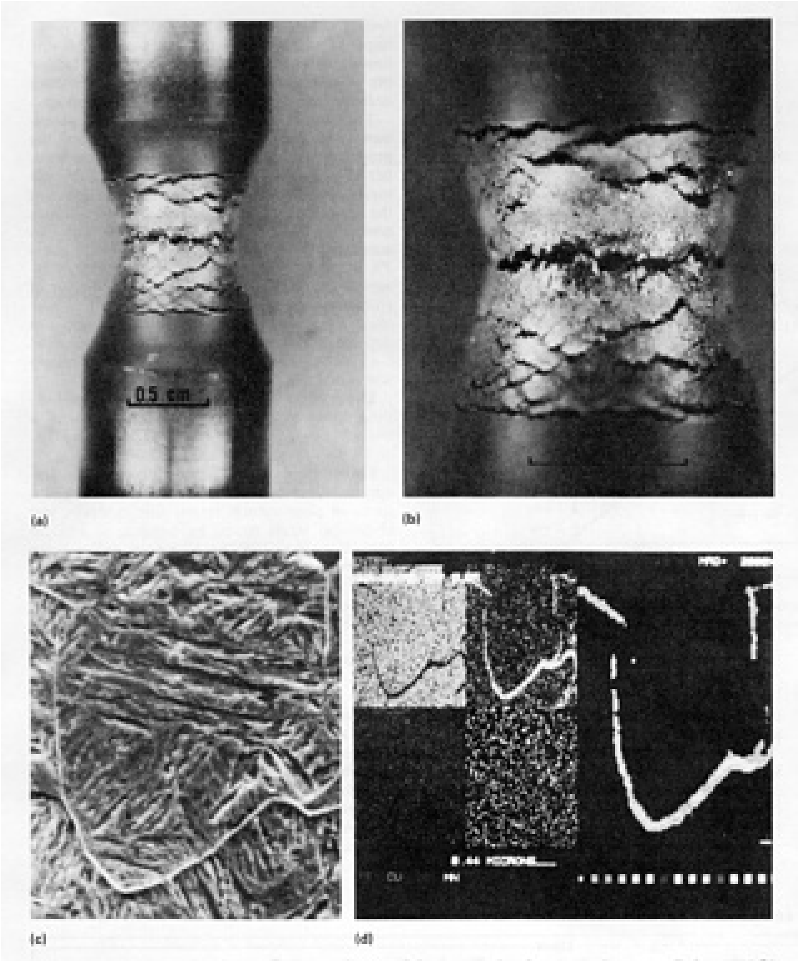

Fig. 71 Copper-induced LME of 4340 steel. (a) and (b) Copper-plated specimen that was pulled at 1100 °C (2010 °F) in a Gleeble hot tensile machine showing liquid copper embrittlement of steel. (c) Scanning electron micrograph of the pulled specimen. 1600×. (d) Computer-processed x-ray map showing the presence of copper in prior-austenite grain boundaries.

Inert Carriers and LME. In some cases, investigation of the embrittlement behavior of a potential solid-liquid metal couple is not possible. The reason is that the solid metal at temperatures just above the melting temperature of the liquid metal is either too ductile to initiate and propagate a brittle crack or the solid is excessively soluble in the liquid metal. It is possible, however, that a solid metal can be embrittled by a liquid metal of high melting point by dissolving it in an inert-carrier liquid metal of a lower melting point. Thus, the embrittling species is effectively in a liquid state at some temperature far below its melting point. In addition, it provides a means of investigating the variation in the degree of embrittlement induced in a solid metal as a function of the concentration and as a function of the chemical nature of the several active liquid-metal species dissolved separately in a common inert-carrier liquid metal.

For example, mercury does not embrittle cadmium, but indium may embrittle cadmium (melting point: 325 °C, or 617 °F). However, cadmium is quite ductile at 156 °C (313 °F), the melting temperature of indium. Mercury dissolves up to 70% ln at room temperature. The indium in the mercury-indium solution at room temperature embrittles cadmium (Fig. 72). In fact, cadmium single crystals, which are ductile even at liquid helium temperature, can be embrittled by indium and cleaved in indium-mercury solutions (Fig. 60). Another example of embrittlement by inert carriers is that of Zircaloy nuclear fuel claddings used in liquid metal cooled nuclear reactors. In liquid cesium, Zircaloy claddings fail in a ductile manner; in cesium saturated with cadmium, Zircaloy is subject to brittle fracture.

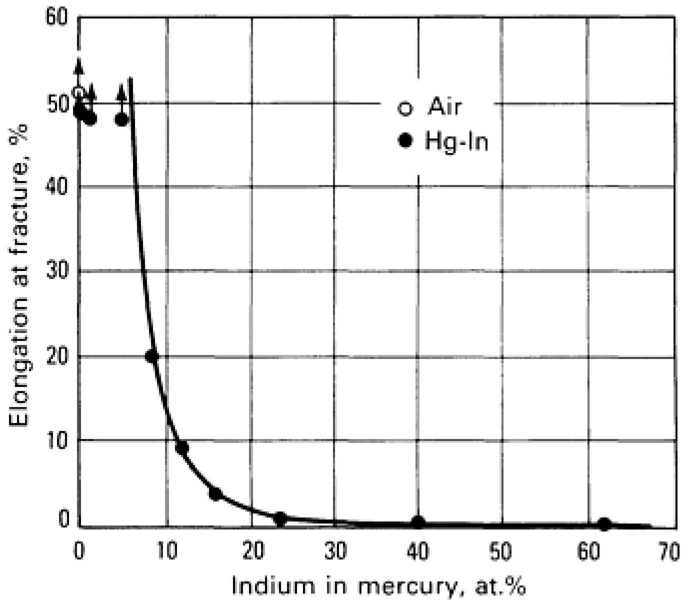

Fig. 72 Variation in ductility of polycrystalline cadmium as a function of indium content of mercury-indium surface coatings. Specimens were tested at 25 °C (75 °F) in air and in mercury-indium solution.

The concept of inert carrier LME is useful in failure analysis where LME has occured in a liquid solution--for example, solder rather than a pure liquid metal. The susceptibility of various species in the solder in causing LME can be investigated by incorporating each species in an inert liquid. This may suggest a means of preventing embrittlement by replacing the most potent embrittler with a nonembrittling species.

Fatigue in Liquid-Metal Environments

Most studies of LME have been concerned with the effects of tensile loading on fracture. Investigations of fatigue behavior are important because this test condition is more severe than other test conditions, including the tensile testing of metals. Thus, a solid tested in fatigue may become embrittled, but the same solid tested in tension may not exhibit embrittlement. This may be because at the high stress level corresponding to yield stress, which is a prerequisite for the occurrence of embrittlement in tough metals, the solid may be sufficiently ductile to prevent initiation of a crack in the liquid.

For example, smooth specimens of high-purity chromium-molybdenum low-alloy steel (yield stress: ~690 MPa, or 100 ksi) are not embrittled by liquid lead, but the same steel specimens containing a fatigue precrack are severely embrittled by liquid lead. The fatigue life in liquid lead is reduced to 25% of that in an inert argon environment. Crack propagation in a liquid-metal environment under fatigue and tensile loading can be significantly different. The stress intensity at failure of 7.7 MPa $\sqrt{m}$(7 ksi $\sqrt{in.}$) for a 4340 steel specimen containing a fatigue precrack tested in cyclic fatigue in liquid lead was five times lower than that for the same specimen tested in tension in static fatigue and was twenty times lower than that in an inert argon environment. Furthermore, the 7.7-MPa $\sqrt{m}$(7-ksi $\sqrt{in.}$) stress intensity was the same whether the specimen had a machined notch (0.13-mm, or 0.005-in., root radius) or had a fatigue precrack at the root of the notch; that is, embrittlement was independent of root radius. These results indicate that embrittlement is very severe and even blunt cracks can propagate to failure. Similar results have also been reported for the same steel tested in liquid mercury.

These results clearly indicate that fatigue testing of a notched or a fatigue precracked specimen provides the most severe test condition and therefore causes maximum susceptibility to embrittlement in a given liquid-metal environment. To determine whether a solid is susceptible to LME in a particular liquid, it is advisable to test the solid metal with a stress raiser or a notch in a tension-tension fatigue test.

Decrease or Elimination of LME Susceptibility

The reduction in the cohesion mechanism of embrittlement indicates that the electronic interactions, resulting in possible covalent bonding due to electron redistribution between the solid- and the liquid-metal atoms, reduces cohesion and thus induces embrittlement. Such interactions at the electronic level are the inherent properties of the interacting atoms and are therefore difficult or impossible to change in order to reduce the susceptibility to LME.

One possibility is to introduce impurity atoms in the grain boundary that have more affinity for sharing electrons with the liquid-metal atoms than for sharing electrons with the solid-metal atoms. For example, additions of phosphorus to Monel segregate to the grain boundaries and reduce the embrittlement of Monel by liquid mercury. Additions of lanthanides to internally leaded steels reduce lead embrittlement of steel. However, in general, the best alternative is to electroplate or clad the solid surface with a metal as a barrier between the embrittling solid-liquid metal couple, making sure that the barrier metal is not embrittled by the liquid metal.

Another possibility is that a ceramic or a covalent material coating on the solid surface will inhibit embrittlement. Apparently, only materials with metallic bonding are susceptible to LME. The severity of embrittlement could be reduced by decreasing the yield stress of the solid below the stress required to initiate a crack or by cladding with a high-purity metal of the alloy that is embrittled but that has a very low yield stress. Thus, Zircaloy, which is clad with a high-purity zirconium, becomes immune to embrittlement by cadmium. The obvious possibility is to replace embrittling liquid metal or solutions by nonembrittling metals or solutions.

Embrittlement of Nonferrous Metals and Alloys*

Zinc is embrittled by mercury, indium, gallium, and Pb-20Sn solder. Mercury decreases the fracture stress of pure zinc by 50% and dilute zinc alloys (0.2 at.% Cu or Ag) by five times that in an inert environment. The fracture propagation energy for a crack in zinc single crystals in mercury is 60% and in gallium is 40% of that in air. Zinc is embrittled more severely by gallium than by indium or mercury.

Aluminum. Mercury embrittles both pure and alloyed aluminum. The tensile stress is decreased by some 20%. Fatigue life of 7075 aluminum alloy is reduced in mercury, and brittle-to-ductile transition occurs at 200 °C (390 °F). Additions of gallium and cadmium to mercury increase the embrittlement of aluminum. Delayed failure by LME occurs in mercury. Dewetting of aluminum by mercury has been found to inhibit embrittlement. The possible cause of dewetting is the dissolution of aluminum by mercury and oxidation of fine aluminum particles by air and formation of aluminum oxide white flowers at the aluminum/mercury interface.

Aluminum alloys are embrittled by tin-zinc and lead-tin alloys. The embrittlement susceptibility is related to heat treatment and the strength level of the alloy. Gallium in contact with aluminum severely disintegrates unstressed aluminum alloys into individual grains. Therefore, grain-boundary penetration of gallium is sometimes used to separate grains and to study topographical features and orientations of grains in aluminum. There is some uncertainty about whether zinc embrittles aluminum. However, indium severely embrittles aluminum. Alkali metals, sodium, and lithium are known to embrittle aluminum. Aluminum alloys containing either lead, cadmium, or bismuth inclusions embrittle aluminum when impact tested near the melting point of these inclusions. The severity of embrittlement increases from lead to cadmium to bismuth.

Copper. Mercury embrittles copper, and the severity of embrittlement increases when copper is alloyed with aluminum and zinc. Antimony, cadmium, lead, and thallium are also reported to embrittle copper. The apparent absence of embrittlement of copper, if observed, should be attributed to the test conditions and metallurgical factors discussed in this article. Mercury embrittlement of brass is a classic example of LME. Embrittlement occurs in both tension and fatigue and varies with grain size and strain rate. Mercury embrittlement of brass and copper alloys has been extensively investigated. Lead and tin inclusions in brass cause severe embrittlement when tested near the melting point of these inclusions. Lithium reduces the rupture stress and elongation at failure of solid copper. Sodium is reported to embrittle copper; however, cesium does not. The embrittling effects of bismuth for copper and their alloys are well documented.

Gallium embrittles copper at temperatures ranging from 25 to 240 °C (75 to 465 °F). Gallium also embrittles single crystals of copper. Indium embrittles copper at 156 to 250 °C (313 to 480 °F).

Other Nonferrous Materials. Tantalum and titanium alloys are embrittled by mercury and by Hg-3Zn solution. Refractory metals and alloys, specifically W-25Re, molybdenum, and Ta-10W, are susceptible to LME when in contact

with molten Pu-1Ga. Cadmium and lead are not embrittled by mercury. However, indium dissolved in mercury embrittles both polycrystalline and single crystal cadium (Fig. 60). The embrittlement of titanium and its alloys by both liquid and solid cadmium is well recognized by the aircraft industry. Cadmium-plated fasteners of both titanium and steel are known to fail prematurely below the melting point of cadmium. Cadmium-plated steel bolts have good stress-corrosion resistance, but cadmium is known to crack steel. Therefore, such bolts are not recommended for use. Zinc is reported to embrittle magnesium and titanium alloys. Silver, gold, and their alloys are embrittled by both mercury and gallium. Nickel is severely embrittled by cadmium dissolved in cesium. The fracture mode is brittle intergranular with bright grain-boundary fracture.

Failure of Zircaloy tubes used as cladding material for nuclear fuel rods has been suspected to result from nuclear-interaction reaction products, such as iodine and cadmium carried by liquid cesium, which is used as a coolant in the reactor. Systematic investigation in the laboratory has shown that cadmium, both in the solid and the liquid state or as a carrier species dissolved in liquid cesium, causes severe liquid and solid metal induced embrittlement of zirconium and Zircaloy-2. Embrittlement of Zircaloy by calcium, strontium, zinc, cadmium, and iodine has also been reported.

Embrittlement of Ferrous Metals and Alloys

Embrittlement by Aluminum. Tensile and stress rupture tests have been conducted on steels in molten aluminum at 690 °C (1275 °F). For short-term tensile tests, a reduced breaking stress and reduction of area were found as compared to the values in air. In the stress rupture tests, the time to failure was dependent upon the applied stress.

Embrittlement by Antimony. AISI 4340 steel tested in fatigue in liquid Pb-35Sb at 540 °C (1000 °F) and in antimony at 675 °C (1250 °F) was very severely embrittled. The embrittlement in lead-antimony occurred 165 to 220 °C (300 to 400 °F) higher than that observed for high-purity lead. Small additions of antimony (~5 wt%) to lead had no effect on embrittlement when tested in fatigue, although 0.002 to 0.2% Sb additions have caused a significant increase in the embrittlement of smooth AISI 4140 steel specimens tested in tension. Embrittlement by antimony increases with temperature and is thought to occur by the grain-boundary diffusion of antimony in steel.

Embrittlement by Bismuth. Upon testing in liquid bismuth at 300 °C (570 °F), no embrittlement was noted in bend tests on a quenched-and-tempered steel. The stress rupture data obtained on the low-carbon steel showed that the time to failure and reduction of area increased with decreasing load, but no intercrystalline attack was noted.

Embrittlement by Cadmium. In several studies of the embrittlement of low-alloy AISI 4340 steel, embrittlement occurred at 260 to 322 °C (500 to 612 °F) but not at 204 °C (399 °F) for high-strength steel. Cracks were observed in samples loaded to 90% of their yield stress at 204 °C (399 °F). The threshold stress required for cracking decreases with an increase in temperature. Cracking at 204 °C (399 °F) was strongly dependent on the strength level of the steel, and embrittlement was not observed for strength levels less than 1241 MPa (180 ksi). Delayed failure occurs in cadmium-plated high-strength steels (AISI 4340, 4140, 4130, and an 18% Ni maraging steel). Failures were observed at 232 °C (450 °F), which is about 90 °C (160 °F) below the melting point of cadmium. Static failure limits of 10% and 60% of the room-temperature notch strength have been reported for electroplated and vacuum-deposited cadmium, respectively, at 300 °C (570 °F). A discontinuous crack propagation mode was observed, consisting of a series of crack propagation steps separated by periods of no apparent growth. This slow crack growth region was characterized by cracks along the prior-austenite grain boundaries. Once the cracks reached a critical size, a catastrophic failure occurred that was characterized by a transgranular ductile fracture.

Embrittlement of high-strength steels occurs when they are stress rupture tested in liquid and solid cadmium. Cadmium produces a progressive decrease in the reduction of area at fracture of AISI 4140 steel over the temperature range of 170 to 321 °C (338 to 610 °F). Cadmium was identified as a more potent solid-metal embrittler than lead, tin, zinc, or indium.

Embrittlement by Copper. The embrittlement of low-carbon steel by copper plate occurred at 900 °C (1650 °F) during a slow-bend test. The embrittling effects of the copper plate exceeded those encountered with brazing alloys. Similar observations have been made for plain carbon steels, silicon steels, and chromium steels at 1000 to 1200 °C (1800 to 2190 °F).

The surface cracking produced during the hot working of some steels at 1100 to 1300 °C (2010 to 2370 °F) also has several characteristics of LME. It is promoted by surface enrichment of copper and other elements during oxidation and subsequent penetration along the prior-austenite grain boundaries. Elements such as nickel, molybdenum, tin, and arsenic that affect the melting point of copper or its solubility in austenite also influence embrittlement. A ductility trough has also been noted, with no cracking produced at temperatures above 1200 °C (2190 °F). Steel plated with copper and pulse heated to the melting point of copper in milliseconds was embrittled by both liquid and solid copper. Hot tensile testing in a Gleeble testing machine at high strain rates produced severe cracking in AISI 4340 steel by both the liquid and solid copper.

Embrittlement by Gallium. The alloy Fe-3Si is severely embrittled by gallium, as are the solid solutions of iron and AISI 4340 steel.

Embrittlement by Indium. Indium embrittles pure iron and carbon steels. Embrittlement depends on both the strength level and the microstructure. Pure iron was embrittled only at temperatures above 310 °C (590 °F), appreciably above the melting point of indium. However, other steels, such as AISI 4140 (ultimate tensile strength of 1379 MPa, or 200 ksi), were embrittled by both solid and liquid indium. Surface cracks were detected at temperatures below the melting temperature of indium. This was interpreted as a local manifestation of the underlying embrittlement mechanism, and it was assumed that the cracks must reach a critical size before the gross mechanical properties are affected.

Embrittlement by Lead. The influence of lead on the embrittlement of steel has been extensively investigated and has been found to be sensitive to both composition and metallurgical effects. The studies fall into two major classifications:

- LME due to contact with an external source of liquid lead
- Internal LME in which the lead is present internally as inclusions or a minor second phase, as in leaded steels

Both external and internal lead-induced embrittlement exhibit similar characteristics, but for the purpose of simplicity, each will be treated individually.

LME Due to External Lead. AISI 4145 and 4140 steels exposed to pure lead exhibit classical LME, as shown by substantial decreases in both the reduction of area and the elongation at fracture. The fracture stress and the reduction of area decreased at temperatures considerably below the melting point of lead and varied continuously through the melting point, suggesting that the same embrittlement mechanism is operative for both solid- and liquid-metal environments.

Additions of zinc, antimony, tin, bismuth, and copper increase the embrittling potency of lead. Additions of up to 9% Sn, 2% Sb, or 0.5% Zn to lead increased the embrittlement of AISI 4145 steel. In some cases, the embrittlement and failure occurred before the UTS was reached. The extent of embrittlement increases with increasing impurity content. No correlation was observed between the degree of embrittlement and wettability. The lead-tin alloys readily wetted steels, but the more embrittling lead-antimony alloys did not.

LME Due to Internal Lead. Leaded steels are economically attractive because lead increases the machining speed and the lifetime of the cutting tools. The first systematic investigation of embrittlement of leaded steels was reported in 1968 (Mostovoy and Breyer). Embrittlement characteristics similar to those promoted by external lead were observed. The degradation in the ductility began at approximately 120 °C (215 °F) below the melting point of lead, with the embrittlement trough present from 230 to 454 °C (446 to 849 °F). This was followed by a reversion to ductile behavior at about 480 °C (895 °F).

The severity of the embrittlement and the brittle-to-ductile transition temperature T_R have been shown to be dependent upon the strength level of the steel, with the degree of embrittlement and T_R increasing with strength level. In these studies, intergranular fracture was produced, which was propagation controlled at low temperatures and nucleation controlled at high temperatures. The degree of embrittlement was critically dependent on the lead composition, and the influence of trace impurities completely masked any variations due to different carbon and alloy compositions of the

steel. Lead embrittlement of a steel compressor disk was induced by bulk lead contents of 0.14 and 6.22 wt%. The lead is associated with the nonmetallic inclusions, and upon yielding, microcracks form at the weak inclusion/matrix interface, releasing a source of embrittling agent to the crack tip that aids subsequent propagation. An electron microprobe analysis of the nonmetallic inclusions identified the presence of zinc, antimony, tin, bismuth, and arsenic. With the exception of arsenic, all these trace impurities have been shown to have a significant effect on the external LME of steel.

The two most promising methods of suppressing LME are the control of sulfide composition and morphology and the cold working of the steel. The addition of rare-earth elements to the steel melt modifies the sulfide morphology and composition and can eliminate LME.

Embrittlement by Lithium. Exposure of AISI 4340 steel to lithium at 200 °C (390 °F) resulted in static fatigue, with the time to failure depending on the applied stress. A decreasing fracture stress and elongation to fracture were noted with increasing UTS of variously treated steels, and catastrophic failure occurred for those steels with tensile strengths exceeding 1034 MPa (150 ksi). The tensile ductility of low-carbon steel at 200 °C (390 °F) was drastically reduced in lithium, with intergranular failure after 2 to 3% elongation, but there was no effect on the yield stress or the initial work-hardening behavior. The fracture stress was shown to be a linear function of $d^{-\frac{1}{2}}$, where d is the average grain diameter, in accordance with the Petch relationship.

Embrittlement by Mercury. It has been shown that mercury embrittlement is crack nucleation controlled and can be induced in low-carbon steel samples by the introduction of local stress raisers. The fracture toughness of a notched 1Cr-0.2 Mo steel was significantly decreased upon testing in mercury. The effective surface energy required to propagate the crack was 12 to 16 times greater in air than in mercury. The fatigue life of 4340 steel in mercury is reduced by three orders of magnitude as compared to that in air.

The addition of solutes (cobalt, silicon, aluminum, and nickel) to iron, which reduced the propensity for cross-slip by decreasing the number of active slip systems and changed the slip mechanism from wavy to planar glide, increased the susceptibility to embrittlement. Iron alloys containing 2% Si, 4% Al, or 8% Ni and iron containing 20% V or iron containing 49% Co and 2% V have been shown to be embrittled by mercury in unnotched tensile tests. The degree of embrittlement behavior was extended to lower alloy contents by using notched samples. No difference in the embrittlement potency of mercury or a saturated solution of indium in mercury was noted.

Effect of Selenium. Selenium had no embrittling effect on the mechanical properties of a quenched-and-tempered steel (UTS: ~1460 MPa, or 212 ksi) bend tested at 250 °C (480 °F).

Embrittlement by Silver. Silver had no significant effect on the mechanical properties of a range of plain carbon steels, silicon steels, and chromium steels tested by bending at 1000 to 1200 °C (1830 to 2190 °F). However, a silver-base filler metal containing 45% Ag, 25% Cd, and 15% Sn has been reported to embrittle A-286 heat-resistant steel in static-load tests above and below 580 °C (1076 °F), the melting point of the alloy.

Effect of Sodium. Unnotched tensile properties of low-carbon steel remained the same when tested in air and in sodium at 150 and 250 °C (300 and 480 °F). Similarly, Armco iron, low-carbon steel, and type 316 steel were not embrittled by sodium at 150 to 1600 °C (300 to 2910 °F).

Embrittlement by Solders and Bearing Metals. A wide range of steels are susceptible to embrittlement and intercrystalline penetration by molten solders and bearing metals at temperatures under 450 °C (840 °F). Tensile tests have revealed embrittlement as a reduction in ductility. The embrittlement increased with grain size and strength level of the steel, except for temper-embrittled steels.

The tensile strength and ductility of carbon steel containing 0.13% C were decreased upon exposure to the molten solders and bearing alloys. The embrittlement was concomitant with a change to a brittle intergranular fracture mode and penetration along prior-austenite grain boundaries. Ductile failure was observed with samples tested in air or in the liquid metal at temperatures exceeding 450 °C (840 °F). No intercrystalline penetration of solder was noted in carbon steels containing 0.77% and 0.14% C at 950 °C (1740 °F).

It has been reported that solder embrittles steel more than Woods metal (a bismuth-base fusible alloy containing lead and tin), particularly if it contains 4% Zn. The bearing metals produced embrittlement similar to the solder containing 4% Zn alloy.

Embrittlement by Tellurium. Tellurium-associated embrittlement has been reported for carbon and alloy steels. Hot shortness occurs in AISI 12L14 + Te steel, with the most pronounced loss in ductility between 810 and 1150 °C (1490 and 2100 °F), embrittlement being most severe at 980 °C (1795 °F). The embrittlement has been shown to occur by the formation of a lead-telluride film at the grain boundary, which melts at 923 °C (1693 °F). The mechanical test data and the examination of fracture surfaces by Auger electron spectroscopy (AES) and scanning electron microscopy (SEM) indicated LME of steel by the lead-telluride compound.

Effect of Thallium. Thallium had no embrittling effects on the mechanical properties of a quenched-and-tempered steel (UTS: $\sim$1460 MPa, or 212 ksi) tested in bending at 325 °C (615 °F).

Embrittlement by Tin. The embrittling effect of tin has been observed in a range austenitic and nickel-chromium steels, the degree of embrittlement increasing with their strength level. Embrittlement depends on the presence of a tensile stress and is associated with intercrystalline penetration.

The embrittlement by solid tin occurs at approximately 120 °C (215 °F) below its melting point. The fracture surfaces exhibited an initial brittle zone perpendicular to the tensile axis that followed the prior-austenite grain boundaries. Layers of intermetallic compound present at the steel/tin interface did not impede the embrittlement process. Embrittlement has been observed in delayed-failure tests down to 218 °C (424 °F) (14 °C, or 25 °F, below the melting point of tin); however, in tensile tests, embrittlement by solid tin was effective at temperatures as low as 132 °C (270 °F), which is 100 °C (180 °F) below melting point.

AISI 3340 steel doped with 500 ppm of phosphorus, arsenic, and tin has been tested in the presence of tin while in the segregated (temper embrittled) and the unsegregated states. Temper-embrittled steels were found to be more susceptible to embrittlement than steel heat treated to a nontempered state.

A lower fatigue limit and lifetime at stresses below the fatigue limit for low-carbon steel and for 18-8 stainless steel have been noted when tested in tin at 300 °C (570 °F). The exposure time to the tin before testing had no influence on the fatigue life of the steel.

Embrittlement of Austenitic Steels by Zinc. Two main types of interaction of zinc and austenitic stainless steel have been observed. Type I relates to the effects on unstressed material in which liquid-metal penetration/erosion is the major controlling factor, and Type II relates to stressed materials in which classic LME is observed.

Type I Embrittlement. Zinc slowly erodes unstressed 18-8 austenitic stainless steel at 419 to 570 °C (786 to 1058 °F) and penetrates the steel, with the formation of an intermetallic βnickel-zinc compound at 570 to 750 °C (1060 to 1380 °F). At higher temperatures, penetration along the grain boundaries occurs, with a subsequent diffusion of nickel into the zinc-rich zone. This results in a nickel-exposed zone adjacent to the grain boundaries, reducing the stability of the γphase and causing it to transform to an α-ferrite; the associated volume change of the $\gamma \rightarrow \alpha$transformation produces an internal stress that facilitates fracture along the grain boundaries. Similar behavior has been observed in an unstressed 316C stainless steel held 30 min at 750 °C (1380 °F), in which penetration occurred to a depth of 1 mm (0.4 in.), and in an unstressed type 321 steel held 2 h at 515 °C (960 °F), in which a penetration of 0.127 mm (0.005 in.) was observed.

Type II embrittlement occurs in stainless steel above 750 °C (1380 °F) and is characterized by an extremely fast rate of crack propagation that is several orders of magnitude greater than that of Type I, with cracks propagating perpendicular to the applied stress. In laboratory tests, an incubation period was observed before the propagation of Type II cracks, suggesting that they may be nucleated by Type I cracks formed during the initial contact with zinc.

At 800 °C (1470 °F), a stressed type 316C stainless steel failed catastrophically when coated with zinc. Cracking was produced at a stress of 57 MPa (8 ksi) at 830 °C (1525 °F) and 127 MPa (18 ksi) at 720 °C (1330 °F), but failure was not observed at a stress of 16 MPa (2 ksi) at 1050 °C (1920 °F).

Liquid-metal embrittlement may be produced by the welding of austenitic steels in the presence of zinc or zinc-base paints. Intercrystalline cracking has been observed in the heat-affected zone in areas heated from 800 to 1150 °C (1470 to 2100 °F), and electron microprove analysis has been used to identify the grain-boundary enrichment of nickel and zinc, together with the formation of a low-melting nickel-zinc compound. The embrittlement of sheet samples of austenitic steel coated with zinc dust dye and zinchromate primer occurs at stresses of the order of 20 MPa (3 ksi).

Embrittlement of Ferritic Steels by Zinc. Embrittlement of ferritic steels and Armco iron by molten zinc has been reported in the temperature range of 400 to 620 °C (750 to 1150 °F). Long exposures and intercrystalline attack were needed to cause a reduction in the elongation to fracture; an iron-zinc intermetallic layer was formed that inhibited embrittlement until the layer was ruptured. High-alloy ferritic steels exhibit embrittlement by zinc at temperatures above 750 °C (1380 °F).

Delayed failure occurs in steel in contact with solid zinc at 400 °C (750 °F), which is 19 °C (34 °F) below the melting point of zinc. The slow crack growth region is characterized by intergranular mode of cracking.

Exposing AISI 4140 steel to solid zinc results in a decrease in the reduction of area and in fracture stress at 265 °C (510 °F), with no significant changes in the other mechanical properties. The tensile fracture initially propagates intergranularly, with the final failure occurring by shear. Liquid zinc embrittles 4140 steel at 431 °C (808 °F), and it has been shown that zinc is present at the crack tip. Figure 73 shows a compilation of liquid-metal embrittling and nonembrittling couples based on the theoretical calculations of the solubility parameter and the reduction in the fracture-surface energy. The embrittlement curve is separated by brittle and ductile fracture. A concise summary of embrittlement couples is provided in Table 5. Both pure and alloyed solids are listed.

Table 5 Summary of embrittlement couples

Solid Metal Induced Embrittlement

M.H. Kamdar, Benet Weapons Laboratory, U.S. Army Armament Research, Development, and Engineering Center

Embrittlement occurs below the melting temperature of the solid in certain LME couples. The severity of embrittlement increases with temperature, with a sharp and significant increase in severity at the melting point, T_m, of the embrittler (Fig. 74). Above T_m, embrittlement has all the characteristics of LME. The occurrence of embrittlement below the T_m of the embrittling species is known as solid metal induced embrittlement of metals.

Although SMIE of metals has not been mentioned or recognized as an embrittlement phenomenon in industrial processes, many instances of loss in ductility, strength, and brittle fracture of metals and alloys have been reported for electroplated metals and coatings or inclusions of low-melting metals below their T_m (Ref 109). Delayed failure of cadmium-plated high-strength steel has been observed below the T_m of cadmium (Ref 110, 111). Accordingly, cadmium-plated steel bolts, despite their excellent resistance to corrosion, are not recommended for use above 230 °C (450 °F). Notched tensile specimens of various steels are embrittled by solid cadmium. Solid cadmium, silver, and gold embrittle titanium. Leaded steels are embrittled by solid lead, with considerable loss in ductility below the T_m of lead; this phenomenon accounts for numerouselevated-temperature failures of leaded steels, such as radial cracking of gear teeth during induction-hardening heat treatment, fracture of steel shafts during straightening at elevated temperature, and heat treatment failure of jet-engine compressor disks. Liquid and solid cadmium metal environments, as well as cadmium dissolved in inert nonembrittling coolant liquid, serve to embrittle the Zircaloy-2 nuclear fuel cladding tubes used in nuclear reactors (Ref 112). Inconel vacuum seals are cracked by solid indium. These reports of brittle failure clearly indicate the importance of SMIE in industrial processes.

Solid metal induced embrittlement was first recognized and investigated in the mid-1960s and early 1970s by studying the delayed failure of steels and titanium in a solid-cadmium environment (Ref 113, 114, 115). Results of these studies are shown in Fig. 75 and 76. A systematic investigation of SMIE of steel by a number of solid-metal embrittling species (Fig. 74) found that solid metal as an external environment can cause embrittlement and for steels represents a generalized phenomenon of embrittlement.

Solid metal induced embrittlement can also occur when the embrittling solid is an internal environment, that is, present in the solid as an inclusion (Ref 108). It has been clearly demonstrated that internally leaded steel is embrittled below the T_m of the lead inclusion of steel (Ref 108).

Brittle fracture in LME and SMIE is of significant scientific interest because the embrittling species are in the vicinity of or at the tip of the crack and are not transported by dislocations or by slip due to plastic deformation into the solid, as is hydrogen in the hydrogen embrittlement of steels. Also, embrittling species are less likely to be influenced by the effects of grain-boundary impurities, such as antimony, phosphorus, and tin, which cause significant effects on the severity of hydrogen and temper embrittlement of metals. Investigations of SMIE and LME, therefore, can be interpreted less ambiguously than similar effects in other environments, such as hydrogen and temper embrittlement of metals. Thus, solid-liquid environmental effects provide a unique opportunity to study embrittlement mechanisms in a simple and direct manner under controlled conditions.

It is conceivable that a common mechanism may underlie solid, liquid, and gas phase induced embrittlement. The interactions at the solid/environment interface and the transport of the embrittling species to the crack tip may characterize a specific embrittlement phenomenon. A study of SMIE and LME may provide insights into the mechanisms of hydrogen and temper embrittlement. It is apparent that the phenomenon of SMIE is of both industrial and scientific importance. A review of the investigations of the occurrence and mechanisms of SMIE follows.

Characteristics of SMIE

To date, SMIE has been observed only in those couples in which LME occurs, suggesting that LME is a prerequisite for the occurrence of SMIE. Solid metal induced embrittlement may occur in the absence of LME if a brittle crack cannot be initiated at the T_m of the embrittler. A recent compilation of SMIE couples is given in Tables 6 and 7, which show that all solid-metal embrittlers are also known to cause LME.

Solid metal induced embrittlement and liquid-metal embrittlement are strikingly similar phenomena. The prerequisites for SMIE are the same as those for LME: intimate contact between the solid and the embrittler, the presence of tensile stress, crack nucleation at the soli/embrittler interface from a barrier (such as a grain boundary), and the presence of embrittling species at the propagating crack tip. Also, metallurgical factors that increase brittleness in metals, such as grain size, strain rate, increases in yield strength, solute strengthening, and the presence of notches or stress raisers, all appear to increase embrittlement. The susceptibility to SMIE is stress and temperature sensitive and does not occur below a specific threshold value. Embrittlement by delayed failure is also observed for both LME and SMIE (Table 8).

Some differences also exist. Multiple cracks are formed in SMIE; in LME, a single crack usually propagates to failure. The fracture in SMIE is propagation controlled. However, crack propagation rates are at least two to three orders of magnitude slower than in LME. Brittle intergranular fracture changes to ductile shear because of the inability of the embrittler to keep up with the propagating crack tip. Incubation periods have been reported, indicating that the crack nucleation process may not be the same as in LME (Ref 116, 117, 118). Nucleation and propagation are two separate stages of fracture in SMIE.

These differences may arise because of the rate of reaction or interactions at the metal/embrittler interface and because the transport properties of solid- and liquid-metal embrittlers are of significantly different magnitudes. It has been suggested that reductions in the cohesive strength of atomic bonds at the tip are responsible for both SMIE and LME (Ref 109, 116, 117, 119, 120). However, transport of the embrittler is the rate-controlling factor in SMIE. Another possibility is that stress-assisted penetration of the embrittler in the grain boundaries initiates cracking, but surface self-diffusion of the embrittling species similar to that proposed for LME controls crack propagation.

Investigations of SMIE

The first investigations of delayed failure were reported in cadmium-, zinc-, and indium-plated tensile specimens of 4340, 4130, 4140, and 18% Ni maraging steel in the temperature range of 200 to 300 °C (390 to 570 °F), as shown in Fig. 77 and 78. The results indicated that 4340 was the most susceptible and that 18% Ni maraging steel was the least susceptible alloy to cadmium embrittlement. The activation energy for steel-cadmium embrittlement was 39 kcal/mol (Fig. 79), which corresponded to diffusion of cadmium in the grain boundary. A thin plated layer of nickel or copper has been reported to act as a barrier to the embrittler and to prevent SMIE of steel (Ref 110). Solid indium is reported to embrittle steels (Ref 117, 118), and an incubation period exists for crack nucleation.

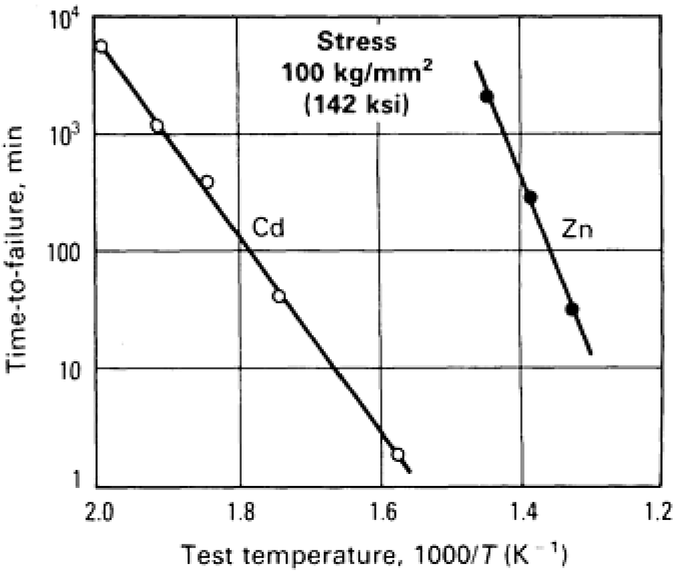

Fig. 79 Arrhenius plots of delayed failure in steel tested in cadmium and zinc. The activation energy Q is 39 kcal/mol for cadmium, 70 kcal/mol for zinc. Source: Ref 110

Embrittlement of different steels in lead was investigated as both an external and internal (leaded steel) environment; SMIE was conclusively demonstrated to be a reproducible effect (Ref 108, 109). It was also demonstrated that SMIE is an extension of LME (Ref 109, 117). Internally leaded high-strength steels are susceptible to severe embrittlement in the range of the T_m of lead, and this embrittlement is a manifestation of LME. However, it was found that the onset of embrittlement occurs some 95 °C (200 °F) below the T_m, of lead (330 °C, or 265 °F) and is continuous up to the T_m, with no discontinuity or anomalies in the variation of the embrittlement with temperature (Ref 109). At the T_m of lead, a sharp increase occurs in the severity of embrittlement, and ductile-to-brittle transition occurs in the temperature range of 370 to 450 °C (700 to 840 °F).

The same behavior was noted for pure lead as an external environment soldered onto 4140 steel and such embrittlement has also been observed for surface coatings of zinc, lead, cadmium, tin, and indium on steel (Ref 109). Embrittlement manifests itself as a reduction in tensile ductility over a range of temperatures extending from about three-quarters of the absolute T_m of the embrittler up to the T_m (Fig. 74). It has been shown the embrittlement is caused by the growth of stable subcritical intergranular cracks and that crack propagation is the controlling factor in embrittlement (Ref 109, 117). This indicated that transport of embrittlers to the crack tip was either by vapor phase or by surface or volume diffusion. In this study, the vapor pressure of the embrittling species at T_m varied widely and ranged from 20 to 6×10^{-36} Pa (1.5×10^{-1} to 4.5×10^{-38} torr) (Table 9). However, the crack propagation times for all embrittlers were similar. The estimated values of the diffusion coefficients ranged in the vicinity of 10^{-4} to 10^{-6} cm^2/s (6.5×10^{-4} to 6.5×10^{-6} in.^{2}/s). These values are comparable to surface or self-diffusion of embrittler over embrittler and suggest that diffusion, not vapor transport, is the rate-controlling process.

Table 9 Embrittler vapor pressures and calculated vapor-transport times at the embrittler-melting temperatures

Embrittler	Vapor pressure		Time, s
	Pa	torr	
Zn	20	1.5×10^{-1}	5×10^{-3}
Cd	10	7.5×10^{-2}	1×10^{-2}
Hg[(a)]	0.3	2.25×10^{-3}	3×10^{-1}
Sb	4×10^{-4}	3.0×10^{-6}	3×10^{2}
K	1×10^{-4}	7.5×10^{-7}	1×10^{3}
Na	2×10^{-5}	1.5×10^{-7}	5×10^{3}
Ti	4×10^{-6}	3.0×10^{-8}	3×10^{4}
Pb	5×10^{-7}	3.75×10^{-9}	2×10^{5}
Bi	2×10^{-8}	1.5×10^{-10}	5×10^{6}
Li	2×10^{-8}	1.5×10^{-10}	5×10^{6}
ln	3×10^{-19}	2.25×10^{-21}	3×10^{17}
Sn	8×10^{-21}	6.0×10^{-23}	1×10^{19}
Ga	6×10^{-36}	4.5×10^{-38}	2×10^{35}

(a) At room temperature.

Delayed Failure and Mechanism of SMIE

If a metal in contact with the embrittling species is loaded to a stress that is lower than that for fracture and is tested at various temperatures, then either the environment-induced fracture initiates and propagates instantaneously, as in a zinc-mercury LME couple, or delayed failure or static fatigue is observed. Examples of these two types of fracture processes are given in Table 8. Investigations of delayed failure provide an opportunity to separate crack nucleation from crack propagation and, specifically, to evaluate the transport-related role of the embrittling species. Solid metal induced

embrittlement is a propagation-controlled fracture process, and the time, temperature, and stress dependence of embrittlement presents an opportunity to study the kinetics of the cracking process.

The most critically investigated embrittlement system is 4140 steel embrittled by solid and liquid indium. Measurement of the decrease in electrical potential has been used to monitor crack initiation and propagation and to investigate the effects of temperature and stress level on delayed failure in 4140 steel by liquid and solid indium (Ref 116). The effects of temperature and stress level on the initiation time (incubation period for crack initiation) for both SMIE and LME are given in Fig. 80. The activation energy of the crack initiation process is approximately 37 kcal/mol and is essentially independent of the applied stress level. The activation energy represents the energy for stress-aided self-diffusion of both liquid and solid indium in the grain boundaries of the steel. Thus, crack initiation in both SMIE and LME occurs first by the adsorption of the embrittler at the site of crack initiation.

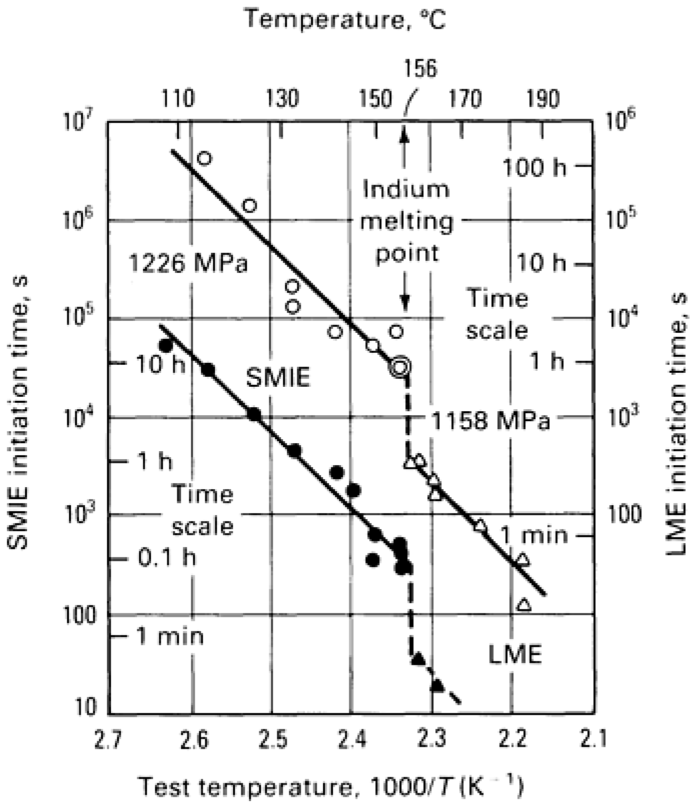

Fig. 80 Initiation time versus temperature in SMIE and LME of 4140 steel in indium at two stress levels. Source: Ref 117

However, because of the presence of an incubation period, the rate-controlling process is stress-aided diffusion penetration of the base-metal grain boundaries. Such penetration reduces the stress necessary to initiate a crack, causing embrittlement of the base metal. On this basis, it is difficult to explain embrittlement of single crystals, which do not contain grain boundaries. Thus, rather than stress-aided diffusion penetration along grain boundaries, the embrittling species may reduced cohesion of atoms at the grain boundaries in accord with the reduction-in-cohesion mechanism. This mechanism would also explain SMIE of single crystals. Crack propagation time as a function of temperature and stress level for both SMIE and LME of steel by indium is plotted in Fig. 81. The activation energy for crack propagation for this couple was 5.6 kcal/mol, which represents the energy for self-diffusion of indium over indium. Thus, propagation is controlled by the diffusion of indium over several multilayers of indium adsorbed on the crack surface or by the so-called waterfall mechanism of embrittlement. This mechanism is a variation of that proposed and discussed in detail as the reduction-in-cohesion mechanism for LME.

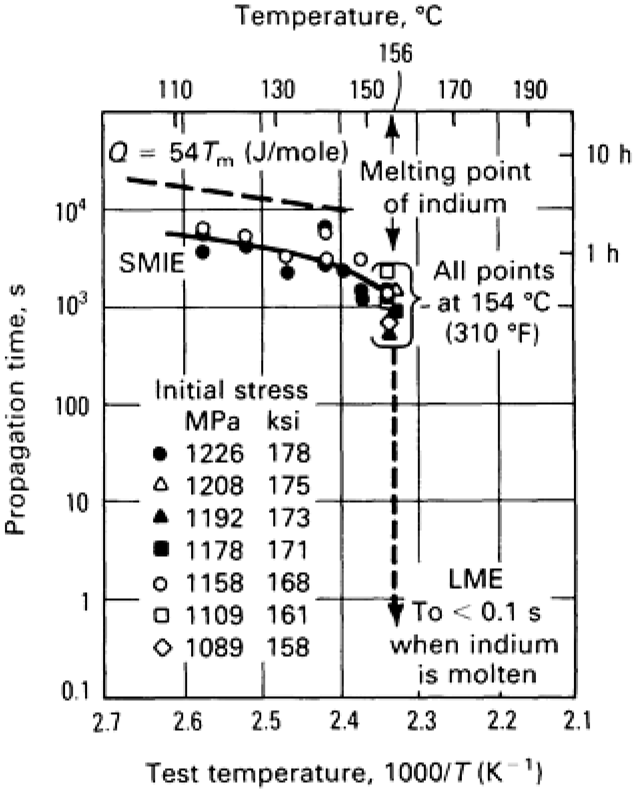

Fig. 81 Propagation time versus temperature for 4140 steel in indium at various temperatures and stress levels. Note the occurrence of SMIE and LME and little dependence on stress level of test. Source: Ref 117

Adsorption of the embrittler at the solid surface is followed by the rate-controlling step of stress-aided diffusion of the embrittler in the grin boundary of the base metal. The embrittler reduces cohesion of the grain-boundary base metal atoms, thus initiating a crack at a lower stress than that observed for the alloy in the absence of the embrittling species, resulting in embrittlement. Crack propagation occurs by multilayer self-diffusion of the embrittling species. These processes are valid for both LME and SMIE in the steel-indium embrittlement couple. It is clear that SMIE is similar to LME except that SMIE is a slower, embrittler transport-limited process. In this regard, the study of SMIE is important in eliminating the possibility in LME that a crack, once nucleated, may propagate in a brittle manner in the absence of the embrittling species at the tip of the crack. Solid metal induced embrittlement is a recent phenomenon, and further research is needed concerning the effects of metallurgical, mechanical, and chemical parameters on embrittlement. However, it is clear that SMIE must be recognized as yet another phenomenon of environmentally induced embrittlement.

Planning and Preparation of Corrosion Tests

Donald O. Sprowls, Consultant

Introduction

CORROSION BEHAVIOR is a combined property of the metal and the environment to which it is exposed. Therefore, there is no universal corrosion test for all purposes. The factors associated with both the metal and the environment should be considered and controlled, when necessary, to establish appropriate exposure conditions during testing.

This article will discuss the basic corrosion-testing philosophy that impacts on all of the various types of testing described in this Section. These remarks have been drawn from several relatively recent books on the subject (Ref 1, 2, 3, 4) and from practical experience in an industrial metallurgical research laboratory.

Properly conducted corrosion tests can mean the savings of millions of dollars. They are the means of avoiding the use of a metal under unsuitable conditions or of using a more expensive material than is required. Corrosion tests also help in the development of new alloys that perform more inexpensively, more efficiently, longer, or more safely than the alloys currently in use. Also, quality-control corrosion tests are a means of ensuring that alloys have the capabilities expected of them. Corrosion-testing programs can be simple ones that are completed in a few minutes or hours, or they can be complex, requiring the combined work of a number of investigators over a period of years.

Careful planning is essential to obtain meaningful test results. Preliminary time and effort spent considering metallurgical factors, environmental variations, statistical treatment, and the interpretation of accelerated test results are often the most useful part of the test procedures (Ref 5, 6).

Test Objectives

The first and most important part of test planning is to define clear objectives and significant criteria for interpreting the test results. The definition of the objective is important because it determines the kind of information that would be most pertinent to the goals of the test. Typical corrosion test objectives include:

- Determining the best material to fill a need (material selection)
- Predicting the probable service life of a product or structure
- Evaluating the new commercial alloys and processes
- Assisting with development of materials with improved resistance to corrosion
- Conducting lot-release and acceptance tests to determine whether material meets specifications (quality control)
- Evaluating environmental variations and controls (inhibitors)
- Determining the most economical means of reducing corrosion
- Studying corrosion mechanisms

In pursuit of most of the test objectives listed above, comparisons and predictions are involved for which statistical treatment of the test results is advantageous. Therefore, specific criteria, such as an acceptable significance level, and a plan of analysis should be determined in advance. Standardized test methods and practices are preferred when available.

In the field of research for alloy or process development and improvement, the investigator seeks to improve for tomorrow the material of today. He will usually begin with small specimens and laboratory tests and, as material variations show promise, will proceed through other types of testing, such as simulated service tests and testing of actual parts.

For some situations in which it is necessary to determine the best material for an application, special test conditions may have to be developed. One should have as through a knowledge as possible of all the service conditions that the product will be called on to withstand. Standardization of test methods has received the most attention, as might be expected, in problem areas that have become acute--for example, in the chemical-processing industries (Ref 7, 8).

After a material has been selected for an application, the fabricator and purchaser then need to know if the quality of incoming material is as specified. Quality-control corrosion tests ensure that the material meets specifications. Such tests must be sufficiently rapid to avoid undue delay of material shipments. Corrosion tests of this type do not require any particular correlation to end use. Alone, they do not necessarily reveal whether or not this alloy will make a better product. They simply ensure that the quality of the material shipped has corrosion resistance that is similar to the material on which the development tests were made.

In fundamental corrosion research, which focuses on determining how or why a particular form or mechanism of corrosion occurs, specialized techniques are often required; these may be quite sophisticated. Standardized test methods are usually not applicable. In recent years, however, considerable progress has been made in standardizing certain practices and techniques. A good example of this is electrochemical testing.

Procurement of Test Materials

In some cases, such as quality-control tests, the material to be tested is predetermined. In most other cases, there is considerable freedom of choice.

Metal Composition and Metallurgical Condition. If commercial alloys are to be tested, the best procedure is to obtain mill-fabricated material representative of current production. If possible, a fabrication history should be obtained listing the major fabricating steps, together with an accurate analysis of the metal composition. At the very least, the material should be certified as being within the composition limits specified for the alloy and meeting the strength or hardness guaranteed for the material. Metallographic examination may also be necessary to ensure that the material is in a proper metallurgical condition. Such basic information may prevent misleading conclusions as a result of off-composition or improper metallurgical treatment.

When nonstandard alloys or metallurgical treatments are to be evaluated, it may be economically impractical to have them fabricated with large production equipment. In such cases, small laboratory casts or heats are made, sometimes weighing only a few pounds. Although this is a valid procedure for initial tests, a promising alloy candidate should be evaluated several times by using specimens from quantities of material large enough to be representative of production before it is produced commercially. Several production lots must be evaluated because promising results from a single lot of material are often not reproduced on subsequent fabrication runs.

Metal Form (Mill Product). Another preliminary decision is the form of metal to be tested. Metals are available in two basic forms: cast and wrought (worked). These two forms should not be interchanged in testing. The various methods of casting (die, permanent mold, sand mold, and so on) and of working (drawing, extruding, forging, rolling, and so on) will affect grain structure and homogeneity, which in turn can affect corrosion resistance. The metal procured should be, as nearly as possible, the type that will be used in the intended application.

In certain types of corrosion tests, such as tests of compatibility with chemical solutions or evaluation of protective coatings, considerations of grain structure may not be critical. When this is so, cast bar or rolled sheet is commonly used because these product forms are readily obtainable and are easy to fabricate into the desired test specimens.

However, if it is anticipated that the final use of a metal will be in a cast form, cast specimens should be evaluated. The same applies for wrought metal specimens. Data obtained from cast and wrought metal forms cannot be reliably interchanged. Similarly, when complex heat-treated alloys are being tested, one wrought form should not be substituted for another.

Preparation of Test Specimens

The sampling of test materials and the preparation of test specimens are extremely important variables in corrosion testing, because corrosion behavior can be significantly influenced by variations in metallurgical structure and the condition of the metal surface. These factors are especially pertinent when various forms of localized corrosion are under evaluation in complex alloys. The uniformity of the metal sample should be checked in advance as part of the plan for

preparation of the test specimens. Problems resulting from this cause are less likely to be encountered with pure metals and homogeneous alloys.

The primary consideration should be the use of test specimens that are truly representative of the specified material, that is, alloy, metallurgical condition, and product form, rather than specimens that are the most expedient for the investigation. For example, it might seem advantageous to obtain flat, uniform disk specimens by machining slices from an extruded rod rather than by shearing or stamping test coupons from rolled sheet (and avoiding residual stresses in the sheared edges). However, the corrosion behavior of the end-grain surfaces of the machined disks could be different from that of the rolled surface of the sheet product.

Surface preparation by various machining or polishing methods and various chemical treatments can be a source of considerable variation in test results and must be controlled. In some cases, it may be desired to evaluate the metal in the mill-finished condition, although this approach will generally result in the greatest variability. As a general rule, corrosion-testing standards contain specific recommendations regarding appropriate surface treatments, depending on the metal alloy system. Judicious use of proper or standardized surface treatments will reduce variability in corrosion test results, as discussed in Ref 9.

Selection of Corrosive Media

The corrosion behavior of a given material depends on the environment and the conditions of exposure as well as the condition of the test material. The most reliable predictor of performance is service experience, followed closely by field testing, because both are based on the actual environment. When service history is lacking and time or budget constraints prohibit field testing, laboratory corrosion tests are used to predict or estimate corrosion performance. They are particularly useful for quality control, materials selection, and materials development.

Laboratory tests can be misleading if appropriate corrosive media relating back to the test objectives are not used. Part of the testing philosophy involves whether the test is intended to reproduce a certain environment accurately or whether it is more advisable to use a corrodent that represents a worst-case situation. In either case, the corrosion investigator must do everything possible to make the test reproducible by exercising explicit control over such environmental factors as concentration of reactants and contaminants, solution pH, temperature, aeration, velocity, impingement and bacteriological effects. Standard test methods should provide for such controls.

Accelerating Test Results. Almost invariably, it is desirable to have results from corrosion tests as quickly as possible, which necessitates speeding up the reactions to obtain quicker results. This is a legitimate approach if conditions are not changed to the point at which some corrosion mechanisms other than that experienced in normal service becomes predominant. The important question is: How can conditions or reactions be accelerated, and how far can they be accelerated before a different reaction is introduced? (Ref 5). Consider, for example, a test of the corrosion rate of a piece of steel in water. It is known that raising the temperature of the water increases the corrosion rate significantly. The tendency might be to accelerate the test by raising the temperature almost to the boiling point, but by doing so, the oxygen in the water--also a contributing factor to the corrosion rate--is driven out. The corrosion rate then decreases instead of continuing to rise with temperature, thus inducing a corrosion mechanism different from the one of interest.

Correlation With Field Experience. The soundness of an accelerated test medium can be shown by correlation with practical service experience or with results of appropriate field tests. However, some methods used to correlate test environments are inadequate and should be avoided.

For example, Fig. 1 shows a hypothetical example of correlations of three accelerated stress-corrosion cracking (SCC) test media (A, B, and C) with a service environment. The resistance to SCC of a given susceptible material is plotted as a function of an independent variable that influences the stress-corrosion performance. The curve labeled service environment represents the established performance of the material when stressed at various levels and exposed to the service environment. Medium A correlates well for specimens under high stress, but not for specimens under low stress; medium C gives the opposite performance. Only accelerated test medium B correlates well at all ranges of applied stress. An investigator should not assume that a good 1:1 correlation at a single level of the independent variable (138 MPa, or 20 ksi) will be similar at a different level (690 MPa, or 100 ksi). Medium A might be useful as a worst case, but medium C appears to be too mild for any case.

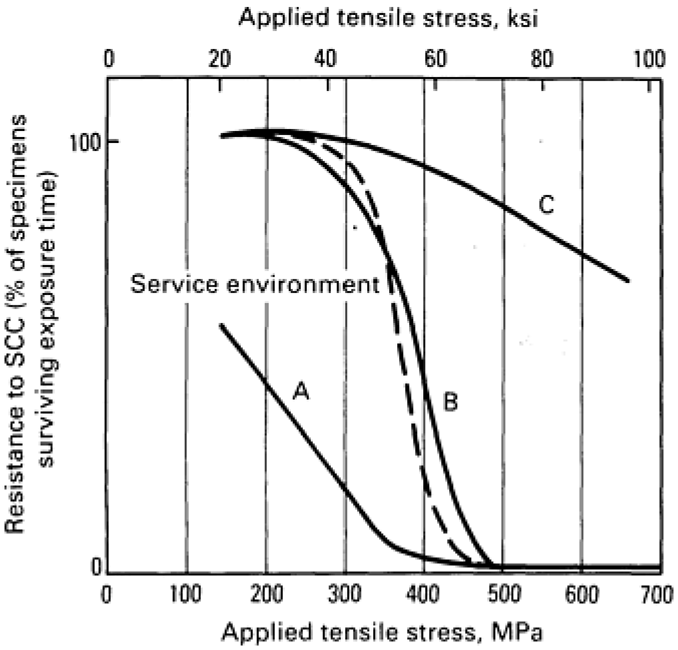

Fig. 1 Example illustrating the importance of correlating laboratory test data with field test data or service experience. A, B, and C represent laboratory SCC test media, but only medium B correlates well with the service environment. See text for explanation.

Assessment of Corrosion Damage

Measurement and evaluation of test results must be closely coordinated with the test objectives so that the measured results will make it possible to achieve the objectives with the greatest degree of directness and clarity. The methods of assessment are limited only by the ingenuity of the investigator, who must try to find the best way to convey the practical meaning of the test results.

Appropriate methods of measuring degradation of the metal also depend on the form of corrosion observed; these methods are discussed in separate articles on the evaluation of specific corrosion behavior in this Volume. For example, the age-old method of measuring corrosion by determining weight loss and calculating average corrosion rates, which is adequate for metals that corrode uniformly, is not a realistic measure of localized forms of corrosion, such as pitting and intergranular attack. Figure 2 illustrates the wide variation in results obtained by measuring the localized corrosion of aluminum alloys in three different ways.

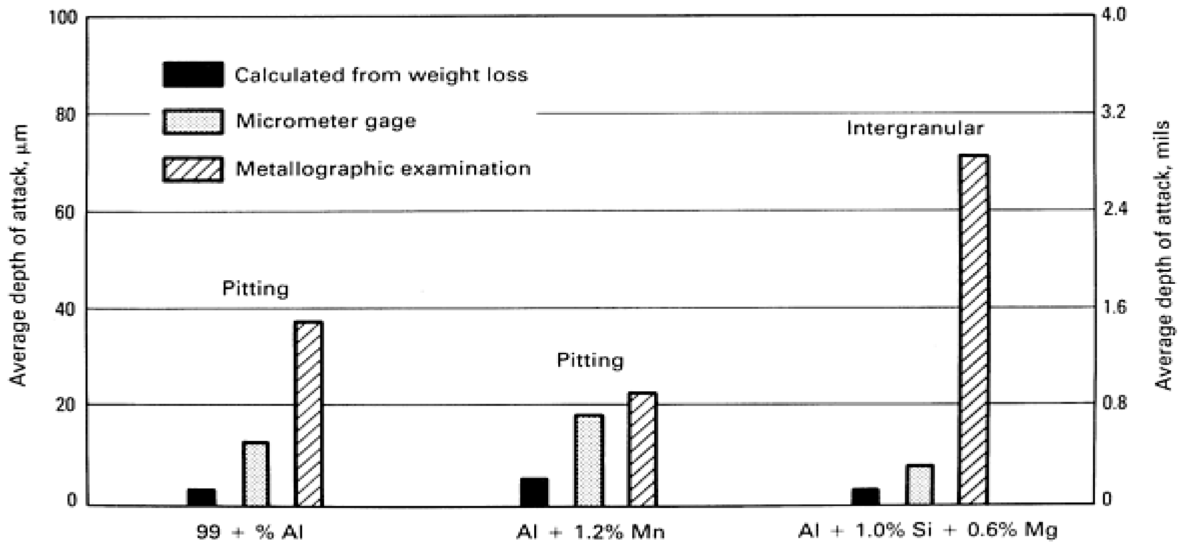

Fig. 2 Comparison of the wide variation in results obtained by different methods of measuring localized attack in aluminum alloys. The data shown are average results for each alloy exposed to seven atmospheric environments for a total of 10 years. Source: Ref 10

Controls. A vital consideration in the corrosion testing of metals is the use of suitable controls, both for the metal and for the test environment. This aspect of corrosion testing is a common source of error--even by experienced investigators (Ref 11).

With some materials, certain characteristics used for assessing corrosion damage will change with time, even in the absence of corrosion. In such cases, a set of control specimens must be provided for each period of corrosion testing. This set is then evaluated at the same time as the corroded specimens. Some alloys, for example, gradually change in strength over long periods of time at room temperature, and the strength of most metals is affected by time at elevated temperatures. Such a case is shown schematically in Fig. 3.

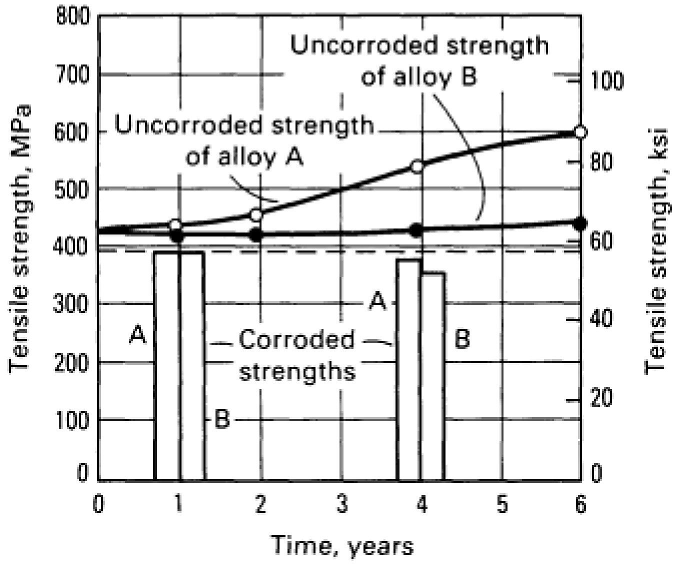

Fig. 3 Example showing the importance of using control specimens when determining strength reduction in alloys whose strength changes with time. Alloy A was appreciably strengthened by natural aging, but alloy B

was not.

The bar graphs in Fig. 3 show the corroded strengths of two alloys after 1 and 4 years of exposure to a corrosive atmosphere. After 1 year of exposure, both alloys show the same strength and a similar reduction from the strength of uncorroded metal. After 4 years of exposure, the corroded specimens of alloy A are somewhat stronger than those of alloy B, but their reduction from the strength of uncorroded metal of the same age is considerably greater. If the corroded strength of alloy A had been compared with the strength of specimens tested at the beginning of the investigation, an erroneous conclusion would have been made regarding the effect of corrosion on this alloy.

Specimens to be used for periodic controls should be protected from corrosion and stored at the same temperature at which the corrosion tests are conducted. In long-term field tests, in which temperature will fluctuate and cannot be controlled (such as tests in natural atmospheres), it may be desirable to store the controls on-site in dry, airtight containers. This ensures that both the corrosion specimens and the control specimens are exposed to the same time and temperature conditions. In tests at elevated temperatures, special precautions may be necessary to ensure that the control specimens themselves do not undergo high-temperature corrosion.

The other required control is a method of determining whether the corrosive medium maintains the intended degree of corrosivity. When an alloy is repeatedly tested by the same method, as in quality-control tests, the investigator may be sufficiently experienced to know whether the visual appearance and resultant data are of the order expected. This is often not the case with new alloys or products, because their corrosion performance is unpredictable. The usual procedure is to expose a well-established previously tested alloy as a control to determine whether the results on it are consistent with past experience. If they are, the new alloy is considered to have received a valid exposure. However, if the effects of corrosion on the well-known alloy are not typical, the investigator is alerted to the possibility of an error in test environment and the necessity for a rerun.

Reliability of Corrosion Test Results

Corrosion-testing methods (and the testers) are often criticized because usage of the test results has led to unfortunate decisions in the application of metals. Critics cite the difficulty in extracting from the results precise numbers that can be used in the design or prediction of service lives, questioning why corrosion tests cannot produce simple numerical results in a short period of time as mechanical tests do. They also assert that more reliable corrosion tests are needed; although this may be true, more careful and realistic interpretation of the test results is also necessary.

Corrosion rates should be used with caution. Corrosion engineers frequently take the results of relatively short-term one-period exposure tests, divide the weight loss (or pit depth) of the metal by the time of exposure, and from this determine a constant rate of corrosion for the particular metal-environment combination. Such early one-point average rates are valid only when the material corrodes linearly with time; however, this is the exception rather than the rule for metals in natural environments. The effect of film formation on the surface varies the corrosion rate with time in a large majority of cases. The creation of a film of corrosion product often shields the metal substrate from the corrosive environment, with a resulting decrease in corrosion rate. In this case, the projection of corrosion rates before a film has formed will be unduly pessimistic.

Figure 4 shows an example of such short-term evaluation errors for copper exposed by continuous immersion in tropical seawater. The actual corrosion rate (curve C) is a function of the square root of exposure time *t*. Decreasing-rate curves similar to that shown for copper in seawater have been observed for other metals in natural waters and in the atmosphere (Ref 10, 13). In other situations, such as low-carbon steels in aggressive marine atmospheres, the corrosion rate is nearly linear after formation of a protective film and, under some conditions, may even increase with time. To determine realistic corrosion rates, several replicate sets of specimens (at least three) should be exposed initially and tested after periods of increasing duration.

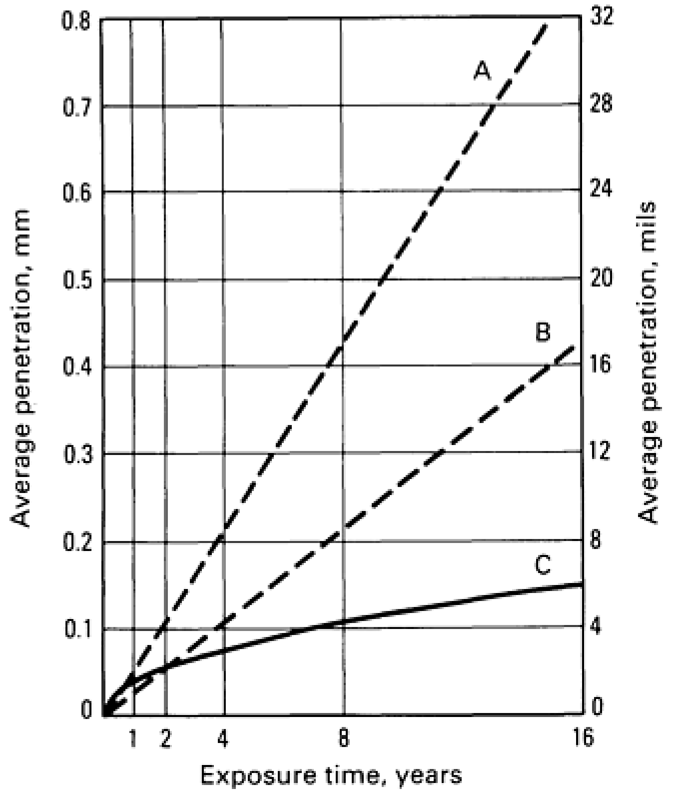

Fig. 4 Example of how short-term corrosion test results can be misleading. A, 6-month rate; B, 2-year rate; C, long-term corrosion of copper in seawater $\cong 1.5\ t^{0.5}$. Curves A and B were calculated from short-term test data; the long-term corrosion rate is more closely approximated by curve C, which is a function of the square root of exposure time *t*. Source: Ref 12

Specimen Replication. A certain amount of data scatter is inevitable in corrosion test results. The amount of scatter depends on the uniformity of the test material, the condition of the specimen surface, and the stability of the exposure conditions. All of these factors influence the precision of corrosion tests. Therefore, accurate testing procedures will provide some provision for double checking to reduce the likelihood of an incorrect conclusion based on a single nontypical result. This is usually accomplished by testing at least two replicate specimens. The number of replicates usually must be accomplished among:

- The accuracy and precision necessary (statistical evaluation)
- The know reproducibility of the test
- The scope of the test program
- The cost of a test

Precision and Bias. At best, the precision of corrosion test results leaves something to be desired because of the relative complexity of corrosion systems. This is particularly true when evaluating forms of localized corrosion, which can often be related to heterogeneous micro-structures in the test material. As progress is being made in the standardization of corrosion test methods, more attention is being directed toward providing potential users of the methods with information to help them assess in general terms its usefulness in proposed applications. The American Society for Testing and Materials (ASTM) recently made it mandatory that statements on the precision (reproducibility) and bias (systematic error) be included in every standard for a test method. If this information is not available to the corrosion investigator, he should include in his test program plans to obtain it. Assistance with this phase of corrosion testing is available in Ref 14.

The Unexpected. Because each corrosion experiment (excluding routine quality-control tests) probes the unknown, the experimenter must be alert for unexpected trends. During the test, frequent examinations should be made, and any unusual effects on the specimens or the test environment should be noted. Interim inspection will often permit corrections of problems with the specimens or the corrosive medium in the case of laboratory tests. A regular schedule of examinations is usually established at the beginning of the test, with the initial inspections being more frequent. Appropriate records of specimens condition and environment stability are often necessary to explain unexpected results.

In-Service Monitoring*

Sheldon W. Dean, Air Products and Chemicals, Inc.; Donald O. Sprowls, Consultant

---

Introduction

IN-SERVICE MONITORING of industrial manufacturing operations is the type of service corrosion testing that presents the greatest challenge and for which there is a great need. In such operations, the expense of corrosion problems can be huge and the risks devastating (Ref. 1). Corrosion monitoring has become an important aspect of the design and operation of modern industrial plants because it enables plant engineering and management personnel to be aware of the damage caused by corrosion and the rate of the deterioration. This article, therefore, will focus on methods of monitoring corrosion in industrial plants. The term monitoring, as used in this context, includes any technique for evaluating the progress or rate of corrosion.

Note

* *Portions of this article were adapted with permission from S.W. Dean, Overview of Corrosion Monitoring in Modern Industrial Plants, in *Corrosion Monitoring in Industrial Plants Using Non-Destructive Testing and Electrochemical Methods*, STP 908, G.C. Moran and P. Labine, Ed., American Society for Testing and Materials, 1986, p 197-220

Selecting a Corrosion-Monitoring Method

A large variety of techniques are available for corrosion monitoring in plant corrosion tests, and much has been written on the subject in recent years (Ref 2, 3, 4, 5, 6, 7, 8, 9, 10, and 11). The most widely used and simplest method of corrosion monitoring involves the exposure and evaluation of the corrosion in actual test coupons (specimens). The ASTM standard G 4 was designed to provide guidance for this type of testing (Ref 12). Additional detailed information on procedures from practical experience is given in Ref 10. Extensive overviews of the newer electrochemical methods of corrosion-monitoring in industrial plants are given in Ref 7 and 8. However, in view of the growing number of methods available, the selection of corrosion-monitoring methods may be somewhat arbitrary.

In the selection of a corrosion-monitoring method, a variety of factors should be considered. First, the purpose of the test should be understood by everyone concerned with the corrosion-monitoring program. The cost and applicability of the methods under consideration should be known, and it is important to consider the reliability of the method selected. In many cases, it will be desirable to include more than one method in order to provide more confidence in the information generated.

Another question of importance is whether there is access to the process streams and equipment in question. If access is available, methods that involve probes or coupons become more feasible. Otherwise, nondestructive methods may be required. An important factor in the selection of monitoring methods is the response time required to obtain the desired information from the method. Coupon methods and techniques that require plant shutdown tend to be relatively slow in generating information. On the other hand, equipment that measures instantaneous corrosion rates can provide fast results. A final consideration is one of safety. In an operating plant, equipment failure can lead to a leak, which can result in loss of product, a hazard potential, and possible shutdown of the plant. It is important for the monitoring apparatus to minimize the possibility of such an incident.

Direct Testing of Coupons

Although they are not intended to replace laboratory tests completely, plant tests are specifically designed to monitor the life of existing equipment, to evaluate alternative materials of construction, and to determine the effects of process conditions that cannot be reproduced in the laboratory.

Advantages of Coupon Testing (Ref 10). Plant coupon testing provides several specific advantages over laboratory coupon testing. A large number of materials can be exposed simultaneously and can be ranked in actual process streams against a common set of process parameters. Testing can be used to monitor the corrosivity of process streams. The coupons can be designed for specific forms of corrosion, and the exposure time is usually unlimited.

Large Number of Coupons. Because many coupons can be exposed simultaneously, they can be tested in duplicate or triplicate (to measure scatter), and they can be fabricated to simulate such conditions as welding, residual stresses, or crevices. These permutations are then ranked; this gives the engineer increased confidence in selecting materials for new equipment, maintenance, or repair.

Actual process streams will reveal the synergistic effects of combinations of chemicals or contaminants. In addition, the possibility is remote that the corrosion of specific coupons will contaminate the process and effect the corrosion resistance of other coupons. However, one potential source of error that must be checked is contamination of the process stream by the corrosion of the existing equipment.

For example, in a hypothetical case, the equipment is fabricated from a nickel-base alloy, and the process is a reducing acid. Contamination of the process by nickel ions may result in an apparent improvement in the corrosion resistance of

titanium test coupons. If the existing equipment is then replaced with titanium based on these false test results, it may corrode rapidly without the beneficial effect of the nickel ions.

Monitoring of Inhibitor Programs. Coupons are widely used to monitor inhibitor programs in, for example, water treatment or refinery overhead streams. With retractable coupon holders, the coupons can be extracted from the process without having to shut down in order to determine the corrosion rate.

Long Exposure Times. Some forms of localized corrosion--for example, crevice corrosion, pitting, and stress-corrosion cracking (SCC)--require time to initiate. To increase confidence in the test results, coupons can be exposed for as long as necessary; this will ensure that the initiation time has been exceeded.

Coupon design can be selected to test for specific forms of corrosion. Coupons can be designed to detect such phenomena as crevice corrosion, pitting, and dealloying corrosion. For example, some pulp mill bleach plant washer drums are electrochemically protected to mitigate crevice corrosion. Specifically designed crevice corrosion test coupons are used to monitor the effectiveness of the electrochemical protection program. These coupons are periodically removed from the equipment and examined for evidence of crevice corrosion.

Disadvantages of Coupon Testing (Ref 10). Coupon testing has four main limitations. First, coupon testing cannot be used to detect rapid changes in the corrosivity of a process. Second, localized corrosion cannot be guaranteed to initiate before the coupons are removed--even with extended test durations. Third, the calculated corrosion rate of the coupon cannot be translated directly into the corrosion rate of the equipment. Lastly, certain forms of corrosion cannot be detected with coupons.

Rapid Changes in Corrosivity. The calculated corrosion rate is an average over a specific period of time; therefore, field coupon testing cannot detect process upsets as they occur. For real-time monitoring, electrochemical methods, such as the polarization resistance technique, may be appropriate (see the section "Polarization Resistance Measurement" in this article).

Corrosion Rates of Coupons Versus Equipment. The corrosion rate of plant equipment seldom equals that calculated on a matching test coupon, because it is very difficult to duplicate the equipment with a coupon. Despite every effort to achieve equivalence, differences in mass and coupon area/solution volume ratio are usually sufficient to render direct comparison meaningless. Useful correlations can be established by monitoring the corrosion rate of the equipment with ultrasonic thickness monitoring and by comparing this corrosion rate with the calculated rate for equivalent coupons.

Corrosion Forms Not Detected. The principal limitation in this area is the simulation of erosion-corrosion and heat transfer effects. Careful placement of the coupons in the process equipment can slightly offset these weaknesses.

Erosion-corrosion is related to process turbulence, and process turbulence is often a function of equipment design. Because coupons tend to shield one another from the effects of process turbulence, field coupon testing is not reliable as a method of simulating erosion-corrosion.

For heat transfer effects, specially designed coupons are required that simulate effects such as those found in heating elements or condenser tubes. Coupons range in design from thermowell-shaped devices to sample tubes in a test heat exchanger. Thermowell-shaped devices are heated or cooled on the inside and project into the process stream (Ref 12). Heat transfer tests can also be conducted in the laboratory. In this environment, the coupon forms part of the wall of the test vessel and can therefore be heated or cooled from one side. Because of the cost involved, heat transfer coupon tests are usually carried out on only one (or perhaps two) alloys that have been selected from a larger group.

Coupon Options (Ref 10). The design of the coupon is an important part of any plant corrosion-testing program. Proper selection of the coupon shape, surface finish, metallurgical condition, and geometry allows evaluation of specific forms of corrosion.

Uniform Corrosion Coupons. The most common coupon shape for the evaluation of uniform corrosion is rectangular. Circular shapes are also used. Rectangular coupons are the most common because most alloys are available in plate or sheet form. Other shapes are used when there are restrictions on available product forms or when a specific material condition is required. Coupon identification must be legible and permanent. The simplest method of identification is stamping and is preferred unless the test material is likely to be susceptible to SCC.

Coupon finish represents a significant contribution to the overall cost. The least expensive finish that is consistent with the test requirements should be selected. For example, an inexpensive surface finish is acceptable where carbon steel coupons are routinely used to monitor additions of inhibitor in water treatment programs. This may be achieved by punching or shearing, followed by glass bead blasting. On the other hand, when it is necessary to rank alloys in a process environment, the coupons must be finished with ground or machined parallel edges and sanded faces.

A wide variety of coupon finishes are available, such as:

- Mill finish
- Glass bead blasted
- Sandblasted
- Steel shotblasted
- Abrasive cloth or paper sanded
- Machined
- Electrolytically polished

The surface finish of the coupon should match the finish of the equipment. This match is very difficult to achieve for several reasons. For example, there is the difference in surface finish between different mill product forms and even between different heats of the same metal or alloy. In addition, there can be wide variation among mill scale and surface deposits from processing operations. The principal requirement of testing is to assess the corrosion resistance of the test alloy in the condition that would be used in actual equipment.

Abrasive cloth or paper sanding is the most common practice. Sanding removes such surface deposits as mill scale and such defects as scratches or pits. A 120-grit finish, which is standard, can be easily produced without specialized equipment. Metallurgical changes that are heat induced, such as the sensitization of stainless steels or nickel-base alloys, can be prevented by keeping the coupon cool through wet sanding with progressively finer abrasives.

Clean polishing belts should be used; this will avoid contamination of the coupon surface. For example, a belt that has been used to polish a brass coupon should not be used to polish an aluminum coupon.

The corrosion resistance of some alloys can be enhanced by a special surface condition. One example of this is the oxide films that are formed on titanium or zirconium. In this case, conditioning of the coupons would take place after mechanical surface preparation. However, some films that form during mill processing or chemical exposure actually reduce corrosion resistance. Magnetite and certain forms of iron sulfide on carbon steel are examples of these types of films. The coupons must be specially treated in such cases.

Coupons that are cut by punching or shearing will have cold-worked edges. The effects of cold work can extend back from the cut edge a distance equal to the material thickness. These effects must be removed by grinding or machining. Cold working can affect the corrosion rate significantly, and it may cause SCC in some materials. An important parameter in the coupon specification is the degree of edge preparation.

Galvanic Corrosion Coupons. Pairs of test coupons are electrically coupled to study the effects of galvanic corrosion. The relative areas exposed usually vary from 1:1 to 10:1 or greater. The area ratios should be reversed for complete assessment, that is, 10:1 and 1:10, although this may not be necessary when a specific effect--for example, simulation of the galvanic corrosion of dissimilar-metal fasteners in column trays--is being studied.

With metals that can become embrittled by hydrogen absorption--for example, titanium, zirconium, tantalum, and hardenable steels--the cathodic (protected) member of the galvanic couple may be subject to the greater damage. However, the typical mass loss measurements would not reveal such damage.

Crevice Corrosion Coupons. Equipment crevices, such as weld backing rings, tube-tubesheet joints, or flanged connections, are common sites for localized corrosion in the process environment. Many metals perform differently in crevices as opposed to unshielded areas. Behavior is dependent on several factors. These include how strongly oxygen reduction (cathode depolarization) controls the cathode reaction or how the crevice alters the bulk process chemistry by lowering the pH or concentrating aggressive species.

The most imaginative form of coupon corrosion testing is the simulation of crevice corrosion (Ref 13). The various techniques that can be used for crevice corrosion testing include rubber bands, spot-welded lap joints, and wire wrapped around threaded bolts. Each crevice test creates a particular crevice geometry between specific materials and has a particular anode/cathode area ratio. Thus, no crevice corrosion test is universally applicable (see the article "Evaluation of Crevice Corrosion" in this Volume).

The two most widely used crevice geometries in field coupon testing employ insulating spacers to separate and electrically insulate the coupons. Spacers are usually either flat washers or multiple-crevice washers. Either type of spacer can be made of materials ranging from hard ceramics to soft thermoplastic resins (Ref 14).

Reference 15 describes an electrochemical monitoring probe for detecting crevice corrosion. An installation consists of two electrodes--one held in an occluded area, and the other freely exposed to the process stream. These two electrodes are connected to a zero-resistance ammeter. When the condition of the system becomes favorable for crevice corrosion, the electrode in the occluded area begins to corrode, and the boldly exposed electrode serves as a cathode. The current flowing between these two electrodes is a measure of the extent of crevice corrosion. This device has been shown to be effective in laboratory tests for indicating the onset of crevice corrosion and for indicating when conditions become unfavorable for crevice corrosion. Prototype cells have been evaluated by several companies as part of a round robin testing program sponsored by the Materials Technology Institute of the Chemical Process Industries (Ref 16).

Stress-Corrosion Coupons. Typical sources of sustained tensile stress that cause SCC of equipment in service are the residual stresses resulting from forming and welding operations and the assembly stresses associated with interference-fitted parts. Therefore, the most suitable coupons for plant tests are the self-stressed bending and residual stress specimens described in the article "Evaluation of Stress-Corrosion Cracking" in this Volume. Convenient coupons are the cup impression, U-bend, C-ring, tuning fork, and welded panel. The method of stressing for all of these coupons results in decreasing load as cracks form and begin to propagate. Therefore, complete fracture is seldom observed, and careful examination is required to detect cracking.

Welded Coupons. Because welding is a principal method of fabricating equipment, welded coupons should be included in the corrosion test program when applicable. Aside from the effects of residual stresses, the primary concern is the behavior of the weld bead and the heat-affected zone (HAZ). In some alloys, the HAZ becomes sensitized to severe intergranular (sometimes called knife-line) attack, and in certain other alloys, the HAZ is anodic to the parent metal. Laboratory potential measurements can be conducted on the weldment to determine whether electrochemical effects are involved. If either the weld bead or the HAZ is anodic to the parent metal, the welded coupons should be made as large as possible so that the cathode/anode ratio will approach that in actual equipment. The concern in this case is the same as that discussed previously for galvanic couples. When possible, it is more realistic to remove welded coupons from production-size weldments than to weld the small coupons.

Sensitized Metal. Sensitization is a metallurgical change that occurs when certain austenitic stainless steels, ferritic stainless steels, nickel-base alloys, and other alloys are heated under specific conditions. This results in the precipitation of carbides at grain boundaries, which reduces corrosion resistance. Any heat-inducing process (for example, stress relief of welding) may cause sensitization, which is time- and temperature-dependent. There is a specific temperature range over which each particular alloy will sensitize rapidly. Sensitization leads to intergranular corrosion in specific environments.

Welding is the most common cause of sensitization. However, welded coupons may not exhibit sensitization, because they may be given insufficient weld passes (compared with actual process equipment). As a result, they spend insufficient time in the sensitizing temperature range, and susceptibility to intergranular corrosion may not be detected.

An appropriate sensitizing heat treatment guarantees that any corrosion susceptibility induced by welding or heat treatment will be detected. The optimum temperature and time ranges for sensitization vary for different alloys. For example, 30 min at 650 °C (1200 °F) is usually sufficient to sensitize AISI type 316 stainless steel.

Some of the corrosion-resistant aluminum-magnesium (5000-series) alloys containing 3 to 6% Mg are also subject to sensitization when heated at temperatures in the range of 65 to 175 °C (150 to 350 °F). Reference 17 describes a test method for susceptibility to this phenomenon. The effective time and temperature conditions depend on the alloy content and metallurgical condition (Ref 18).

The advantage of using sensitized coupons is that, if corrosion occurs, they flag a potential problem. The user is thus obliged to consider how the equipment will be welded and heat treated and to determine whether high-temperature excursions will occur during operation.

Test Rack Design. It may be possible to expose corrosion coupons under stagnant or slowly flowing conditions by simply hanging them on an insulated wire or plastic cord, but this procedure is generally inadequate. Instead, specimen holders and test racks are usually used to support and insulate the coupons. These racks must hold coupons firmly in place to prevent mechanical damage and metal loss from causes other than corrosion. They must also electrically isolate the coupons from contact with each other and from the vessel itself to prevent unintentional electrochemical interactions. The basic types of racks will be discussed briefly below. They are described in detail in Ref 2, 5, 10, and 12.

Spool (Birdcage) Rack. A typical spool rack is useful in open vessels, such as reactors and tanks, for which access to the spool is readily achieved (Fig. 1). It has the advantage that a relatively large number of coupons can be accommodated.

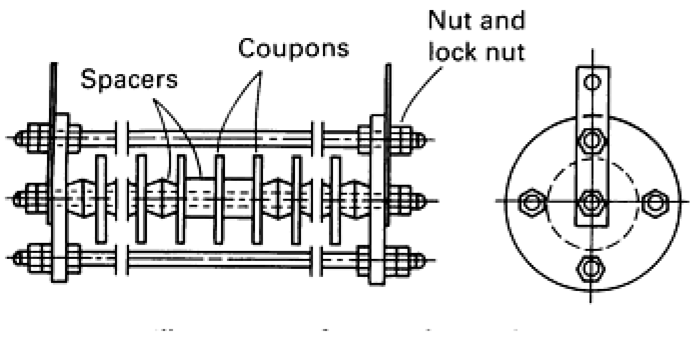

Fig. 1 Illustration of typical spool-type coupon rack. Source: Ref 12

The insert rack is convenient for use in pipes or other units that have flanged connections that alloy easy access to the system. for larger-diameter pipes or nozzles, a dutchman-type rack can be used. Such a rack consists of a suitable spool-type piece with the coupons mounted crosswise on a bar (Fig. 2). In both cases, the equipment must be shut down during installation and removal of the racks.

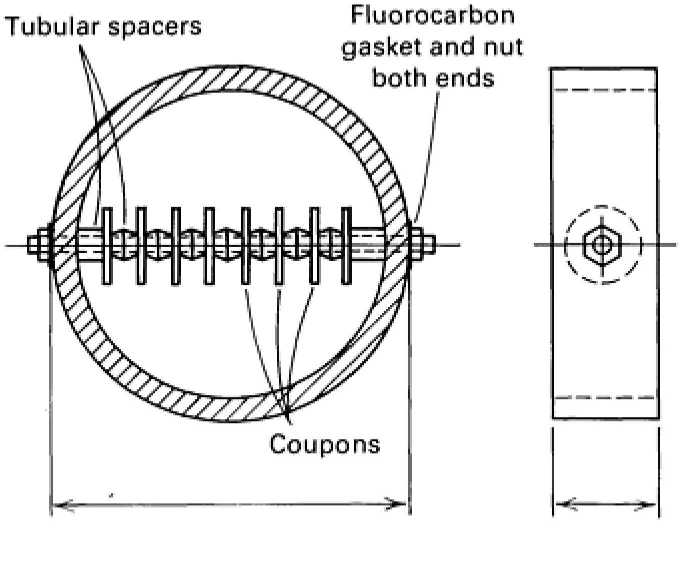

Fig. 2 Illustration of typical dutchman coupon rack. Source: Ref 12

A slip-in rack is designed to be inserted into and removed from equipment that is in operation. A retractable coupon holder makes this type of rack especially useful (Fig. 3). The slip-in rack requires a gate valve and a suitable-sized nozzle to serve as a retraction chamber. A rod-shaped coupon holder is contained in the retraction chamber, which is flanged to the gate valve. The other end of the retraction chamber contains a packing gland through which the coupon holder passes. Coupons are mounted on the rod in the extended position and are then drawn into the retraction chamber. The chamber is bolted to the gate valve, which is then opened to alloy the coupons to be slid into the process stream. The sequence is reversed to remove the test coupons.

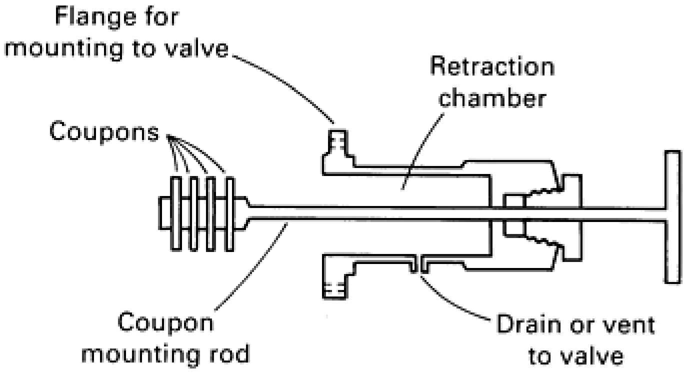

Fig. 3 Illustration of retractable coupon holder. Source: Ref 10

Coupon Cleaning and Evaluation. The test coupons should be cleaned as soon as possible after removal from the test. The procedures for cleaning and weighing, which depend on the test material and the extent of corrosion, are described in Ref 4, 10, and 19. These methods are overviewed in the article "Interpretation and Use of Corrosion Test Results" in this Volume.

Examination of the coupons after cleaning and weighing reveals the forms of corrosion that may be expected in equipment made of the coupon material. Because the coupons used for calculating corrosion rates are usually small, they should be examined very carefully for signs of localized corrosion effects that could invalidate the mass loss data. Coupons are examined with the unaided eye and then at increasing magnifications up to 30 to 50× with a binocular microscope. The scanning electron microscope is an extremely useful tool for detecting superficial localized effects.

In some cases, coupons must be bent and/or sectioned and metallographically examined to reveal certain types of corrosion damage. There are special localized corrosion effects that could not only jeopardize determination of realistic corrosion rates but also signal other serious types of behavior. These effects include edge attack, crevice corrosion, stress corrosion near stenciled identification numbers, pitting, selective corrosion (such as dealloying), knife-line attack, blistering, intergranular corrosion, embrittlement, and erosion-corrosion. In addition to the various corrosion effects, there may be inadvertent mechanical or galvanic corrosion damage. Techniques for evaluating specific forms of corrosion are described in various articles in this Section.

Electrical Resistance Probes

Electrical resistance probes (Fig. 4) are specially designed corrosion coupons. Their corrosion rate is calculated from measurement of electrical resistance rather than mass loss. These measurements are made by installing a wire or other device fabricated from the material in question in such a way that its electrical resistance can be conveniently measured. Corrosion reduces the cross section of the exposed element; therefore, its electrical resistance will increase with exposure time if corrosion is taking place. A temperature-compensating element should be incorporated in such a probe because the resistance of the probe is also influenced by the temperature.

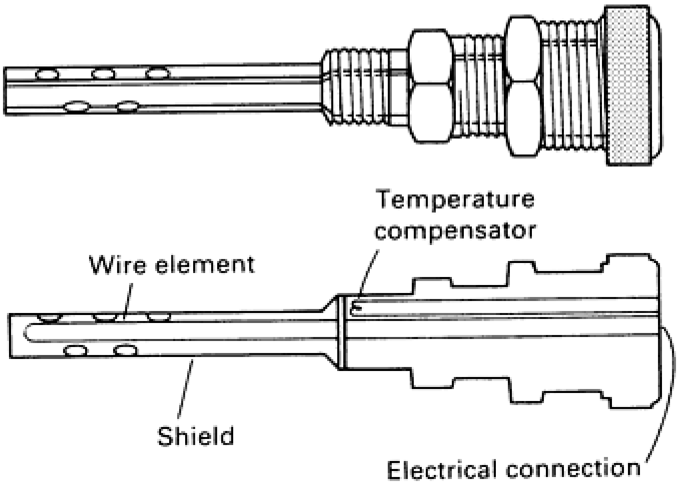

Fig. 4 Electrical resistance probe. Source: Ref 7

Electrical resistance probes measure the remaining average metal thickness. To obtain the corrosion rate, a series of measurements is made over a period of time, and the results are plotted as a function of exposure time. The corrosion rate can be determined from the slope of the resulting plot.

There are several advantages to this approach. Because probes are relatively small, they can be installed easily. To determine the metal remaining, the probe can be wired directly to a control room location or to a portable resistance bridge at the probe location. For systems that are wired directly to control rooms, a computer system can be used to obtain the data and to reduce the results to corrosion rate values. Commercial electrical resistance equipment is widely available. Use of electrical resistance probes does not depend on the environment; there are two reasons for this. First, only the remaining metal is measured, and second, the conductivity of the corrosive environment is usually inconsequential. This is not true in, for example, molten salts are liquid metals; the high conductivity of the environment in such systems precludes the use of electrical resistance probes. Thus, no problems exist in measuring corrosion that occurs in liquid or vapor streams. Electrical resistance probes are used in various applications, such as monitoring the corrosivity of cooling water systems (Ref 20).

However, there are some disadvantages to this approach. Vessel and piping walls must be penetrated in order to install the probes; such penetration results in the potential for leaks. It is expensive to direct wire the probe to a control room location, and such work must be carried out with care to avoid spurious signals and errors. On the other hand, it is time consuming and sometimes impossible to take measurements at the probe site with a portable bridge. The temperature compensation device reacts slowly, and it can be a source of error if the temperature varies when the measurement is taken. Corrosion rate measurements obtained in short periods of time can be inaccurate because the method measures only the remaining metal, not the rate of attack; this increases the signal-to-noise ratio in short exposures. This method provides no information on localized attack.

Ultrasonic Thickness Measurements

Ultrasonic thickness measurements can be used to monitor corrosion rates *in situ.* Ultrasonic thickness measurements involve placement of a transducer against the exterior of the vessel in question. The transducer produces an ultrasonic signal. This signal passes through the vessel wall, bounces off the interior surface, and returns to the transducer. The thickness is calculated by using the time that elapses between emission of the signal and its subsequent reception, along with the velocity of sound in the material. To obtain a corrosion rate, a series of measurements must be made over a time interval, and the metal loss per unit time must be determined.

One advantage of this method is that it is not necessary to penetrate the vessel to make the measurements. In addition, the results are obtained in terms of thickness. Small hand-held probes and reading devices are available for making these measurements and are relatively easy to use.

There are also several disadvantages. Ideally, a bare metal surface free of paint, thermal insulation, and corrosion products must be exposed. A coupling agent, such as grease, petroleum jelly, or oil, must be used so that the signal can pass from the probe into the metal and return. Problems may arise when vessel walls are at high or low temperatures. Serious problems may exist in equipment that has a metallurgically bonded internal lining, because it is not obvious from which surface the returning signal will originate.

Despite these drawbacks, the ultrasonic thickness approach is widely practiced where it is necessary to evaluate vessel life and suitability for further service. It must be kept in mind, however, that depending on the type of transducer used the ultrasonic thickness method can overestimate metal thickness when the remaining thickness is under approximately 1.3 mm (0.05 in.).

Polarization Resistance Measurement

Unlike the previously discussed methods, which provide information on remaining thickness, the technique of polarization resistance provides an estimate of the corrosion rate. This method is based on the Stearn-Geary equation (Ref 21). The theory behind the technique is that the corrosion rate of a probe is inversely proportional to its polarization resistance, that is, the slope of the potential-current response curve near the corrosion potential. It is necessary in a plant situation to use a probe that enters the vessel in the area where the corrosion rate is desired (Fig. 5). The electrodes of the probe are fabricated from the material in question. An electronic power supply polarizes the specimen about 10 mV from the corrosion potential. The resulting current is recorded as a measure of the corrosion rate. Polarization resistance yields an instantaneous estimate of corrosion rate.

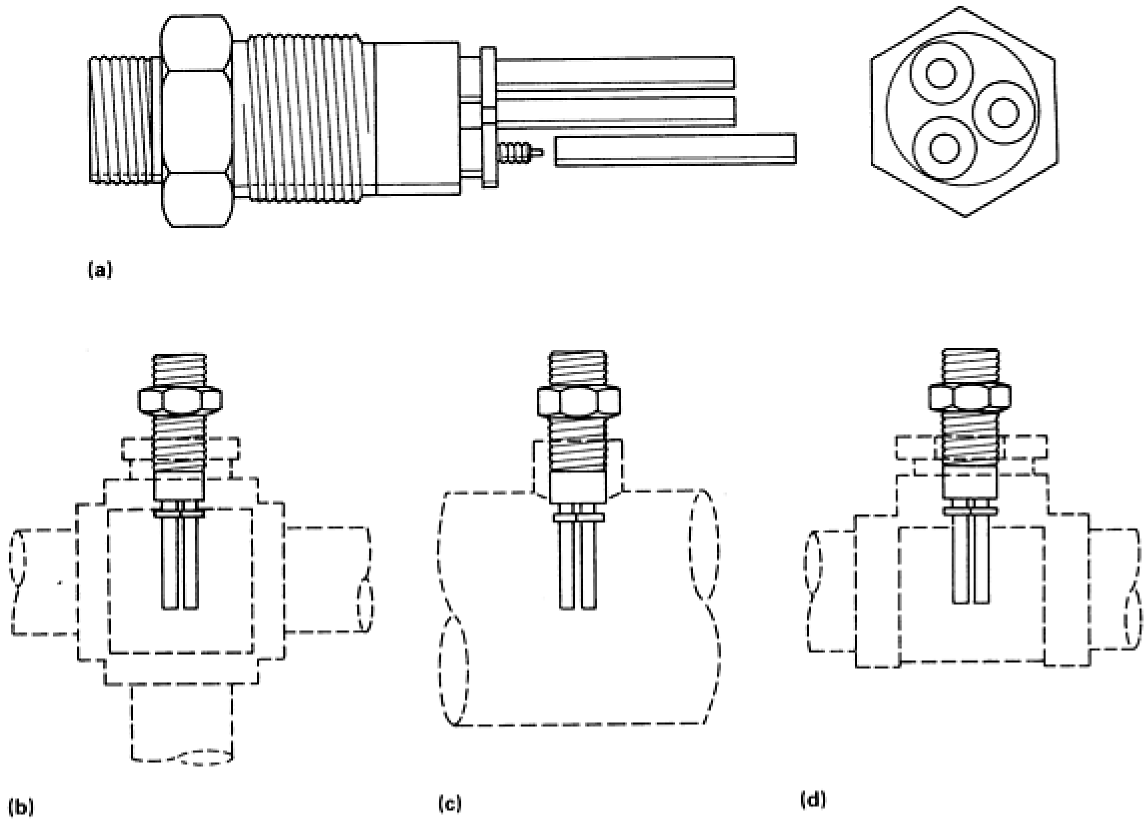

Fig. 5 Typical three-electrode polarization resistance probe (a) and installations of such probes. (b) Probe in a 38-mm (1 ½-in.) pipe fitting. (c) Probe in welded line. (d) Probe in 50-mm (2-in.) pipe tee. Source: Ref 7

Several commercially available probes and analyzing systems can be directly interfaced with remote computer data acquisition systems. Alarms can also be used to signal plant operators when high corrosion rates are experienced.

There are several limitations to this approach. The corroding environment must be an electrolyte with reasonably low resistivity. High-resistivity electrolytes produce erroneously low corrosion rates. The vessel wall must be penetrated, and this involves concerns regarding leaks, personnel safety, and other problems. The ability to use direct wiring from the probe location to a remote control room is desirable, but the installation of these wiring systems is costly. In addition, these systems do not provide information on localized corrosion, such as pitting and SCC. Also, the corrosion rate values are approximate at best, and the method is best suited for use during periods when substantial corrosion rate changes occur.

Measurement of Corrosion Potentials

The use of corrosion potential measurements for in-service corrosion monitoring is not as widespread as the use of polarization resistance. However, this approach can be valuable in some cases, particularly where an alloy could show both active and passive corrosion behavior in a given process stream. For example, stainless steels can provide excellent

service as long as they remain passive. However, if an upset occurs that would introduce either chlorides or reducing agents into the process stream, stainless alloys may become active and may exhibit excessive corrosion rates. Corrosion potential measurements would indicate the development of active corrosion, and they may be coupled with polarization resistance measurements as additional confirmation of high corrosion rates (Ref 8).

The success of corrosion potential measurements depends on the long-term stable performance of a standard reference electrode. Such electrodes have been developed for continuous pH monitoring of process streams, and their application for measuring corrosion potentials is straightforward. However, the conditions of temperature, pressure, electrolyte composition, pH, and other possible variables can limit the applications of these electrodes for corrosion-monitoring service.

Alternating Current Impedance Measurements

Alternating current (ac) impedance-polarizing techniques are being increasingly used in electrochemical evaluation. In principle, the same probe elements used for polarization resistance measurements can be used for ac impedance studies. As shown in Fig. 6, the ac impedance approach permits the separation and independent analysis of the resistive and capacitive elements of the electrochemical corrosion reaction (Ref 22). The method is particularly useful for high-resistivity electrolytes, such as steam condensate. In these cases, polarization resistance measurements provide readings that are erroneously low, because the bulk resistance of the electrochemical cell adds to the measured resistance. This problem is avoided with the ac approach.

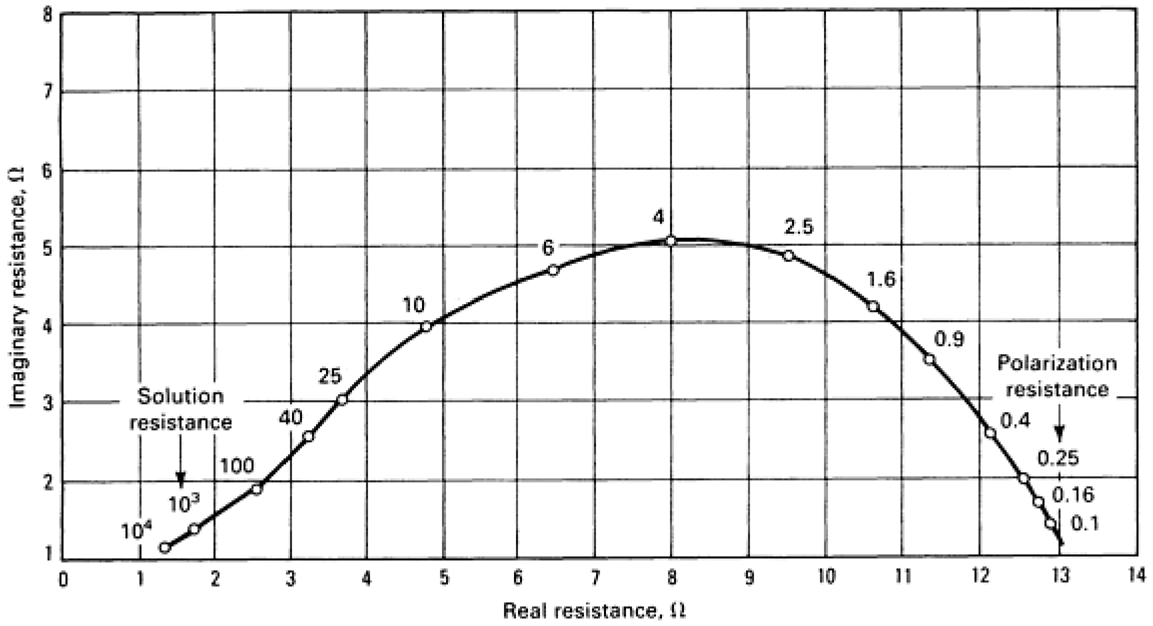

Fig. 6 Typical plot of ac impedance data in terms of real and imaginary resistance. The numbers on the curve indicate the frequency in hertz. Source: Ref 7

A sophisticated ac frequency generator and analyzer system is necessary to obtain results such as those shown in Fig. 6. Some investigators have suggested using only two frequencies to characterize ac impedance behavior (Ref 23). Although this will minimize the number of measurements, it does not reveal the details of the behavior. It is necessary to be familiar with the approach in order to interpret the results of ac impedance studies. The specimen designs used in commercial polarization resistance probes have not been optimized for ac analysis. For this reason, a full frequency response curve is desirable in order to verify that the behavior can be analyzed by conventional techniques, although it may take several hours to obtain a complete frequency response curve. Thus, more development is necessary before the ac impedance technique will achieve widespread acceptance for in-service corrosion monitoring. Another drawback is that the Stearn-Geary constant (Ref 21) or Tafel slopes must be known in order to convert ac impedance data into corrosion rate information.

Hydrogen Probe

The concept of the hydrogen probe is based on the fact that one of the cathodic reaction products in nonoxidizing acidic systems is hydrogen. The hydrogen atoms thus generated diffuse through the thickness of the vessel and are liberated at the exterior surface. A hydrogen probe--in one variation, the probe is a piece of palladium foil--is applied to the exterior surface. The probe serves as collector and catalyst for the subsequent oxidation of the hydrogen (Ref 24). The cell is attached to the palladium foil. The current employed in the oxidation reaction is supplied by a stainless steel working electrode (Fig. 7). The electrolyte is 90% sulfuric acid. The current that is required to oxidize the hydrogen is measured; it is directly proportional to the corrosion rate of the interior of the vessel.

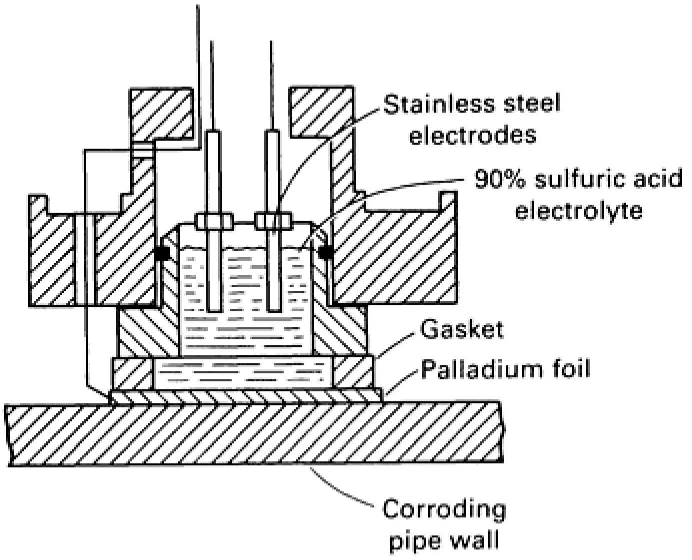

Fig. 7 Design of palladium foil hydrogen patch probe. Source: Ref 24

Hydrogen probe analysis measures the corrosion rate, unlike ultrasonic thickness measurements and other techniques, which measure remaining wall thickness. However, hydrogen probe analysis is limited to systems in which the temperature is close to ambient and the diffusion rate of hydrogen is high. Gas pipeline service is the most common application. In this case, corrosion can occur when hydrogen sulfide, water, and sometimes carbon dioxide (CO_2)are present. This approach has another variation that consists of simply attaching a chamber to the exterior of the pipe and monitoring hydrogen liberation through increasing pressure (Ref 2).

One advantage of exterior hydrogen monitoring is that it does not require penetration of the pipe wall in order to obtain the corrosion rate. It is assumed in this method that all of the hydrogen liberated in the corrosion reaction diffuses through the steel vessel wall instead of being liberated as hydrogen gas at the surface, and this is true when hydrogen recombination poisons such as hydrogen sulfide (H_2S) are present. Commercial devices are available for corrosion monitoring by this technique, although it is questionable whether such devices could be positioned and allowed to operate unattended for extended periods of time. In addition, these units have all of the problems associated with any electrochemical measuring device, namely the need for complex electronic equipment and wiring and the need for operators and installers with a sensitivity to the requirements of such equipment. Also, this method is in practice limited to steel, which has a high hydrogen diffusivity and low solubility of hydrogen.

Exterior hydrogen monitoring does not supply a quantitative measurement of hydrogen damage. However, it does provide a means of measuring the relative severity of corrosion damage and of evaluating the effects of process changes on the severity of corrosion.

Analysis of Process Streams

Another useful in-service corrosion monitoring technique is analysis of the process streams for the presence of corrosion products. This straight-forward approach usually does not require the installation of specialized equipment. For example, process streams from the bottom of the distillation column can be routinely sampled, and atomic absorption analysis techniques can be used to determine such heavy metals as iron, nickel, and chromium at very low levels. The concentration of such impurities is then directly proportional to the corrosion rate multiplied by the area of metal corroding if the only source of metal ions is corrosion and if the corrosion products are not precipitating. One problem is that the corroding area may not be known with certainty; therefore, the results are relative. However, they do help to determine whether conditions have improved.

Sentry Holes

In this monitoring technique, small sentry holes are drilled into the outside of a vessel or pipe at areas that are considered to be particularly susceptible to corrosion. The holes are drilled to the pressure design thickness. Thus, when corrosion has almost consumed the corrosion allowance, the appearance of a small leak indicates that action must be taken to prevent a major failure. Sentry holes may be threaded or may have nipples attached to facilitate plugging. Nondestructive testing is frequently performed in the area near the leak to determine the extent of the damage before repair or shutdown.

Side-Stream (Bypass) Loops

It is sometimes advantageous to operate a side-stream loop to determine the effect of chemical process changes without making these changes in the entire process system. This provides the advantage of an in-service corrosion test with product streams, yet permits evaluation of the effects of additives, inhibitors, and other changes in the environment without affecting the main process stream.

In the simplest case, a side stream from a major piece of equipment is run through a small tank or a widened section of the line in order to permit changes in the product stream and insertion of corrosion-monitoring devices. In such a case, the effluent from the side stream is usually discarded. In a more complicated installation, the entire cycle of the operation may be duplicated on a small scale using a portion of the mainstream. Obviously, a more sophisticated side-stream apparatus can approach the complexity and the expense of a pilot plant.

Strategies in Corrosion Monitoring

Monitoring Locations. A principal part of any corrosion-monitoring program is deciding where to locate the corrosion-monitoring devices. Because corrosion will probably not occur uniformly throughout the plant, it is desirable in any corrosion-monitoring program to find sites at which the highest corrosion rates will be experienced.

The problems involved in developing corrosion-monitoring programs for a plant are illustrated in the example of a distillation column. The most logical points for corrosion monitoring in a distillation column are the feed point, the overhead product receiver, and the reboiler or bottoms product line. These points are the locations at which the highest and lowest temperatures are encountered, as well as the points at which the most and least volatile products are concentrated. However, these points are usually not the locations of the most severe corrosion.

The species causing the corrosion will often concentrate at an intermediate point in the column because of chemical changes within the column. Therefore, if there is a possibility of concentrating a corrosive species within the distillation column, several monitoring points would be required throughout the column for the corrosion-monitoring program to be comprehensive (Fig. 8). A monitoring program can be restricted to the most corrosive location within the column once this area has been identified (Ref 25).

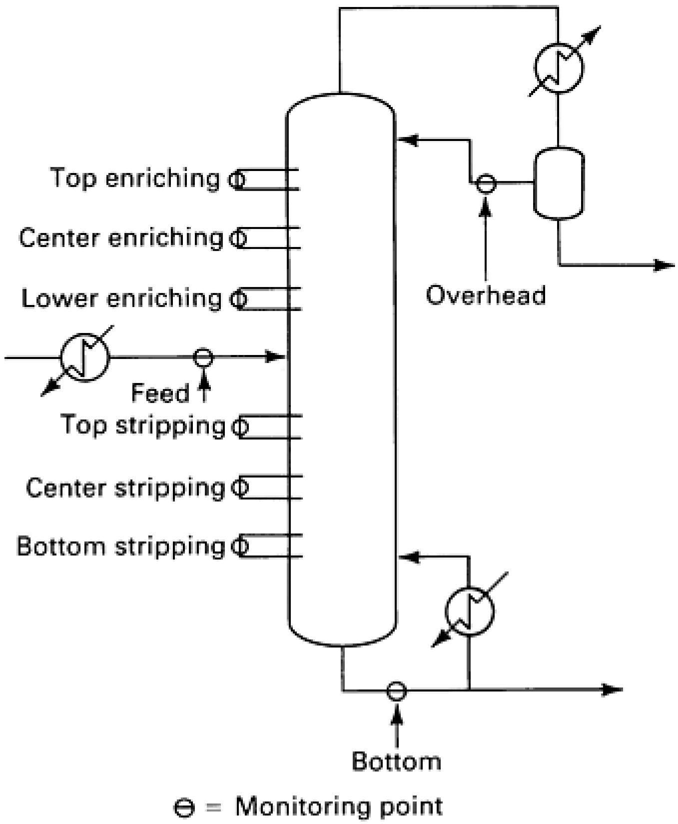

Fig. 8 Distillation column showing preferred locations of monitoring probes or other devices. Source: Ref 7

Another problem with distillation columns is that the liquid on trays tends to be frothy. This creates difficulties for electrochemical methods. One solution to this problem is to install bypass loops that remove liquid from the column, pass it over the corrosion-monitoring probes, and reinject it at a lower point in the column (Ref 2). This practice avoids the problem of foam and froth and provides a more controlled flow rate over the corrosion-monitoring equipment. Use of a bypass loop also allows removal of liquid samples at times of high corrosion rates (Fig. 9).

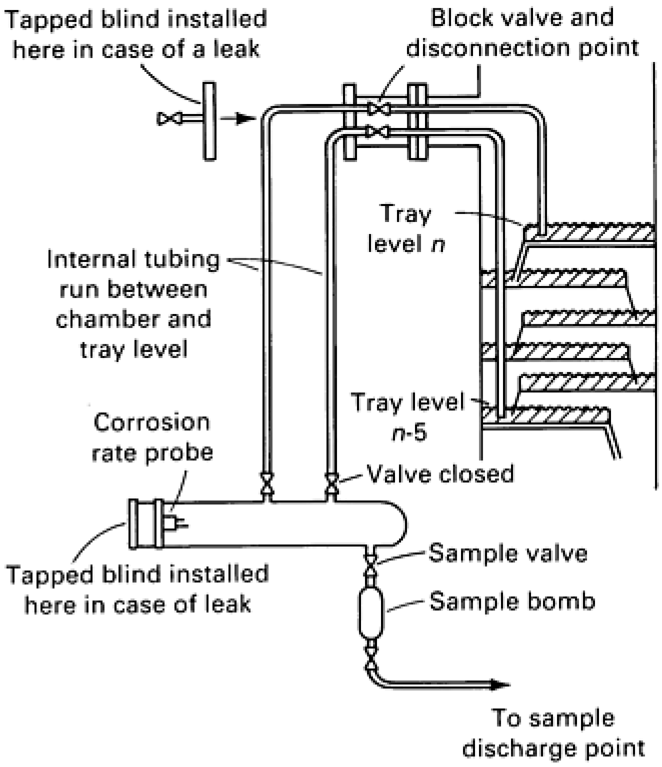

Fig. 9 Use of a side-stream (bypass) loop to monitor corrosion in a distillation column. Source: Ref 7

The process stream can be sampled in locations other than distillation columns. A sample tap can be helpful in conjunction with polarization resistance devices. The alarm on polarization resistance monitoring equipment can be used to signal the need to remove samples. This is particularly desirable in the case of pilot plant operation, in which wide variations in processing conditions are encountered. It is also helpful in plants that produce different products in the same equipment.

High-velocity gas streams in pipes may cause problems with conventional monitoring systems. In this case, the presence of an aqueous phase is usually restricted to a thin layer on the surface of the pipe. A probe that protrudes into the pipe may miss the liquid layer that is present only close to the pipe wall. A flush-mounted surface probe can be used in such cases. This probe permits the measurement of polarization resistance in order to estimate the corrosion rate of the pipe wall (Ref 26).

Probe location is also critical in storage tanks containing nonaqueous liquids. The most corrosive location in these tanks may be at the liquid level if the liquid in the tank has a density exceeding that of water. In this case, the corrosion-monitoring probe should be mounted on a floating platform. In this way, the probe can detect the presence of a corrosive aqueous phase. However, when the liquid stored in the tank is less dense than the water, the corrosion-monitoring device should probably be positioned at the bottom of the tank.

Ultrasonic Thickness Data Analysis. Ultrasonic thickness measurements are often obtained during turnaround periods when the plant is not operating. A well-designed program will provide a series of thickness measurements at specified locations throughout the plant. Assuming that the original thickness of a vessel was constant, a diagram similar to that shown in Fig. 10 can be drawn. Figure 10 shows the inverse relationship between the average corrosion rate and the remaining thickness. It is then possible to estimate the remaining life of the vessel from the maximum corrosion rate and the remaining corrosion allowance. In cases in which corrosion rate varies randomly, the highest corrosion rate and the smallest remaining thickness can be estimated by using statistical analysis. This approach provides a rational method of estimating remaining life when faced with a quantity of thickness readings from an ultrasonic thickness survey.

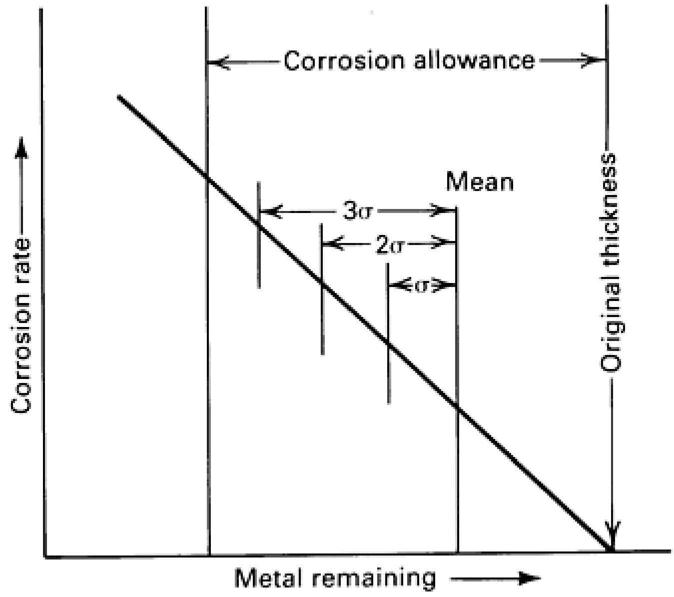

Fig. 10 Typical plot of metal thickness remaining versus calculated corrosion rate obtained from ultrasonic thickness data. Statistical analysis can be used to estimate the remaining corrosion allowance in terms of standard deviation σ. Source: Ref 7

Redundancy is also important in designing corrosion-monitoring programs. The use of at least two different types of corrosion-monitoring devices at any location is often desirable. For example, the use of an electrical resistance probe with a polarization resistance probe allows measurement of both instantaneous corrosion rates and an average corrosion rate. The data thus obtained can be correlated, and this is very helpful in identifying spurious or inaccurate readings.

In another approach, the polarization resistance probe is weighed before and after the test in order to correlate mass loss with the average corrosion rate that the probe suffered. There is reason to expect that the electrochemical value is in error if the average corrosion rate and the mass loss of the probe do not agree. Also, to obtain time average corrosion rate values, independent coupons can be installed together with polarization resistance probes.

A variety of corrosion-monitoring approaches must be used when designing pilot or demonstration plants. Coupon tests can be very helpful in selecting optimum materials for processes based on pilot plant experience. Polarization resistance monitoring is very useful for determining whether certain processing conditions cause corrosive situations to develop. Because the corrosion mechanisms are often not well understood and because the result of erroneous information can be serious overdesign or exposure to unexpected hazards, redundancy in the design of such monitoring systems is important in pilot plants.

Other Issues. A primary difficulty with corrosion-monitoring equipment is the need to install wires from the probes to the control room or to the instruments and data storage systems. Hard wire systems are usually more expensive than the probes and electronic instruments. In addition, wiring systems are often sources of problems due to breakage, moisture entry, and connection difficulties. One option is the use of devices to transform the data to coded CB radio signals. These small battery-operated units can be installed at probe locations, and they provide the desired information to the base station upon command. The base station would be located in the control room. Acceptance of this approach may increase as such systems become more available and more reliable.

The problem of leaks is another important issue in corrosion-monitoring systems. Leaks can cause hazards and can shut down operating plants. The corrosion-monitoring system must be installed such that leaks from the probe can be handled with minimal interruption. A device that penetrates the wall of the vessel may leak; therefore, it is essential to have contingency plans for dealing with leaks before the devices are installed.

A related problem concerns packing glands on pressure vessels that have removable devices. The pressure within a system exerts a force on any removable device. Therefore, it is important to prevent the device from being blown out,

which would injure personnel attempting to remove the device or would expose such personnel to the fluid within the vessel. For this reason, restraining rods, chains, and so on, must be used.

Interpretation and Reporting

In-service monitoring, more than any other type of corrosion testing, requires the utmost skill in interpretation and reporting. Important economic decisions are often based on the test results. Although there are a number of standards that provide guidelines for certain procedures, there is no standard that is comprehensive. To plan an appropriate test program, the investigator must know or have good advice on both the chemistry and the mechanics of the processes involved; that is, the investigator must understand the entire corrosion system. There must be a strong emphasis on the strategy of the program and a searching analysis of the test results. It is important to prepare detailed records of what was done as part of the experiment, and it is also important to document any unplanned changes that occur in the process stream or the equipment during the investigation. Without a valid interpretation and effective (timely) reporting, the price of the work can be significantly greater than the cost of time and materials. However, the consequences of corrosion failures go beyond additional costs. Also involved are personal safety risks (and liability), hazard potentials, and product quality and pollution problems.

Simulated Service Testing

Introduction

SIMULATED SERVICE TESTING is the most reliable predictor of corrosion behavior short of actual service experience. This includes exposures of either structural components or test specimens in outdoor environments that are representative of many general service situations. These so-called natural environments include exposures to the atmosphere, waters, and soil. Test materials are subjected to the cyclic effects of the weather, geographical influences, and bacteriological factors that cannot be realistically duplicated in the laboratory.

This type of testing is important for such objectives as materials selection, predicting the probable service life of a product or structure, evaluating new commercial alloys and processes, and calibrating laboratory corrosion tests. This type of information sought determines the selection of test specimens and the methods of assessing the corrosion effects.

Simulated Service Testing

The corrosion or degradation of materials in the atmosphere occurs naturally. The rate of degree of degradation varies for different materials and is influenced by several environmental factors. Many of these factors are natural in origin, but some result from man-made sources. Among the latter sources, which are known to affect atmospheric degradation of materials, are the SO_x and NO_x compounds produced as fossil fuel combustion by-products. These species can react in the

atmosphere and result in acid deposition. Although considerable public attention is focused on the effects of acid deposition on our ecosystem, the potential damage to materials may represent the largest economic impact of acid deposition.

Over the years, considerable attention has been devoted to the weathering of building materials. Observations of materials corrosion performance in the atmosphere have ranged from those made on existing structures to carefully designed experimental programs. These data represent an excellent base for understanding the behavior of given materials. However, much of the existing data suffer from two primary differences. First, many testing programs have been limited to a specific characterization of a material for a given application. This has resulted in variations in experimental methods such that the results of one testing program cannot be compared unambiguously to the results of others. Second, and most serious for present considerations, these programs have generally been conducted with an absence of comprehensive atmospheric monitoring. This has prevented the establishment of cause and effect relationships for some phenomena and has precluded the establishment of a baseline understanding of the atmospheric environmental characteristics for which a considerable materials degradation data base exists. To assess the impact of atmospheric variables on materials, it is necessary to monitor or have available relevant environmental parameters in association with controlled atmospheric exposures of materials of interest.

Types of Atmospheres

Before the materials or materials data can be evaluated, the atmospheric variables of the exposure site should be determined and periodically recorded during the test period. The variability of atmospheric-corrosion severity has been well documented (Ref 1, 2, 3). The severity of the environment is usually indicated by designating an environment as rural, urban, industrial, marine, or a combination of these. Table 1 lists the typical activity ranges of SO_x and Cl^- in these environments, which are discussed below.

Table 1 Typical activity ranges of SO_x and chlorides measured in various atmospheres

These are average activity ranges measured over a 20-25 month period.

	mg SO_x/dm^2/d	mg Cl^-/m^2/d
Industrial	0.5-2	nil
Urban	0.5-4	nil
Rural (semi)	nil-2	nil
Marine	nil-0.5	25-150

Source: Ref 4

A rural atmosphere is normally classified as one that does not contain chemical pollutants, but does contain organic and inorganic dusts. Its principal corrodent is moisture and, of course, oxygen and carbon dioxide. Arid or tropical atmospheres are special cases of the rural environment because of their extreme relative humidities and condensations (Ref 5). The rural atmosphere is generally the least corrosive.

An urban atmosphere is similar to the rural environment in that it is away from the industrial complexes. Materials exposed in these areas are subjected to the normal precipitation patterns and typical urban contaminants of SO_x and NO_x emitted by motor vehicles and home fuels.

An industrial atmosphere is typically identified with heavy industrial manufacturing facilities. These atmospheres can contain concentrations of sulfur dioxide, chlorides, phosphates, nitrates, or other specific industrial emissions. These emissions combine with precipitation or dew to form the liquid corrosive.

A marine atmosphere is laden with fine particles of sea salt carried by the winds and deposited on materials. The marine atmosphere is usually one of the more corrosive atmospheric environments. It has been shown that the amount of salt (chlorides) in the marine environment decreases with increasing distance from the ocean and is greatly influenced by wind direction and velocity (Ref 6). Marine atmospheres are discussed in detail in the article "Marine Corrosion" in this Volume.

Relative Corrosivity

Several programs have been conducted to assess the relative corrosivity at various locations over a finite period of time (Ref 4, 7, 8, 9). The use of calibration specimens to measure corrosivity can be traced to J.C. Hudson (Ref 8), who established the ranking of ten different environments based on the corrosion of wrought iron (Table 2). Table 3 summarizes additional site comparisons for the atmospheric-corrosion behavior of steel and zinc.

Table 2 Relative corrosivity of atmospheres at different locations

Location	Type of atmosphere	Average weight loss of iron specimens in 1 year, mg/cm^2	Relative corrosivity
Khartoum, Sudan	Dry island (arid)	0.08	1
Singapore	Tropical/marine	0.69	9
State College, PA	Rural	1.90	25
Panama Canal Zone	Tropical/marine	2.28	31
Kure Beach, NC (250-m, or 800-ft, lot)	Marine	2.93	38
Kearny, NJ	Industrial	3.92	52
Pittsburgh, PA	Industrial	4.88	65
Frodingham, UK	Industrial	7.50	100
Daytona Beach, FL	Marine	10.34	138
Kure Beach, NC (25-m, or 80-ft, lot)	Marine	35.68	475

Source: Ref 8

Table 3 Measured atmospheric-corrosion rates for steel and zinc

Site	**Location**	**Type of atmosphere**	Relative corrosivity	
			Steel	Zinc
1	Normal Wells, Northwest Territory	Rural	0.02	**0.2**
2	Saskatoon, Saskatchewan	Rural	0.2	**0.2**
9	State College, PA[(a)]	Rural	1.0	**1.0**
17	Pittsburgh, PA (roof)	Industrial	1.8	**1.5**
18	London (Battersea), UK	Industrial	2.0	**1.2**
27	Bayonne, NJ	Industrial	3.4	**3.1**
28	Kure Beach, NC (250-m, or 800-ft, site)	Marine	3.6	**1.9**
31	London (Stratford), UK	Industrial	6.5	**4.8**
33	Point Reyes, CA	Marine	9.5	**2.0**
37	**Kure Beach, NC (25-m, or 80-ft, site)**	**Marine**	**33.0**	**6.4**

Source: Ref 10

(a) The average weight losses on two 100- × 150-mm (4- × 6-in.) specimens after one year of exposure at the indicated site were used to calculate the relative corrosivity of the site. The losses in the rural atmosphere at State College, PA, were taken as unity and the relative corrosiveness at each of the other sites is given in this table as a fraction or a multiple of unity.

Atmospheric Factors

Methods have been developed for measuring many of the factors that affect atmospheric corrosion (Ref 4). The quantity and composition of atmospheric constituents and their variation with time have been determined. The factors that should be considered for measurement include, but are not limited to, those listed in Table 4.

Table 4 Environmental parameters suggested for consideration of their influence on the atmospheric degradation of materials

Wet Deposition
pH
Conductivity
Cations: calcium (Ca^{2+}), magnesium (Mg^{2+}), sodium (Na^{+}), potassium (K^{+}), ammonium (NH_4^+), and hydrogen (H^{+})
Anions: sulfates (SO_4^{2-}), nitrates (NO_3^-), and chlorides (Cl^-)
Dry Deposition
Sulfur dioxide (SO_2)
Nitrogen dioxide (NO_2), nitric acid (HNO_3)
Ammonia (NH_3)
Particulate matter, sulfates, nitrates
Meteorology
Wind speed
Wind direction
Relative humidity (dew point)
Temperature
Solar radiation
Rainfall volume and intensity
Others
Test specimen surface temperature

Time of wetness

Note: Time of wetness and the quantity of SO_2 and chloride are the most important variables in determining atmospheric corrosion. Such factors as hydrogen sulfide, nitrogen compounds, and other specific pollutants may be significant at specific sites if sources of these pollutants are located nearby.

Conducting Atmospheric-Corrosion Tests

The type of data or information required from the corrosion test often dictates the specifics of the test program. For example, the purpose of the program may be to evaluate the general corrosion behavior of the material or to determine its resistance to solar radiation, coatings discoloration, pitting, galvanic effects, loss of strength, or other changes in physical properties. The information one hopes to obtain from the exposure program must be determined in the planning stages of the work.

Materials To Be Exposed. Atmospheric-corrosion studies are usually carried out for a period of months and even years to ascertain the environmental effects on the degradation of the materials evaluated. Therefore, it is important to select standard or reference materials (control specimens or materials) that will be exposed alongside of the materials, alloys, or coating of interest. Control materials with a prior performance record in the exposure environment are extremely important for comparison purposes and for monitoring site corrosivity. For example, the International Organization for Standardization (ISO) has provided recommendations on low-carbon low-copper steel, commercial-purity aluminum, commercial-purity zinc, and commercial-purity copper as recommended control metals. The various reference materials selected by ISO for their exposure programs were chosen because they are representative engineering materials that are widely used and most frequently employed in external exposures. The materials were also selected, for comparison purposes, because they have known performance records in various environments and documented corrosion behaviors to different atmospheric constituents. Site corrosivity varies occasionally and underscores the need for simultaneous exposure of test and reference materials.

The number of duplicate or replicate specimens depends on the exposure period and the number of scheduled removals. For visual observations, two specimens for each environment are usually sufficient. Specimens that have been removed and cleaned should not be reexposed, because reexposure would in essence be starting the exposure period at time zero again.

Atmospheric Specimens. American Society for Testing and Materials (ASTM) and ISO guidelines for standard specimen designs for flat panels, stress corrosion, and other types of specimens such as the ISO wire helix specimen (Fig. 1) are outlined in Table 5. Guidelines from ASTM, the National Association of Corrosion Engineers (NACE), or ISO should be consulted for the proper cleaning procedures required before exposure and for cleaning and evaluation after exposure (these guidelines are summarized in Table 6).

Table 5 Recommendations for specimen design for atmospheric-corrosion testing

Type	Reference	Typical size[(a)]
Flat panel	ASTM G 50 (Ref 12)	Ferrous: 100 × 150 mm (4 × 6 in.)
		Nonferrous: 100 × 200 mm (4 × 8 in.)
Stress corrosion		
U-bend	ASTM G 30 (Ref 13)	3 mm × 15 mm × 130 mm × 32 mm diam (0.12 in. × 0.6 in. × 5 in. × 1.25 in. diam)
Bent beam	ASTM G 39 (Ref 14)	3 point: 1 mm × 5 mm × 65 mm span (0.04 in. × 0.2 in. × 2.5 in. span); 2 point: 25 mm wide × 180 mm span (1 in. wide × 7 in. span)
C-ring	ASTM G 38 (Ref 15)	12 mm wide × 25 mm diam (0.5 in. wide × 1 in. diam)
Direct tension	ASTM G 49 (Ref 16)	Specimen size depends primarily on the dimensions of the product to be tested.
Welded	ASTM G 58 (Ref 17)	The thickness and size of the test specimen should represent the actual structural member.
Galvanic		
Disk	B-3 (Ref 18)	36 mm diam × 1.6 mm (1.4 in. diam × 0.06 in.), 33.5 mm diam × 1.6 mm (1.3 in. diam × 0.06 in.), 30 mm diam × 1.6 mm (1.2 in. diam × 0.06 in.), 25 mm diam × 1.6 mm (1 in. diam × 0.06 in)
Plate	ISO/TC 156/WG3/N11 (Ref 19)	90 mm × 150 mm × 2 mm (3.5 in. × 6 in. × 0.08 in.), 70 mm × 25 mm × 2 mm (2.75 in. × 1 in. × 0.08 in.), 45 mm × 90 mm × 2 mm (1.8 in. × 3.5 in. × 0.08 in.), 25 mm × 70 mm × 2 mm (1 in. × 2.75 in. × 0.08 in.)
Open helix (metallic wire)	ISO/DP 9226 (Ref 20)	Wires with a diameter of 2-3 mm (0.08-0.12 in.) and 1000 mm (40 in.) long rolled into helix and attached to polyamide or metallic holder. See Fig. 1

Source: Ref 11

(a) The appropriate ASTM or ISO document should be consulted before selecting a specimen size.

(a) DP denotes draft proposed for an international standard currently in circulation within the responsible ISO committee.

(b) This procedure applicable only to SO_x-containing atmospheres

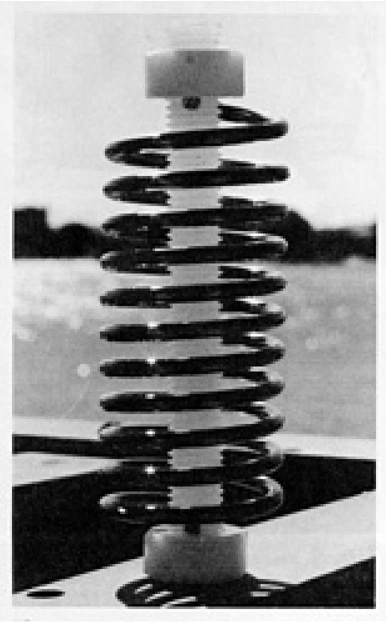

Fig. 1 ISO wire helix specimen

A suitable means of identification should be used. Stamped code numbers are suitable for the more corrosion-resistant materials, but will be lost on the more corrodible materials. For these materials, drilled holes or side notches according to a number template can be used. A plastic tag affixed through a drilled hole with a nonmetallic tie has also been successfully used. In all cases, the method of identification of the specimen should not bias the corrosion evaluation. It is also good practice to map the specimens on the exposure rack; that is, one should draw, sketch, or list according to exposure the identity of each specimen in case the codes or tags are corroded away or lost.

Exposure Guidelines. Specimens are normally exposed on a test rack similar to that shown in Fig. 2. The rack is then attached to a frame or stand (ASTM G 50 or ISO DP8565). Specimen sizes are normally 100 × 150 mm (4 × 6 in.), but can be any size necessary to evaluate the behavior of the material properly. For example, large panels (Fig. 3) and stress-corrosion cracking (SCC) U-bend specimens (Fig. 4) are used in the sizes and configurations required to determine the performance of the material in the environment of interest.

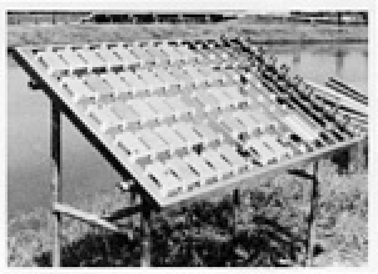

Fig. 2 Atmospheric-corrosion test rack

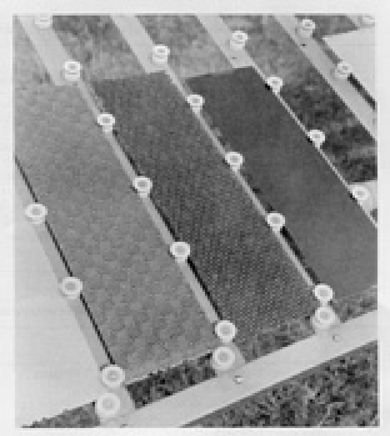

Fig. 3 Large atmospheric-corrosion test panels

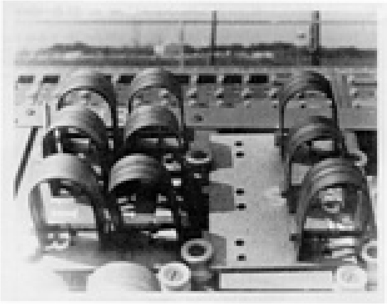

Fig. 4 U-bend specimens used for atmospheric-corrosion testing

For special situations, the exposure rack can be streamlined for small areas or for specialized exposures by using a corrosion spool rack similar to that shown in Fig. 5. In all cases, unless the objective of the exposure is to determine galvanic effects, the specimens should be isolated from each other and the exposure rack by some nonconductive material, such as the porcelain insulators visible in Fig. 2.

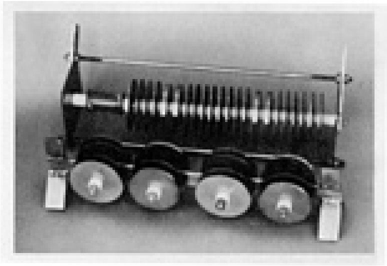

Fig. 5 Atmospheric-corrosion spool rack

The normal convention used for specimen orientation is as follows: Specimens exposed in the northern hemisphere normally face south, and specimens exposed in the southern hemisphere face north. Also, it is common practice to expose specimens facing the most corrosive direction if the exposure site is close to a source of corrodent, such as seawater or power plant stacks. The ASTM standard G 50 recommends that specimens be exposed on an angle of 30° to the horizontal (this angle has been established to be 45° in Europe). If maximum exposure to sunlight is desired, the specimens should be exposed at an angle equal to the latitude of the site.

Evaluation of Results. After exposure to the atmosphere, a number of techniques are available evaluating the test panels and interpreting test results (Table 7). The most important step in atmospheric-corrosion testing is the documentation of results and observations for future reference and application. This reporting can take the form of internal company reports, technical papers, or presentations. In all cases, the author should attempt to outline the objectives of the work, the exposure details, and the conclusions of the exposure program.

Table 7 Evaluation techniques for atmospheric-corrosion specimens

Technique	Value
Photographic documentation	Photographs of the specimens before and after cleaning give a permanent record of the performance of the material in the particular atmosphere.
Corrosion product analysis and surface deposits	Atmospheric-corrosion specimens usually have the corrosion product and airborne deposits on the surface at the time of removal. This adds a wealth of information on the observed behavior of the material.
Weight loss	For uniform corrosion, this is simple and can be converted to corrosion rate as $g/m^2/d$, mils per year, etc.
Pitting and localized corrosion	Yields information on the susceptibility of a material to localized attack. Pitting corrosion is often reported as average or maximum depth of attack and is usually measured with a dial depth gage or vernier microscope. Where possible, pitting data should be treated statistically with recognized methods covered in various standards. Weight loss data should not be used indiscriminately to calculate corrosion rates where the primary

	form of corrosion is localized.
Rust or rust stain	Data reveal the propensity of a material to rust and the degree of rust staining. Also, through cleaning procedures, it can be determined if the original appearance was retained.
Tensile test and other physical tests	Can often yield information on the atmospheric effect on the strength of materials, cracking behavior, etc.
Appearance	Effect of environment on appearance, color retention, etc.

Corrosion Testing in Water

Calvin H. Baloun, Chemical Engineering Department, Ohio University

As an environment in which corrosion occurs, water can be categorized as treated or natural. Regardless of the original intent for which a test has been developed, application can be extended to include any use. For example, ASTM G 78, which is described in the section "Methods of Analysis" in this article, is a guide for crevice corrosion testing of iron- and nickel-base alloys in seawater. The crevice assembly described could be installed on any alloy type in any environment if crevices are being studied. Only when quality control or acceptance stipulates a particular test method is there no room for departure. Some test methods involve the insertion of coupons or test panels into a conduit, with the environment at actual velocity and aeration. Other test methods involve the insertion of a test section into the flow line, especially if wall effects might be important. Still other tests require immersion of specimens in relatively open bodies of water.

Tests used as criteria for acceptance and/or quality control may require a very specific water chemistry and values of such factors as hardness, pH, aeration, temperature, alkalinity, and specific dissolved ion concentrations. It is usually valuable to monitor some of these factors in testing any water because compositions and contaminants change with time as sources (well, river, estuary, storm drains) and climatic conditions (wind direction, temperature, acid rain) vary. A variation in the mixture of sources might change test results significantly. When interpreting test results, it is important to be aware of the factors that can affect those results.

Unless galvanic action is being investigated (and it probably should be in most cases), specimens of differing alloy composition or thermomechanical treatment should be electrically isolated or insulated from each other and from the support framework. The factors that require consideration in water supplies are discussed in Ref 21, 22, 23, 24, and 25. Many standardized and nonstandardized tests, methods, and practices are discussed in Ref 26, 27, 28, 29, and 30.

Test Method Selection and Precautions

It is necessary to exercise sound judgment when selecting suitable testing procedures. For example, the results of static-immersion tests or alternate-immersion tests bear little relationship to pipelines flowing full within an operating plant. Test coupons inserted into an operating process line, or at least into a laboratory test loop using process fluids at operating temperatures and velocities, will produce results that agree much better with actual plant experience. Because corrosion is often accelerated at metal/liquid/vapor interfaces, these interfaces should be duplicated in the testing procedure if they are present in the plant or should be omitted from the testing if they are not an actual factor.

Test Specimens. Specimen geometry, ratio of environment solution volume to exposed specimen area, or other shape and area factors should be as similar as possible to true plant conditions. Exposed, cut specimen edges, which are often attacked more rapidly than other parts, should be examined and discounted if edges are not exposed in plant equipment. Similarly, stamped specimen identification characters may suffer increased rate of attack or may be sites of stress-assisted or accelerated corrosion.

Virtually every specimen size has been used in immersion testing. Popular laboratory test specimen sizes range from 1 cm^2 (0.15 $in.^2$) of exposed surface to 25 × 100 mm (1 × 4 in.), both of which are used frequently, to 100 × 150 mm (4 × 6 in.). In-plant and seawater tests sometimes involve specimens measuring 150 × 250 mm (6 × 10 in.) or larger. When weldments or projections are of concern, either the weldment or the projection should be incorporated into the specimen.

Entire components are seldom tested in the laboratory, but may be installed in pilot plant or works scale operations (pumps, condensers, heat exchangers).

Effect of Water Variables. To date, no compilation of relative rankings of alloy types in various aqueous environments is available. However, for iron-base alloys, the corrosion rate is relatively uniform in most waters, whether they are of high or low purity. The rate seems to vary more with aeration, that is, from less than 0.05 mm/yr (<2 mils/yr) in deaerated water to more than 1.25 mm/yr (>50 mils/yr) in aerated water. In tap, brackish, or seawater, pitting tends to occur. In tap water and seawater, yellow brass tends to dezincify (especially when conditions are near stagnation), although corrosion rates are less than 0.05 mm/yr (<2 mils/yr) and more than 0.5 mm/yr (>20 mils/yr) for tap water and seawater, respectively. Detailed information on dezincification can be found in the articles "Metallurgically Influenced Corrosion" (see the section "Dealloying Corrosion") and "Corrosion of Copper and Copper Alloys" in this Volume. Information on the effects of various types of water (salt, potable, brackish, etc.) on alloy corrosion can be found in the Section "Specific Alloy Systems" in this Volume.

There are no definite rules concerning the effect of flow rates, temperatures, and/or pH on the corrosion of alloys in water systems, although in waters free of passivators (including dissolved oxygen) increasing flow rates tend to erode any protective corrosion films that may have formed. Corrosion rates of most alloys over the pH range of 4 to 10 show little effect of pH. Outside this range, that is, 0 to 4 and 10 to 14, the environment cannot technically be considered water, except for some highly unusual acid rain cases. Increasing temperatures sometimes precipitate protective salts, such as calcium carbonate, which decrease corrosion rates in normal-to-hard waters.

Very pure or very soft waters are often excellent solvents for metallic ions, such as copper. If these waters are used to prepare laboratory solutions for test purposes, dissolved copper from copper water lines can deposit or plate out on more active metal surfaces. In the case of aluminum alloys, this deposited copper can greatly accelerate corrosion immediately adjacent to the copper. The effect of dissolved copper ion on localized corrosion of aluminum is cited in ASTM Standards G 4, section 4.5 (Ref 31); G 52, section 6.1 (Ref 32); and G 71, section 4.2.1 (Ref 33). See also the article "Corrosion of Aluminum and Aluminum Alloys" in this Volume. Similar effects of lesser intensity have been observed on most active metals.

Temperature differentials between points in a flow system can produce accelerated attack due to differences in ionic activity. Although this attack usually occurs at the point of higher temperature, protective scales occasionally precipitate on the high-temperature surface, with attack occurring at the cooler sites. In any system involving differential temperature, the investigator should be aware of this possible behavior.

Another temperature effect in open, aqueous systems is the decreasing solubility of gases, particularly oxygen, with increasing temperature. This effect reduces the cathodic action, or more exactly that portion due to oxygen reduction, and thus decreases the amount of anodic reaction that occurs.

Similarly, the solubility of air and oxygen in saline solutions decreases with increasing concentration of salt, but the solution conductivity increases with the dissolved salt concentration. The two effects combine in oxygen reduction cathodic systems to produce increasing corrosion rates up to about 3.5 wt% sodium chloride (NaCl) solutions and decreasing corrosion rates above that value. This particular effect is not observed in freshwater systems.

Natural waters, depending on the source, may contain variable concentrations of dissolved carbonates. These are principally calcium, magnesium, and/or sodium, with the solubility controlled by both the partial pressure of carbon dioxide and the solubility product of calcium carbonate as it varies with alkalinity and temperature. Deposition of a thin continuous film of carbonate can protect the underlying metal where a lack of the same would allow attack. On the other hand, a film that is too thick impedes heat transfer and can lead to reduced flow and ultimately to possible tube burn-out. Carbonate scaling, measurement through the Langelier Index, and controlling treatments are discussed in Ref 24 and 34.

Methods of Analysis

As stated previously in this section, a number of references describe methods of analysis for testing waters and materials in waters. The ASTM and NACE standards that are directly or indirectly applicable include the following:

ASTM Standards

- Standard Test Methods for pH of Water (D 1293). These methods cover the determination of pH by electrometric measurement, using the glass electrode as the sensor. Two procedures are discussed. Method A covers the precise laboratory measurement of pH in water with the use of at least two of seven standard reference buffer solutions for equipment standardization. Method B concerns the routine or continuous measurement of pH in the laboratory and the measurement of pH under various continuous process conditions
- Standard Practice for Oxidation-Reduction Potential of Water (D 1498). This practice covers the apparatus and procedure for the electrometric measurement of oxidation-reduction potential in water
- Standard Test Methods for Particulate and Dissolved Matter, Solids, or Residue in Water (D 1888). These methods cover the determination of particulate (suspended) and dissolved matter in water containing more than 25 ppm of total matter and 25 ppm or less of total matter, respectively. The measured constituents are those that can be removed by filtration or are the residue upon evaporation to dryness of filtered or unfiltered samples
- Standard Test Methods for Corrosivity of Water in the Absence of Heat Transfer (Weight Loss Methods) (D 2688). These methods cover the determination of the corrosivity of water by evaluating pitting and by measuring the weight loss of metallic specimens. Additional information on pitting corrosion can be found in the articles "Localized Corrosion" and "Evaluation of Pitting Corrosion" in this Volume
- Standard Test Methods for Corrosivity of Water in the Absence of Heat Transfer (Electrical Methods) (D 2776). These methods cover the electrical resistance method and the polarization method for determining the corrosivity of water. The electrical resistance method (Method A) measures the corrosion rate of a metal sample, mounted on a probe, by periodically determining its change in electrical resistance as the cross-sectional area of the metal sample decreases because of corrosion. The observed measurement is the change in resistance ratio between a measuring element exposed to water and a reference element in proximity to, but protected from, the corrosive environment. The polarization resistance method (Method B) operates on the principle that when a prescribed voltage (usually 5 to 30 mV in water) is impressed across the interface boundary between a metal electrode surface and a conductive liquid, the resulting current flow will be directly proportional to the corrosion occurring on the metal electrode surface, if the current measurement includes both anodic and cathodic polarization characteristics
- Standard Test Method for Efficacy of Microbiocides Used in Cooling Systems (E 645). This method covers the effect of bactericides and fungicides in controlling microbial growth in cooling water by using water collected from operational cooling water systems. Additional information can be found in the articles "Control of Environmental Variables in Water Recirculating Systems" and "Evaluation of Microbiological Corrosion" in this Volume
- Standard Practice for Conducting Surface Seawater Exposure Tests on Metals and Alloys (G 52). This practice covers conditions for exposure of metals and alloys to surface seawater and presents the general procedures that should be followed in conducting seawater exposure tests so that meaningful comparisons can be made for different locations. Detailed information on seawater environments can be found in the article "Marine Corrosion" in this Volume
- Standard Guide for Crevice Corrosion Testing of Iron-Base and Nickel-Base Stainless Alloys in Seawater and Other Chloride Containing Aqueous Environments (G 78). This guide provides information for conducting crevice corrosion tests and identifies factors that may affect results and influence conclusions. These procedures can be used to identify the conditions that will most likely result in crevice corrosion and to provide a basis for assessing the relative resistance of various alloys to crevice corrosion under certain specified conditions. Additional information on crevice corrosion can be found in the articles "Localized Corrosion" and "Evaluation of Crevice Corrosion" in this Volume

NACE Standards

- Laboratory Methods for the Evaluation of Protective Coatings Used as Lining Materials in Immersion Service (TM-01-74). This standard gives guidelines to assist manufacturers and users of protective

coatings in selecting materials by providing standard test methods for evaluating protective coatings used as linings for immersion service. Two test methods are discussed for the evaluation of protective coatings on any substrate, such as steel, copper, or aluminum, so that both the factors of chemical resistance and permeability can be considered

- Method of Conducting Controlled Velocity Laboratory Corrosion Tests (TM-02-70). This method covers laboratory corrosion tests that may be reproducibly conducted under velocity conditions. The method described is applicable only to the study of the effects of solution velocity on corrosion rate of a metal and is not to be used to determine the effect of a solution impinging on a metal surface
- Dynamic Corrosion Testing of Metals in High-Temperature Water (TM-02-74). This standard provides guidelines for corrosion testing of metals exposed to the high-temperature water used in high-pressure steam plants or water-cooled nuclear reactor plant systems. Standardized test methods for determining the effects of high-temperature water are also covered
- Preparation and Installation of Corrosion Coupons and Interpretation of Test Data in Oil Production Practice (RP-07-75). The use of uniform industry-proven methods to monitor corrosion in oil production systems are emphasized in this standard. Procedures for preparing, analyzing, and installing corrosion coupons are also outline

Corrosion Testing in Soil

E. Escalante, Corrosion Group, National Bureau of Standards

An approach to evaluating the durability of a metal in soil will be described in this section. Specimen design, preparation, burial, and retrieval techniques will be discussed. The type of information sought during soil-induced corrosion evaluation controls the design configuration and the nature of the corrosion measurements. Consideration of these factors during the planning stage will help the corrosion engineer obtain a maximum amount of information with a minimum number of future problems in the program.

The corrosion of metals underground can be divided into two broad categories: corrosion in undisturbed soils and corrosion in disturbed soils. Corrosion in undisturbed soil is always low, regardless of soil conditions, and is limited only by the availability of the oxygen necessary for the cathodic reaction. Steel piles driven into soil fall under this category and therefore undergo limited corrosive attack.

Corrosion of metals in disturbed soils is strongly affected by soil conditions. Soil resistivity, pH, and soil composition play important roles in determining whether corrosion is a serious problem. Any metal buried by backfilling is in a disturbed soil and is subject to corrosion attack, depending on the characteristics of the soil. Most metals in soil are exposed to disturbed-soil conditions. Because it is the more common of the two, the disturbed-soil condition will be discussed in this section.

Soil Characteristics

Soil is a complex, dynamic environment that changes continuously, both chemically and physically, with the seasons of the year. Precipitation, plant growth, and animal life all have their effects on the environment, but perhaps a greater effect results from buildings, roads, electric power lines, landfills, farming, snow removal with salts, and so on. Characterizing a soil for its corrosivity is difficult at best. However, certain empirically derived facts are known to affect the corrosivity of soils.

Soil resistivity is recognized as an important parameter in underground corrosion (Ref 35). The ions must migrate through the electrolyte in a soil to supply the metal surface with the electron donors or acceptors necessary for the corrosion reaction to proceed. The concentration of these salts in the electrolyte is important; soil resistivity is a measure of the concentration of the ions and how easily they move through the soil environment (Ref 36). A high soil resistivity suggests a low corrosion rate because of the low rate of ion diffusion.

The composition of these salts is also critical. Chlorides, for example, are known to enhance the breakdown of the protective oxide on some metals (Ref 37). Copper ions accelerate the attack on aluminum (Ref 34). Sulfates can provide oxidizers for bacterial corrosion (Ref 38). Other salts, such as carbonates, can affect the pH of the soil. Thus, the

corrosivity of a soil can be strongly affected by the presence of certain chemical species, and a soil that is corrosive for one metal may not be corrosive for some other metal.

The acidity or the alkalinity of most soils is stable because of the buffering action of the soluble minerals available. However, soils across the country can differ in pH from 5 to 10. This pH range has a small effect on general and pitting corrosive attack, but has a large effect on the susceptibility to hydrogen embrittlement of ferrous alloys (Ref 39). Furthermore, some metals, such as zinc, copper and aluminum, are amphoteric and can undergo corrosive attack at high and low pH values; these metals may be susceptible to attack in acid and alkaline soils (Ref 34). These effects on the corrosion process make it desirable to measure the soil pH of a test site (Ref 40).

The ways in which soil resistivity, pH and soil composition interact to determine soil corrosivity is not well understood despite extensive amounts of data that have been collected over the years (Ref 35, 41, 42). Soil temperature has been found to have a strong effect on soil resistivity and an effect on oxygen solubility. Because these are opposing reactions competing to control the corrosion process, their cumulative effect on corrosion is minimized (Ref 39). Clearly, many factors affect soil corrosivity, and their interrelationship is complex.

Test Approach

Although soil characteristics can give some indication of the corrosivity of a soil environment, the optimum test is to bury some specimens of the metals in question in the soil of interest. The concept is simple, but there are some considerations that should be thought out. The type of data sought determines the design of the specimen. For example, provision must be made for electrochemical corrosion measurements to be carried out during the burial period. Periodic retrieval of specimens of an alloy requires that identical sets be buried, one set per retrieval. It is necessary to mark the specimens for future identification and to mark the location of the specimens at the site. The importance of maintaining permanent, clear, detailed records cannot be overemphasized. The longer the period of burial, the more important these records become.

Specimen Preparation

The design of the specimen is usually determined by the type of data needed. If the corrosion of a pipe is under consideration, then pipe material should be used. To avoid internal corrosion effects, the ends can be sealed by capping. Corrosion of a tank container suggests the use of sheet or plate material for testing. If welds are expected then welded material should be included. If dissimilar metals will be in contact, then galvanically coupled materials are required. Stressed U-bend or C-ring specimens, for example, are necessary for stress-corrosion or hydrogen embrittlement studies. Control specimens should also be included. These control specimens could be uncoated when the effect of coatings is being evaluated. Similarly, unstressed specimens should be included when stressed specimens are being studied.

Before cleaning and weighing, the specimen is marked for proper identification by stamping or notching the specimen. In addition to this identification on the specimen, plastic tags are attached to the specimen in case corrosion is sufficiently severe to destroy the identification markings. Because these tags are often lost during retrieval or transportation, they should not be a primary marking system. Where retrievals are planned on a periodic basis, duplicate specimens must be provided, and each must have its own unique identification mark.

Electrical contact to a specimen is required when electrochemical measurements are to be made during the burial period. This contact can be achieved with a 14-gage (~1.9-mm, or 0.075-in. thick) insulated conductor that extends above ground and is soldered or bolted to the specimen. Solder can be removed after retrieval and before reweighing by heating the joint and wiping away the solder, but this is possible only with high melting point metal specimens, such as ferrous alloys. To avoid galvanic attack of the specimen or the conductor, the joint should be coated. Similar electrical conductors to both electrodes of a galvanic couple allow galvanic currents to be measured.

Specimen Burial

A frequently used technique for burial is to dig a trench that is long enough to allow placement of the specimens about 300 mm (12 in.) apart along its length. If specimens are to be retrieved periodically, for example, 1, 2, or 4 years, then all specimens of a given retrieval increment should be grouped together. That is, all specimens to be recovered at the end of 1 year are grouped separately from those that are to be retrieved at the end of 2 years, and so on.

To facilitate retrieval of the specimens, it is useful to tie a small-diameter (3-mm, or 0.12-in.) nylon rope to every specimen in a retrieval group. Thus, when one specimen is found, digging can proceed by following the rope until all of the specimens are recovered. Wood posts can be used to mark the location of the ends of a group of specimens, and the rope can be tied to these posts. If the trench is in a straight line, it is a simple matter to dig up a post, find the rope, and dig between the posts. Where posts cannot be used, metal stakes positioned slightly below the surface of the ground can mark the location of the specimens. These metal markers can then be located with a metal detector. It is useful to have a clearly visible surface marker that identifies the site and an individual or company that can be contacted for information; this may also avoid future problems.

In every case, an accurate map of the area identifying the exact location of all specimens is mandatory. Although describing the details of burial and recovery may seem mundane, important data can be lost simply because a few precautions have not been taken.

Conductors attached to the specimens must be carefully and permanently marked for identification at the surface end of the conductor. These conductors can then be attached to contact points on the wood posts.

Corrosion Measurements

In general, engineers are interested in obtaining data on the corrosion rate of a metal in soil, and this requires knowledge about weight loss and length of exposure. Rate of pit growth, however, may be more important when a material is used as a container or a pipeline. For some stressed metals and alloys, SCC or hydrogen embrittlement may more likely be the mode of failure. Some or all of these factors may have to be considered in carrying out the exposure study.

Uniform Corrosion. Gravimetric mass loss is the reference by which all other weight loss measurements are judged when evaluating the general corrosive attack of a metal in soil. Gravimetric mass loss determinations involve weighing the specimen before the exposure period and then reweighing it after retrieval. When properly carried out, the loss in mass represents the material lost because of corrosion. This technique, however, generally requires long exposures (for example, months) so that the mass losses are measurable and significant. Specimens of 1000 g or less should be weighed to an accuracy of 0.5 mg. Sample size may be limited by the capacity of the balance available. An excellent source of information on preparing, cleaning, and evaluating specimens is ASTM G 1 (Ref 43).

If data are obtained only through periodic retrievals nothing can be learned about corrosion losses between retrieval times. One method of obtaining corrosion rate data in the intervening months is to use electrical measurements that take advantage of the electrochemical nature of underground corrosion.

In the polarization resistance technique, the potential of a metallic specimen is changed by 10 mV or less, and the amount of current applied to make this change is measured (Ref 44). Three electrodes are usually used: the working electrode (the metal of interest), the reference electrode (used to measure the potential of the working electrode), and the counter electrode (used to apply current to the working electrode). Figure 6 illustrates the configuration of the three electrodes in a typical measurement in soil. The effects of i_R, a measurement error that arises when measuring a potential in the presence of current flowing through a resistive medium, must be eliminated (Ref 45). Details of this polarization technique are described in the section "Electrochemical Methods of Corrosion Testing" of the article "Laboratory Testing" in this Volume.

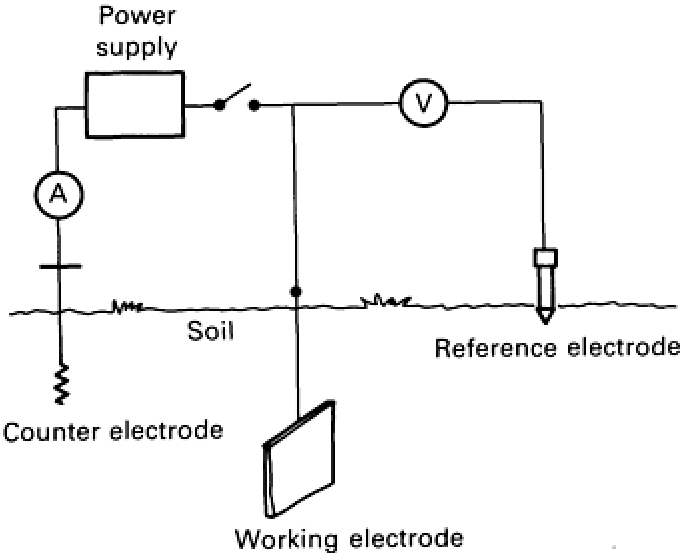

Fig. 6 Configuration of electrodes used in a polarization measurement of metals in soil

Pitting corrosion, unlike uniform corrosion, cannot be evaluated by *in situ* electrical measurements. Therefore, the only option available is to measure the pit depth after retrieval of the specimens, as described in ASTM G 46 (Ref 46). Large, shallow pits can be easily measured with pit micrometers. A narrow, deep pit is more difficult to measure because a pit micrometer cannot be used. One approach is to insert a small-diameter wire of known length into the pit and measure the length of wire extending out of the pit. Although not very satisfactory, this method will reveal the minimum depth of a pit. A more accurate but time-consuming method is to cross section the specimen and use an optical means to measure the pit. A micrometer stage on a low-power microscope is useful for this type of measurement.

Whichever method is used, the objective is to measure the deepest pits. By measuring the maximum pit depth of duplicate specimens over a period of time, a rate of maximum pit growth can be obtained. The distribution of the pits (percentage of surface pitted) may also be of interest. Time to perforation data can be obtained by designing a specimen that is pressurized with air. This pressure is then monitored over a period of time until failure is indicated by a decrease (Ref 47). It is important to design the system so that the specimen being tested fails before the monitoring lines.

Stress-Corrosion Cracking and Hydrogen Embrittlement. Preparation of stressed specimens for underground performance studies is more time consuming because the specimen must be properly stressed before burial. Any fixtures or bolts attached to the specimen must be nonmetallic, electrically insulated from the specimen, or coated to avoid galvanic effects. Electrochemical measurements of the SCC specimens will not reveal information on the failure of the metal. However, if the hydrogen embrittlement specimen is cathodically charged with a sacrificial anode, it may be useful to monitor the current between the two electrodes and the electrical potential of the couple versus a reference electrode (Ref 48).

Time to failure data can be obtained by attaching a hollow tensile specimen to a stressing ring (Fig. 7) by monitoring the change in strain or diameter of the ring. Stress is applied to the tensile specimen by turning the stressing nuts so that the stressing ring is elastically deformed. The stressed tensile specimen is then embedded in the soil, with the stressing ring extending above ground (Fig. 7). This and other special designs can provide failure data before retrieval. Retrieval of the specimen soon after failure will reduce subsequent destruction of the failure surface before it is obliterated by general corrosive attack. Examination of this surface may provide further information on the mode of failure.

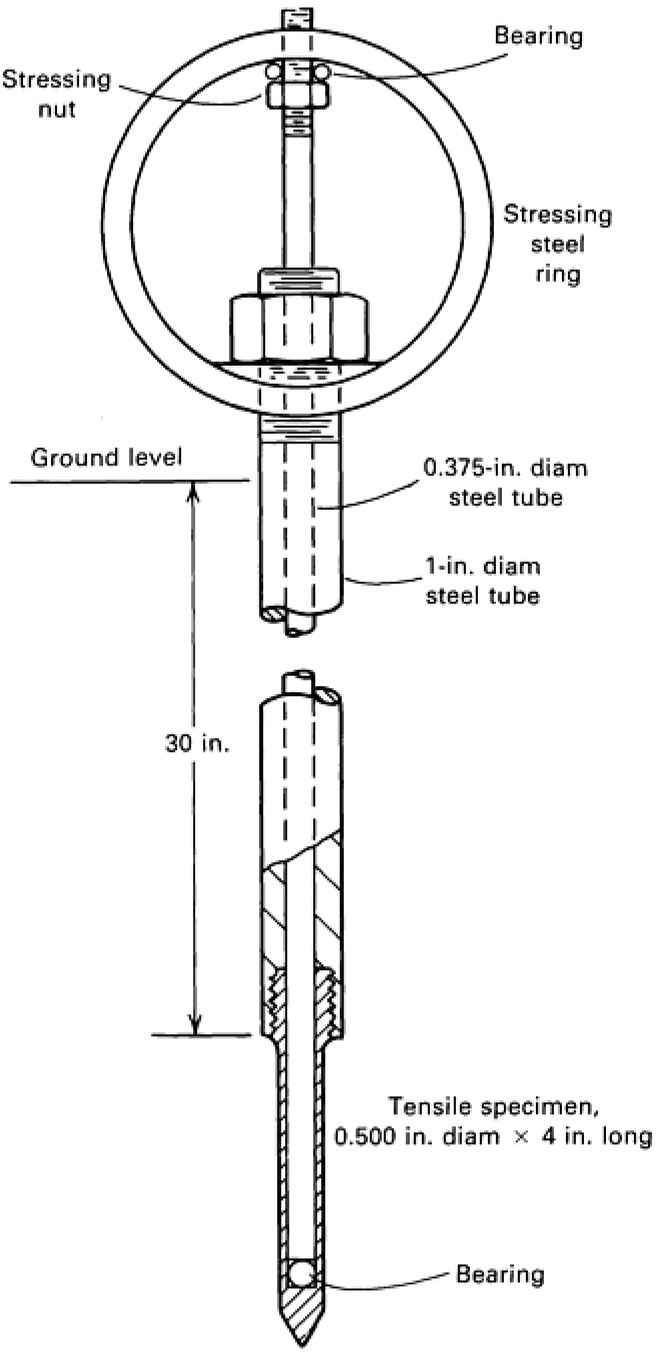

Fig. 7 Surface-monitored ring-stressed hollow specimen for SCC and hydrogen embrittlement studies of metals in soil. Source: Ref 49

Specimen Retrieval

If the specimens have been buried as described in the section "Specimen Burial" in this article, the retrieval process should proceed smoothly. Although the initial surface digging can be carried out with power equipment, the final few centimeters of soil must be removed by careful hand shoveling to reduce the possibility of specimen damage or loss of identification labels. A cursory examination of specimens, along with the maintenance of records and photographs of observations during this retrieval period, can be very useful--for example, Did the specimen fail during transit after retrieval? A final detailed examination of the specimens is then carried out in the laboratory. Depending on the situation, it may be desirable to clean and dry the specimen immediately after removal.

Summary

Corrosion of metals in undisturbed soil is very low and is independent of soil characteristics, but corrosion in disturbed soil is strongly influenced by the soil environment. Because of the difficulty in determining soil corrosivity through soil characterization or because data on specific alloys are needed, it is sometimes necessary to conduct an underground corrosion study. Information on the durability of metals in soil can be obtained by using physical and electrochemical measurements.

Gravimetric measurements of electrochemical polarization measurements will provide information on deterioration due to uniform corrosion. Similarly, pit depth measurements and surface monitoring of pressurized vessels provide data that can be used to determine perforation rates. The susceptibility of metals to hydrogen embrittlement and SCC can also be determined by physical measurements at the soil surface or by periodic retrieval of stressed specimens. Monitoring the potential and the galvanic current of cathodically charged stressed specimens reveals the susceptibility of an alloy to hydrogen embrittlement as a function of pH and galvanic current.

Specimen design depends on the type of data sought. It is essential to mark burial specimens properly, to map burial sites, and to maintain permanent records. This type of study consists of the following steps:

- Define the problem
- Identify the types of corrosion measurements that will supply the information needed
- Design the specimen to provide information on this need
- Choose a system for specimen identification
- Maintain good, permanent records at all stages of the program
- Bury the specimens with a connecting nylon cord for ease of retrieval
- Handle specimens with care during retrieval, and keep identification tags with the specimens
- Carry out final cleaning and evaluation in the laboratory with the utmost care

Laboratory Testing

Introduction

LABORATORY CORROSION TESTS are used to predict corrosion behavior when service history is lacking and time or budget constraints prohibit simulated service (field) testing. They can also be used as screening tests prior to simulated-service testing. Laboratory tests are particularly useful for quality control, materials selection, materials and environmental comparisons, and the study of corrosion mechanisms. These tests cover a spectrum ranging from simple immersion tests to various kinds of cabinet and autoclave controlled environments to sophisticated electrochemical tests. Most of these are accelerated tests by design; therefore, they must be used with caution. Because almost everything about these tests is based on assumptions, the testing conditions are arbitrary, and the problems of selecting the most pertinent testing method and a realistic interpretation are always present.

Standardized test methods are very useful for specifications and for routine tests used to compare experimental alloys and such products as inhibitors, coatings, and insulation materials. Many such tests are described in the Annual Book of ASTM Standards (Vol 03.02, *Metal Corrosion, Erosion, and Wear*) and in product specifications. However, it is often necessary for special tests to be set up that require creativity on the part of the investigator. This article will deal with basic procedures and approaches to laboratory corrosion testing but will not attempt to cover all of the published literature on specialized testing.

Electrochemical Methods of Corrosion Testing

John R. Scully, David W. Taylor Naval Ship Research and Development Center

Corrosion is an electrochemical process. Electrochemical processes require anodes and cathodes in electrical contact and an ionic conduction path through an electrolyte. The electrochemical process includes electron flow between the anodic and cathodic areas; the rate of this flow corresponds to the rates of the oxidation and reduction reactions that occur at the surfaces. Monitoring this electron flow provides the capability of assessing the kinetics of the corrosion process, not simply the thermodynamic tendencies for the process to occur spontaneously nor only the accumulated metal loss registered after the test. Measurements of this type have become known as electrochemical measurements of corrosion. Several textbooks cover many of the major aspects associated with the application or electrochemical methods in corrosion (Ref 1, 2, 3, 4, 5, 6, 7, 8).

Electrochemical techniques are finding increased use in corrosion research and in engineering applications. Such methods are practical because the corrosion behavior of material-electrolyte combinations is a direct function of the mechanisms as well as the kinetics of the electrochemical reactions responsible. The availability of better electrochemical techniques and the demonstrated accuracy of such methods for investigating corrosion phenomena have been the subject of several recent technical symposia (Ref 9, 10, 11, 12, 13, 14).

The earliest applications of electrochemical techniques were attractive because they offered a direct method of accelerating a corrosion process without changing the environment, that is, adding a strong oxidizer or increasing temperature as in other nonelectrochemical laboratory tests. However, recent advances have made the technique more of a nondestructive tool for the evaluation of corrosion phenomena and reaction rates, and this offers the possibility of *in situ* (field) as well as *ex situ* (laboratory) investigations. Thus, electrochemical techniques can be used to measure corrosion rates without removing the specimen from the environment or altering the sample itself. This capability offers distinct advantages over weight loss and visual observation testing procedures because the kinetics of the corrosion process can be quantitatively studied and because of the added convenience.

Most, if not all, of the typical forms of corrosion, including uniform, localized, galvanic, dealloying, stress corrosion, and hydrogen-induced failure, can be investigated by electrochemical techniques. Topics such as passivation, anodization, cathodic and anodic protection, and barrier and sacrificial coatings on metal substrates can also be investigated by using electrochemical techniques. Also available are electrochemical techniques that have been optimized for the study of hydrodynamic (mass transport controlled) corrosion processes (Ref 15) as well as those techniques designed to avoid dominance of the measured quantity by mass transport control, that is, transient electrochemical methods (Ref 16).

Although they have been limited to near ambient temperature aqueous corrosion studies in the past, electrochemical techniques are now being applied to high-temperature, high-pressure aqueous applications as well as to the study of corrosion processes in nonaqueous environments and aqueous environments of low conductivity. In the remainder of this section, specific examples will be given on the application of various electrochemical methods to the typical categories of corrosion attack mentioned above.

Fundamentals

Corrosion is an electrochemical process that is characterized by mass transport as well as the electrical and ionic charge transfer associated with a corroding solid or solids electrically in contact. The corroding system consists of anode and cathode sites electrically in contact and a surrounding electrolyte (Ref 17). According to mixed-potential theory, any net electrochemical reaction can be algebraically divided into two or more oxidation and reduction reactions, and there can be no net electrical charge accumulation. In a corroding system in the absence of applied potential, the oxidation of the metal and the reduction of some species in solution occur simultaneously at the metal/electrolyte interface (Ref 1, 3). Under these circumstances, the net measurable current is 0, however, a finite rate of corrosion is occurring at local anodic sites on the metal surface. Such a current-potential relationship is shown schematically in Fig. 1.

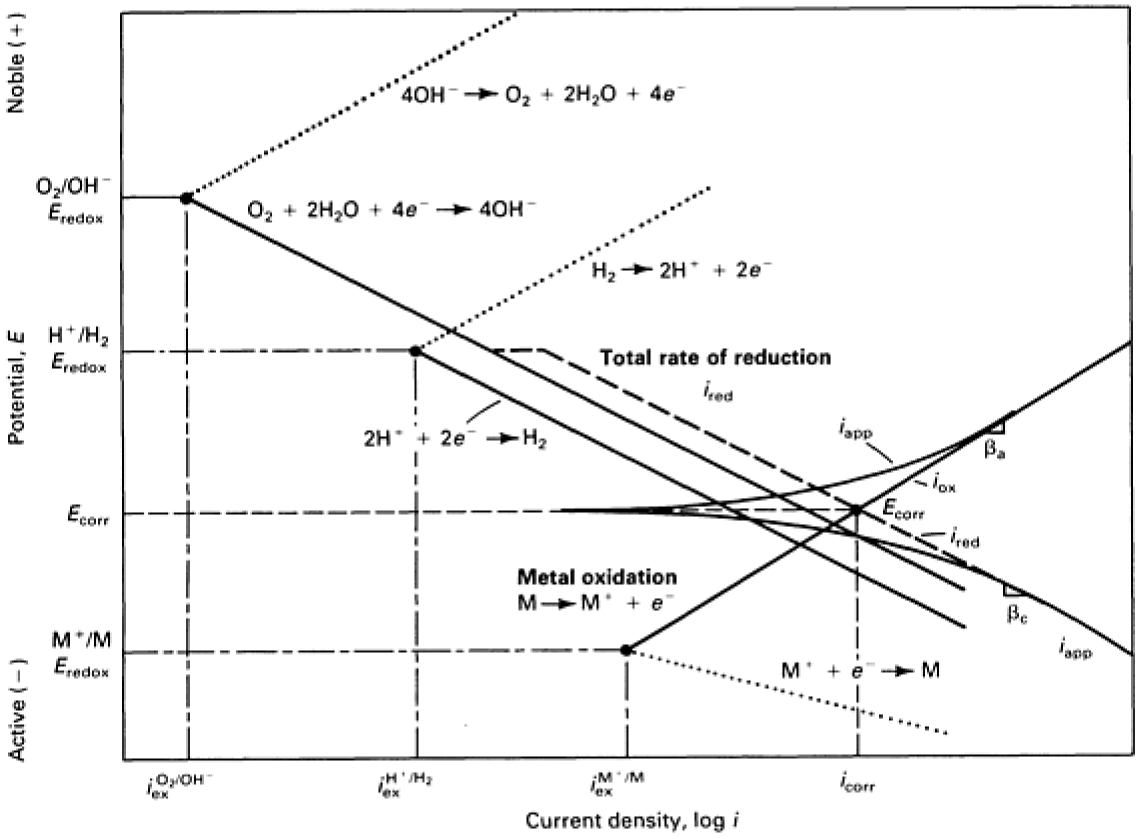

Fig. 1 Schematic electrochemical potential-current relationship for a corroding system consisting of two cathodic reactions and one anodic electrochemical reaction

When the corrosion potential is located at a potential that is distinctly different from the reversible electrode potentials (redox potential, E_{redox}) of either the corroding metal or the species in solution that are cathodically reduced, the oxidation of the cathodic species or the reduction of any of the ions of the corroding metal that are in solution becomes negligible. The corrosion potential, E_{corr}, indicates the potential at which the oxidation rate equals the reduction rate and the net current measured externally is 0:

$$i_{app} = i_{ox} - i_{red} \qquad \textbf{(Eq 1)}$$

Because the oxidation current present at the corrosion potential is the quantity of interest in the corroding system, this parameter must be determined independently of the reaction rates of other adsorbed or dissolved reactants. Electrochemical polarization methods can be used to determine corrosion rates. More detailed information on the fundamentals associated with aqueous corrosion can be found in the articles "Thermodynamics of Aqueous Corrosion" and "Kinetics of Aqueous Corrosion" in this Volume.

Conducting an Electrochemical Polarization Experiment

The electrochemical polarization of metallic samples is accomplished with a power supply known as a potentiostat. An auxiliary electrode supplies the current to the working electrode (test specimen) in order to polarize it. The potential between the working electrode and a reference electrode is monitored or set at a fixed value, as in the potentiostatic test.

Figure 2(a) illustrates schematically a typical experimental arrangement. The system is designed so that only an extremely small current can pass between the reference electrode and the working electrode; the current needed to polarize the working electrode is supplied from the auxiliary electrode (Ref 1). The potentiostat actually contains an operational

amplifier or similar device in order to provide the feedback of the current necessary for maintaining the fixed potential between the working and reference electrode. Figure 2(b) illustrates a typical electrochemical cell. The potential can be applied in a ramp fashion, stepped as a function of time (sometimes called potentiostaircase), or held at a fixed level as in the potentiostatic method (Ref 18). Conversely, the current can be applied in a continuous galvanostatic or stepped galvanostaircase manner, and the change in potential monitored. Several American Society for Testing and Materials (ASTM) standards discuss methods for performing these experiments (Ref 19, 20).

Conversion of Electrochemical Current Data to Corrosion Rates

Measurement of I_{ox} at the potential of interest, where $I_{ox} = i_{ox} \cdot A$, over a known period of time leads to direct determination of the weight loss:

$$W = \frac{(I \cdot t \cdot M)}{nF} \quad \textbf{(Eq 2)}$$

where *W* is the weight loss (grams), $I \cdot t$ equals the current multiplied by time or coulombs (C), *n* is the number of electrons involved in the electrochemical reaction, *F* is Faraday's constant (96,487 C/gram-equivalent), and *M* is the

molecular weight of the electroactive species. This relation is known as Faraday's Law. Rearrangement of Eq 2 leads to a straightforward determination of the penetration rate (applicable only when I_{ox} is uniformly distributed over the entire wetted surface area or where the localized actively corroding area, *A,* is known), as follows:

$$CR = \frac{3.27 \times 10^{-3} \cdot i_{ox} \cdot E.W.}{d} \quad \textbf{(Eq 3)}$$

where CR is the corrosion rate (in millimeters per year), where E.W. is the equivalent weight in grams, *d* is the metal or alloy density in grams per cubic centimeter, and i_{ox} is the corrosion current density in microamps per square centimeter.

For alloys, the equivalent weight E.W. should be calculated using the atomic fractions of each alloying element in an expression such as:

$$\text{Alloy E.W.} = \sum_{i=1}^{m} \frac{f_i M_i}{n_i} \quad \textbf{(Eq 4)}$$

where f_i is the atomic fraction of the *i*th component of the alloy, M_i is the atomic weight of the *i*th component element, n_i is the electron loss required to oxidize the *i*th component element under the conditions of the corrosion process (n_i is usually equal to the stable valence of the element, or must be determined from either a Pourbaix (potential-pH) diagram or experimentally from an analysis of the corroding solution), and *m* is the number of component elements in the alloy.

This expression assumes that all the component elements oxidize when the alloy corrodes and that they are all oxidizing at essentially a uniform rate. In some situations, these assumptions are not valid; in these cases, the calculated corrosion rate will be in error. For example, if an alloy is composed of two or more phases and one phase preferentially oxidizes, the calculation must take this into consideration.

Electrochemical Methods For the Study of Uniform Corrosion

Polarization Methods. The following relationship observed between applied current and potential provides the basis for the electrochemical polarization technique (Ref 1, 2, 21):

$$i_{app} = i_{corr}\left[\exp\frac{2.3(E - E_{corr})}{\beta_a} - \exp\frac{-2.3(E - E_{corr})}{\beta_c}\right] + C\left(\frac{dE}{dt}\right) \quad \textbf{(Eq 5)}$$

where i_{app} is the applied current density based on the electrochemical surface area; i_{corr} is the corrosion current density; *E* is the applied voltage; E_{corr} is the open-circuit, or freely corroding, potential; *C* is the interfacial capacitance associated with the electrochemical doublelayer (Ref 1, 2); β_a and β_c are the anodic and cathodic Tafel coefficients related to the slopes of the polarization curves in the anodic and cathodic regimes, respectively; and *dE/dt* is the time rate of change in applied potential, or voltage, scan rate. Ideally, the second term of the expression $C \cdot dE/dt$ approaches 0 at, for example, very low potential scan rates. Note that i_{app} becomes approximately equal to either i_{ox} or i_{red} at large overpotential. At very large anodic or cathodic overpotentials, Eq 5 can be rearranged in a more simplistic form (Ref 1, 2, 3, 5, 7):

$$\eta_a = \beta_a \log\left(\frac{i_{app}}{i_{corr}}\right) \quad \textbf{(Eq 6)}$$

$$\eta_c = -\beta_c \log \left(\frac{i_{app}}{i_{corr}} \right) \quad \text{(Eq 7)}$$

Tafel Extrapolation. By plotting potential versus log i_{app}, a linear relationship between current density and potential can be developed (Ref 1, 5, 7, 21). Extrapolation of the applied current from either the anodic or the cathodic Tafel region to the open-circuit potential or position of zero overpotential allows determination of i_{corr}. Figure 3 illustrates this method.

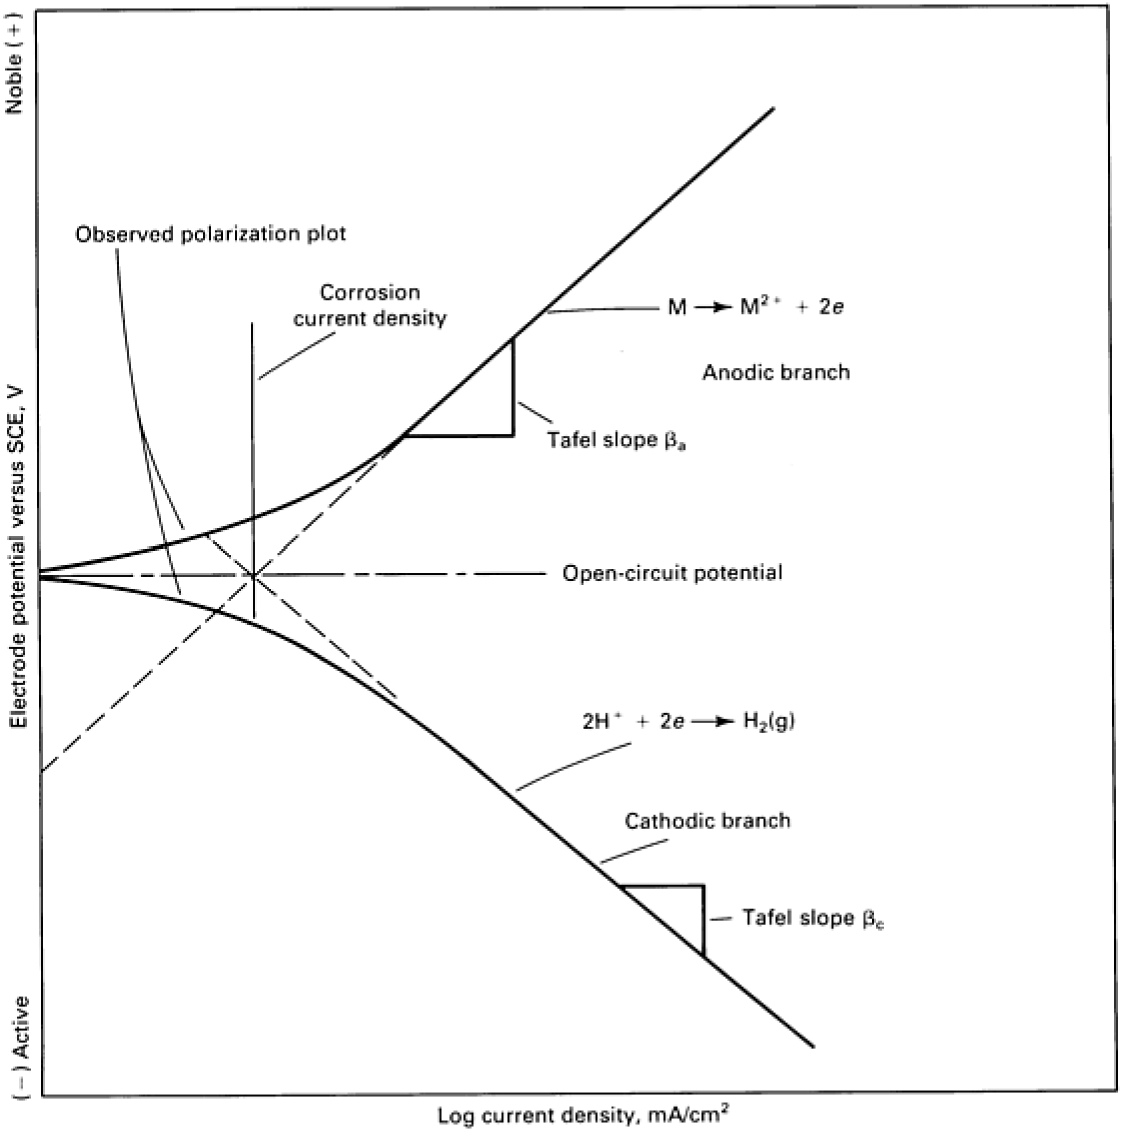

Fig. 3 Experimentally measured Tafel polarization plot. Source: Ref 22

Complications of the Polarization Method Involving Solution Resistance. Polarization techniques can be complicated by several factors. One such factor arises from the resistivity of the solution, depending on the geometry, the location of the reference electrode, and the magnitude of applied current (Ref 2, 6). Placement of the reference electrode near the working electrode is facilitated through the use of a Luggin-Haber capillary. This arrangement is desired in order to minimize the solution resistance error, which can be estimated from the product of the applied current, the solution resistivity, and the distance from the Luggin probe to the specimen surface. The error contributes to the measured overpotential in the following manner:

$$\eta_{app} = \eta_{true} + \eta_{iR} \quad \textbf{(Eq 8)}$$

where η_{iR} is equal to $i_{app} \cdot R_{soln}$ (the resistance of the solution). Thus, the true overpotential is overestimated at each applied current density, and the Tafel slope becomes inaccurate. The true scan rate in the potentiodynamic technique may also be altered. Several excellent reviews are available on the subject of the voltage error introduced from solution resistance (Ref 23, 24, 25).

Complications Involving Concentration Polarization Effects. The Tafel relationship established above is dependent on pure activation control, or charge transfer control. An additional consideration involves the concept of concentration polarization. In this case, the reaction rate is large enough that the electroactive species is depleted or concentrated at the reacting surface in order to maintain the reaction rate through diffusion. The reaction becomes diffusion controlled at the limiting current density. The deviation from activation control is described by (Ref 5):

$$\eta = \frac{2.3RT}{nF} \log \left(1 - \frac{i_{app}}{i_L}\right) \quad \textbf{(Eq 9)}$$

where R is the gas constant, and T is the absolute temperature. Many corroding systems are frequently under what is termed mixed activation and mass transport control (Ref 5). This behavior can be described mathematically by the algebraic combination of Eq 5 and 9. To increase the reaction rate and thus minimize the contribution of Eq 9 to the overpotential, the diffusional boundary layer thickness is decreased by solution stirring or by the use of a rotating cylinder or disk electrode (Ref 15).

Other Issues Concerning Tafel Extrapolation. Experimentally, there are several problems with the Tafel extrapolation method. Large applied current densities may not be representative of the true corrosion situation occurring at open circuit. This is particularly true in the case of anodic polarization, in which the surface is changing because of corrosion and/or passivation of the metal. In the cathodic case, an excess of adsorbed hydrogen or a build up of hydroxyl ions in solution at the metal surface may result in alterations of surface chemistry not representative of the freely corroding case. In addition, concentration polarization may eliminate the Tafel region entirely.

Polarization Resistance Methods. For anodic and cathodic polarization within 10 mV of the corrosion potential, it is often observed that the applied current density is approximately linear with potential (Ref 1). This behavior is shown in Fig. 4 for the type 430 stainless steel in sulfuric acid (H_2SO_4). The slope of this plot is determined at a corrosion potential, as shown in Fig. 4 (Ref 26, 27). This slope has units of resistance area and is known as the polarization resistance. Stern and Geary simplified the fundamental equations describing charge transfer controlled reaction kinetics (Eq 5) for the case of small perturbations of the corrosion potential, that is, low polarization or overpotential (Ref 27, 28). This relationship has the form:

$$I_{corr} = \left(\frac{\Delta i_{app}}{2.3 \cdot A \cdot \Delta E}\right) \left(\frac{\beta_a \cdot \beta_c}{\beta_a + \beta_c}\right) \quad \textbf{(Eq 10)}$$

$$i_{corr} = \left(\frac{1}{2.3 \cdot R_p}\right) \left(\frac{\beta_a \cdot \beta_c}{\beta_a + \beta_c}\right) \quad \textbf{(Eq 11)}$$

where R_p is the polarization resistance, and β_a and β_c are the anodic and cathodic Tafel slopes, respectively. The value R_p is determined from the current density, not the current measurement; the surface area of the working electrode must be known. Knowledge of R_p and Tafel slope values permit direct determination of the corrosion rate at any instant in time (Ref 27, 28, 29, 30). The ASTM standards G 59 (Ref 20) and D 2776 (Ref 31) describe procedures for conducting polarization resistance measurements. These standards do not address many of the complications that may arise.

Complications With Polarization Resistance Measurements. Numerous papers have addressed complications and possible alternative methods for use of the polarization resistance method (Ref 32, 33, 34, 35, 36, 37). Three of the most obvious errors that are possible when using these methods involve invalidation of the results through oxidation of some other electroactive species besides the corroding metal in question, a change in the open-circuit or corrosion potential during the time taken to perform the measurement, and the application of a large applied potential resulting in inadvertent departure from linear current density versus potential behavior. Several techniques actually take advantage of the departure from nonlinearity in order to calculate the anodic and cathodic Tafel slopes at a low overpotential and thus avoid some of the problems associated with large polarization (Ref 37).

Another source of error involves cases in which both the anodic and cathodic reactions are not under charge transfer control, as required for the derivation of Eq 10. Possible corrections to Eq 10 for cases in which pure activation control is not maintained, such as in the case of partial diffusion control or passivation (Ref 38). Other researchers have attempted to calibrate their results through the use of weight loss measurements (Ref 39). In fact, in one case, polarization resistance data for a number of alloy-electrolyte systems were compared to the observed corrosion currents (Ref 30). A linear correspondence was obtained over six orders of magnitude in corrosion rates.

Two other frequently encountered complications are the need to correct data for the electrolyte (solution) resistance R_s and the effects of capacitive hysteresis, *C,* occurring as a function of the voltage scan rate (Ref 2). Hysteresis in the current density-potential plot is observable when the time rate of change, *dE/dt,* of the applied potential is scanned in a cyclic manner under the conditions in which the sweep rate is large, the interfacial capacitance is large, or both. The effect can be minimized by performing the polarization resistance test by taking two or more dc current density-potential measurements instead of cycling the potential. The solution, or ohmic resistance, on the other hand, still complicates the measurement because the algebraic sum of the polarization resistance and the solution resistance is measured in a dc or pseudo-dc measurement.

Many treatments of this subject have used to electrical equivalent circuit model, which simulates the corroding metal/electrolyte interface (Ref 40, 41). The simplest form of such a model, the Randles circuit, is shown in Fig. 5. The three parameters discussed above (R_p, R_s, and *C*) are shown in the relationship to one another that best approximates a corroding electrochemical interface of a metal. The sum of the polarization resistance and the solution resistance is measured when a dc measurement is performed because the capacitive reactance approaches infinity. Thus, the true corrosion rate will be underestimated when R_s is appreciable. Conversely, any measurement at a cyclic applied potential that is scanned as a function of time causes the algebraic sum of the ohmic resistance and the resultant parallel impedance of the parallel resistive-capacitive network to be measured. If R_s is small compared to R_p, the capacitive error considered alone will usually result in an overestimation of the true corrosion rate. These complications can be overcome, as discussed below.

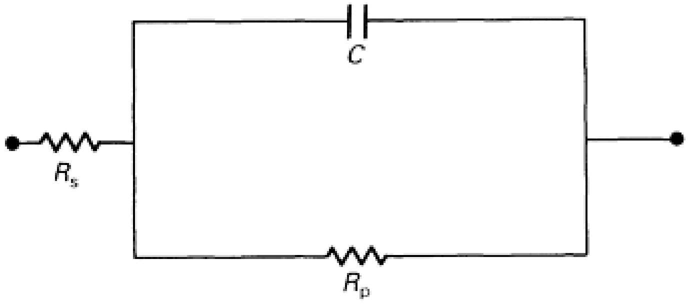

Fig. 5 Electrical equivalent circuit model simulating simple corroding metal/electrolyte interface. See also Figure 6

Electrochemical Impedance Methods. One approach to determining the corrosion rate of a metal without the complications discussed above involves the electrochemical impedance (sometimes known as ac impedance) method (Ref 40, 41, 42, 43). In this technique, a small-amplitude sinusoidal potential perturbation is applied to the working electrode at a number of discrete frequencies. At each one of these frequencies, the resulting current waveform will exhibit a sinusoidal response that is out of phase with the applied potential signal by a certain amount. The electrochemical impedance is a frequency-dependent proportionality factor that acts as a transfer function by establishing a relationship between the excitation voltage signal and the current response of the system. As such, an electrochemical impedance is a fundamental characteristic of the electrochemical system it describes. A knowledge of the frequency dependence of impedance for a corroding system allows a determination of an appropriate equivalent electrical circuit describing that system. Figure 5 illustrates in the most simple case the equivalent electrical circuit model for an active corroding metal. The following expression describes the impedance for that system:

$$Z_{metal} = R_s + \frac{R_p}{(1 + \omega^2 \cdot R_p^2 \cdot C^2)} - \frac{j\omega CR_p^2}{(1 + \omega^2 \cdot R_p^2 \cdot C^2)} \quad \text{(Eq 12)}$$

where Z is the impedance magnitude, $\omega = 2\pi f$ is the frequency of the applied signal in radians per second, C is the interfacial capacitance, and $j = \sqrt{-1}$. Experimentally, it can be easily seen from Fig. 6 that at very low frequencies:

$$Z_{metal} = R_s + R_p \quad \text{(Eq 13)}$$

while at very large frequencies:

$$Z_{metal} = R_s \quad \text{(Eq 14)}$$

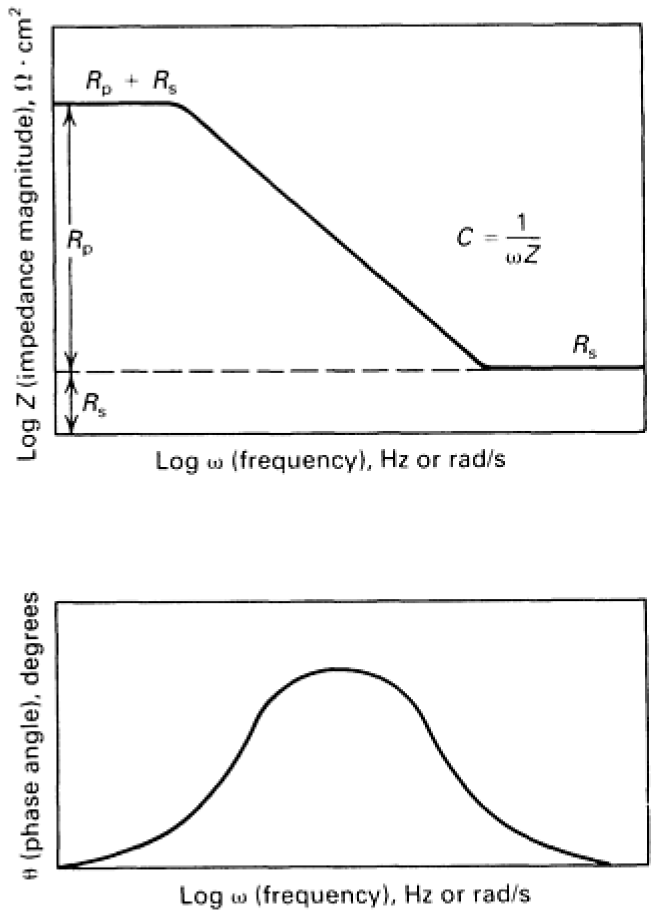

Fig. 6 Bode phase and magnitude plots demonstrating the frequency dependence of electrochemical impedance for the circuit model shown in Fig. 5

As evident from the above, a calculation of the polarization resistance is possible in media of quite high resistivity because R_p can be mathematically separated from R_s. In addition, capacitive hysteresis is eliminated. Other information determined from this technique includes the value of C, the capacitance. In the simple case of active corrosion, C may be found to scale linearly with the true electrochemical surface area from the relationship $C = c \cdot A$, where c is a specific

capacitance per unit area, and A is the true electrochemical surface area. Determination of the corrosion rate also requires accurate values for the anodic and cathodic Tafel slopes β_a and β_c, as shown in Eq 10.

Electrochemical Methods for the Study of Galvanic Corrosion

Methods Based on Mixed-Potential Theory. Galvanic corrosion can be described in terms of mixed-potential theory, as schematically illustrated in Fig. 7. However, in the case of bimetal or multimetal galvanic attack in which two or more metals are electrically in contact with one another, there will be at least in theory a minimum of two cathodic and two anodic reactions. One of each of these reactions is occurring on each metal. In this case, the more noble of the two metals is cathodically polarized in the electronegative direction, and its anodic reaction rate will thus be suppressed. Conversely, the less noble, or more sacrificial, anodic material is anodically polarized, and the anodic reaction rate is accelerated. The mixed potential (the galvanic couple potential) of the galvanic couple and the resulting galvanic current can be uniquely determined from the sums of all of the anodic and cathodic currents for each material at each potential when the following condition is met:

$$\sum i_a \cdot A_a = \sum i_c \cdot A_c \quad \textbf{(Eq 15)}$$

where $\sum i_a \cdot A_a$ is the sum of the anodic currents (current density multiplied by area), and $\sum i_c \cdot A_c$ is the sum of the cathodic currents.

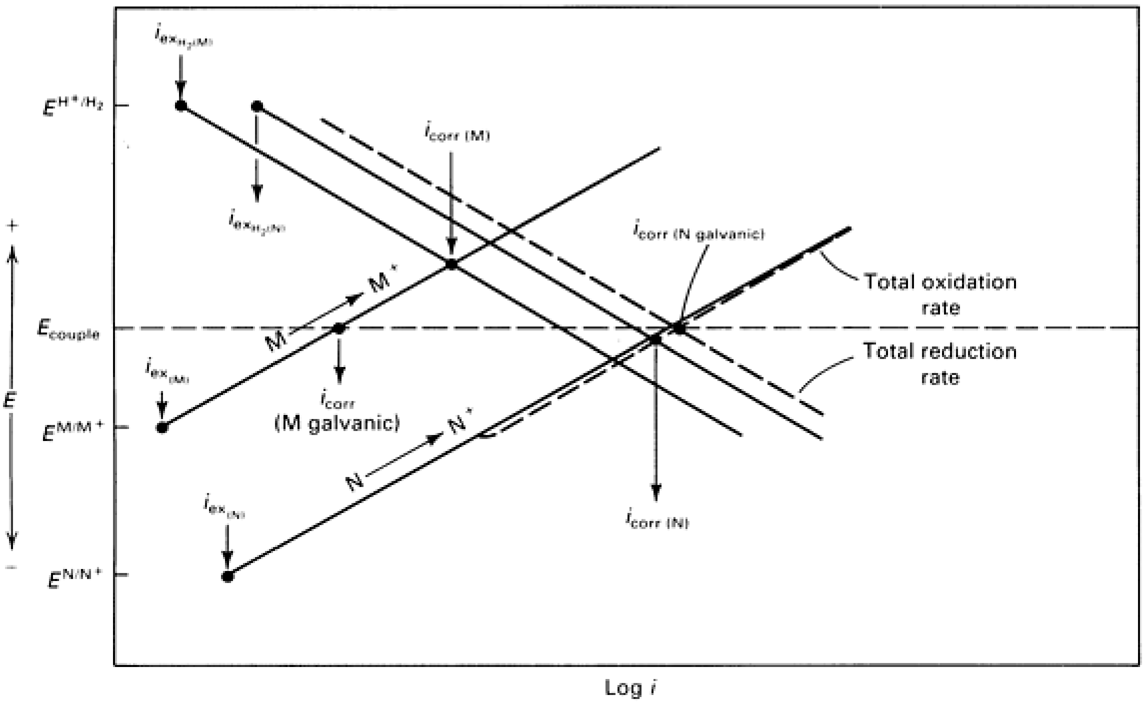

Fig. 7 Potential-current relationships for the case of a galvanic couple between two corroding metals. M, more noble metal; N, less noble metal. Source: Ref 3 and 5

This relationship will be uniquely satisfied at one value of the applied potential and can be determined if potential versus anodic and cathodic current data are available for each material in the galvanic couple. Thus, this mixed potential will depend entirely on kinetic considerations rather than thermodynamic considerations. In simple bimetal cases, direct superposition of polarization data (corrected for wetted surface) will yield the same result (Ref 44). This technique is schematically illustrated in Fig. 7. However, because applied currents, not anodic or cathodic currents, are actually measured in the polarization experiment, the technique will introduce the least error when the cathodic reaction rate is negligible on the anode material and the anodic reaction rate is negligible on the cathode material at the galvanic couple potential (the mixed potential). Otherwise, a correction must be made. Obviously, when the open-circuit potentials of the

anode and cathode materials are similar, this complication is more likely to arise, but in this case galvanic corrosion is less likely to be significant. In addition, special care must be taken in the procedures used to develop the polarization data (Ref 44), especially if time effects are to be taken into consideration when evaluating galvanic-corrosion behavior.

Direct Measurement of Galvanic-Corrosion Rates. A more straightforward procedure involves immersing the two dissimilar metals in an electrolyte and electrically connecting the materials together by using a zero-resistance ammeter to measure current (Ref 45, 46, 47). In this method, the galvanic current can be directly determined as a function of time. A reference electrode can be used in the usual manner to determine the galvanic couple potential.

Electrochemical Methods for the Study of Localized Corrosion

Pitting and crevice corrosion are usually associated with the breakdown of passivity (Ref 48). The anodic electrochemical behavior of a passive alloy in deaerated acid is schematically shown in Fig. 8(a). Figure 8(b) illustrates the results for type 430 stainless steel in H_2SO_4. The characteristics of this diagram will aid in determining the resistance of an alloy to localized attack.

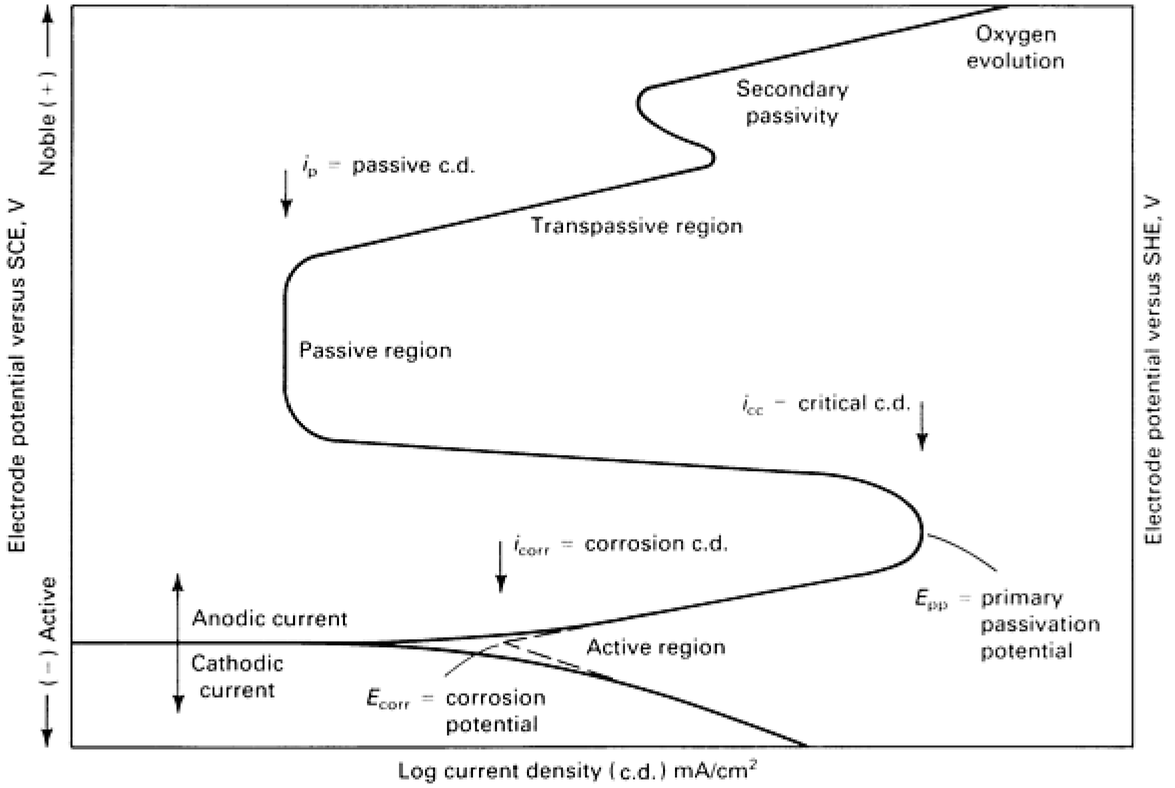

Fig. 8(a) Hypothetical anodic and cathodic polarization behavior for a material exhibiting passive anodic behavior. Source: Ref 22

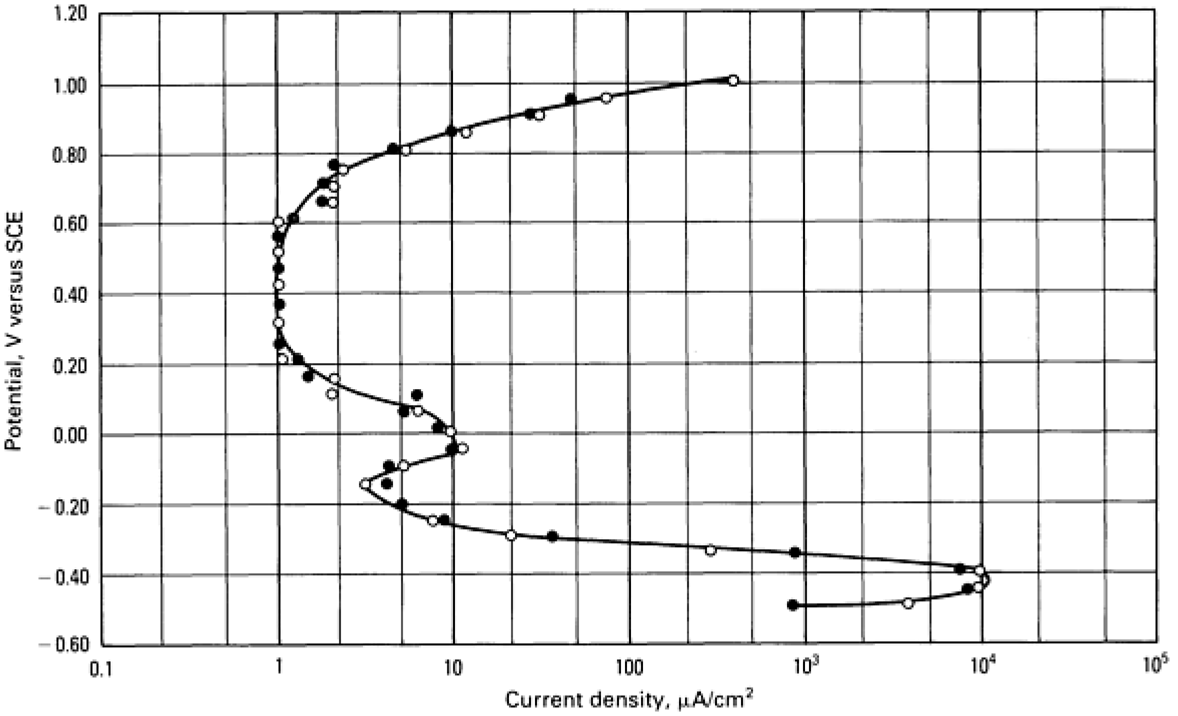

Fig. 8(b) Actual potentiostatic passive anodic polarization behavior for type 430 stainless steel in a 1 *N* H_2SO_4, H_2 purge, 30 °C (85 °F), 50 mV for 5 min (each specimen). Closed and open circles (data points) illustrate laboratory repeatability. Source: Ref 19

Tests for evaluating the susceptibility of a material to pitting and crevice corrosion include potentiodynamic tests, galvanostatic tests, potentiostatic tests, scratch potentiostatic tests, tribo-ellipsometric methods, pit-propagation rate curves, and electrochemical noise measurements (Ref 49). Several excellent review papers discuss these methods in more detail (Ref 48, 49, 50).

Cyclic Potentiodynamic Polarization Methods. The ASTM standard G 61 describes a procedure for conducting cyclic potentiodynamic polarization measurements to determine relative susceptibility to localized corrosion (Ref 51). The method is designed for use with iron- or nickel-base alloys in chloride environments. In this test, a cyclic anodic polarization scan is performed at a fixed voltage scan rate.

Particular attention is focused on two features on the cyclic anodic polarization behavior diagram. These are the potential at which the anodic current increases considerably with applied potential or the breakdown potential. In general, the more noble this potential, obtained at a fixed scan rate in this test, the less susceptible the alloy to the initiation of localized attack. the second feature of great interest is the potential at which the hysteresis loop is completed upon reverse polarization scan. In general, once initiated, localized corrosion can propagate at some potential more electropositive than that at which the hysteresis loop is completed (when determined at a fixed scan rate). Therefore, the more electropositive the potential at which the hysteresis loop is completed, the less likely that localized corrosion will occur. This potential is known as the protection potential. Figure 9 illustrates cyclic polarization behavior for Hastelloy C-276 and type 304 stainless steel in 3.56% sodium chloride (NaCl) solution. Based on the above criteria for evaluation, it is evident that Hastelloy C-276 is relatively more resistant to localized corrosion in this environment.

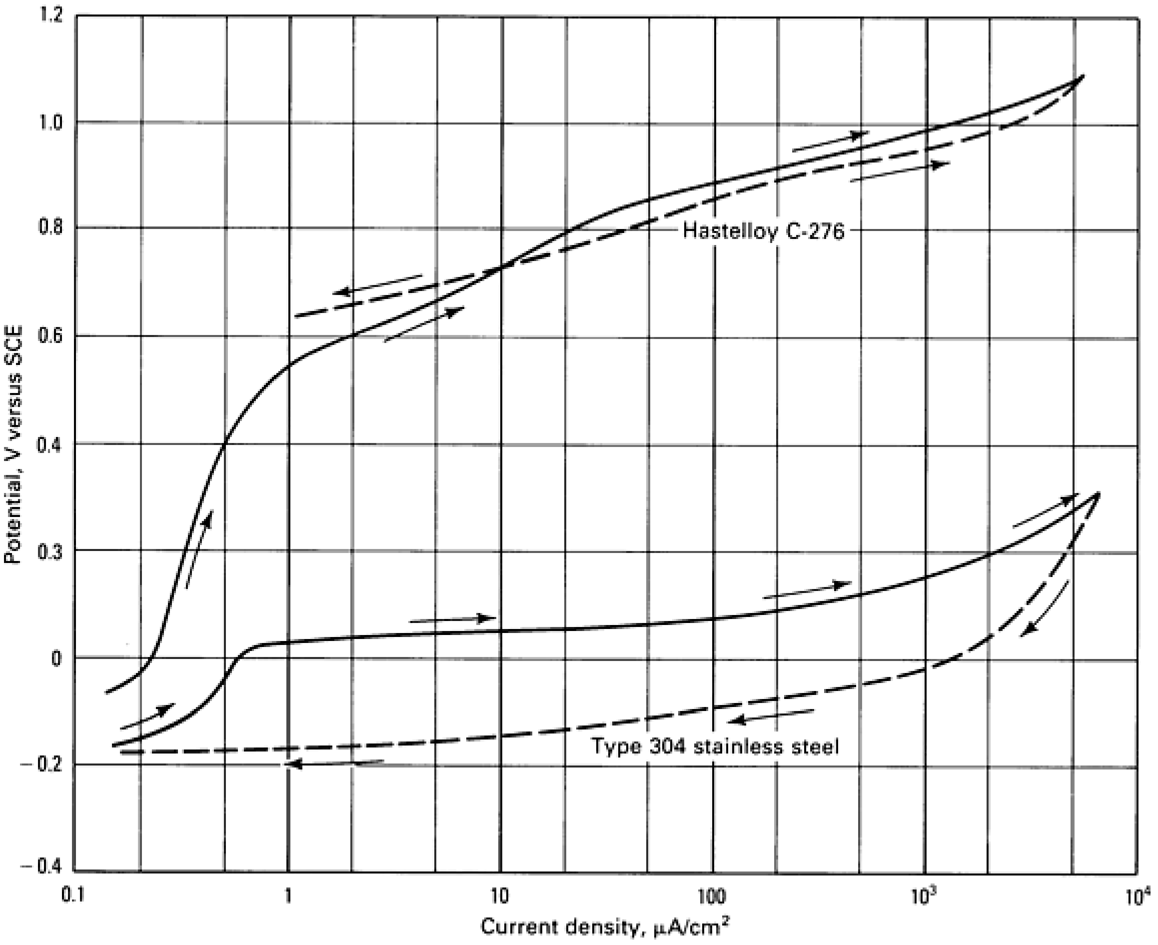

Fig. 9 Cyclic potentiodynamic polarization curves for Hastelloy C-276 and type 304 stainless steel in 3.56 wt% NaCl solution. Source: Ref 51

Complications With Cyclic Potentiodynamic Polarization Methods. Although it is a reasonable method of screening variations in alloy composition and environments, the cyclic potentiodynamic polarization method has been found to have a number of shortcomings (Ref 50, 51, 52, 53, 54). One major problem concerns the effect of the potential scan rate. The values of both the protection potential and the breakdown potential are a strong function of the manner in which the tests are performed, particularly the potential scan rate employed. This problem is predominately related to the induction time required for pitting, the repassivation rates, and the complications arising from allowing too much pitting propagation to occur along with the accompanying chemistry changes before the reversal in the scan direction.

Potentiostatic and Galvanostatic Methods for Localized Corrosion. The shortcomings of the cyclic potentiodynamic polarization method have become the basis for several other electrochemical techniques. Four other methods are schematically illustrated in Fig. 10. Potentiostatic methods can be used to overcome the inherent problems involving scan rate. There are two general methods. The first is mainly associated with the study of initiation, and the second is mainly associated with the study of propagation and repassivation.

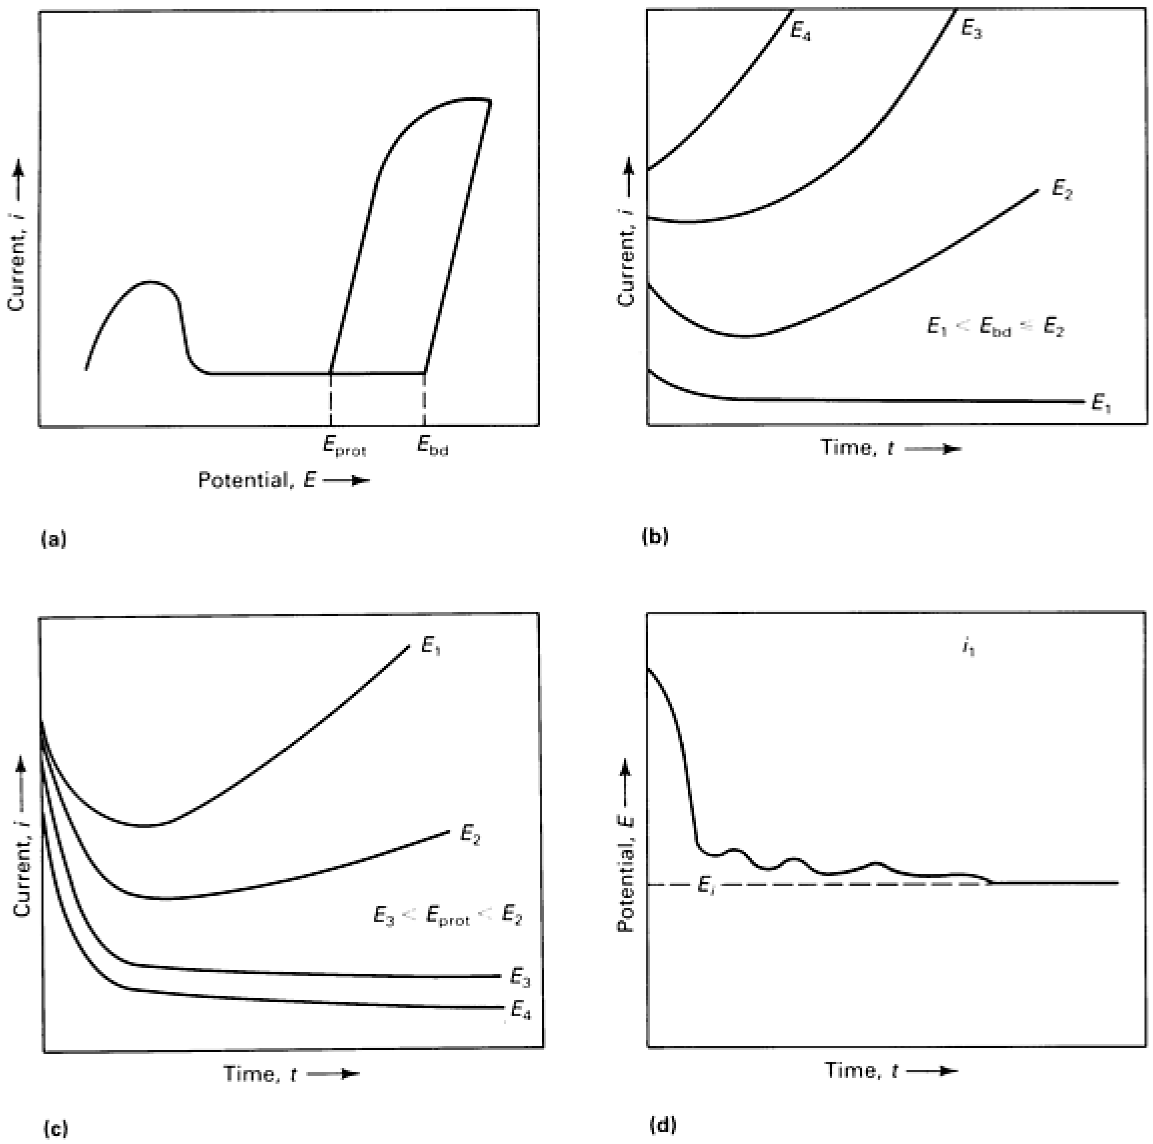

Fig. 10 Schematic representations for (a) a cyclic potentiodynamic polarization curve, (b) potentiostatic current-time curves with a passivated surface, (c) potentiostatic current-time curves for an activated surface, and (d) a galvanostatic potential-time curve. Source: Ref 48

The first method (Fig. 10a) simply provides a means of determining the breakdown potential by polarizing individual samples at potentials above and below an approximate E_{bd} determined from the potentiodynamic method. Eventual initiation is indicated by a current increase. In the second method (Fig. 10b and c), initiation of pits is intentionally induced by applying a potential above the breakdown potential and then quickly shifting to a potential below that value. If the final applied potential is above the protection potential, propagation of the existing pits will continue and the current will increase. However, at E less than the protective potential, E_{prot}, the pits will eventually repassivate, and the current will subsequently decrease with time. The galvanostatic or galvanostaircase technique (Fig. 10d) measures potential versus time at a constant applied current. Measurements are often made until the time rate of change in potential approaches 0. The technique is under development in ASTM G 1 as a test method for application with aluminum alloys.

The Scratch-Repassivation Method for Localized Corrosion. One additional technique to be mentioned in the area of localized corrosion involves the scratch method (Ref 55). In this method, the alloy surface is scratched at a constant potential, and the current is measured as a function of time. The potential dependencies of the induction time and the repassivation time are determined by monitoring the current change over a range of different potentials. This is illustrated in Fig. 11. From this information, the critical pitting potential, thought to be located somewhere between the

breakdown potential and the protection potential, can be determined. Other methods of studying localized corrosion are also available (Ref 49).

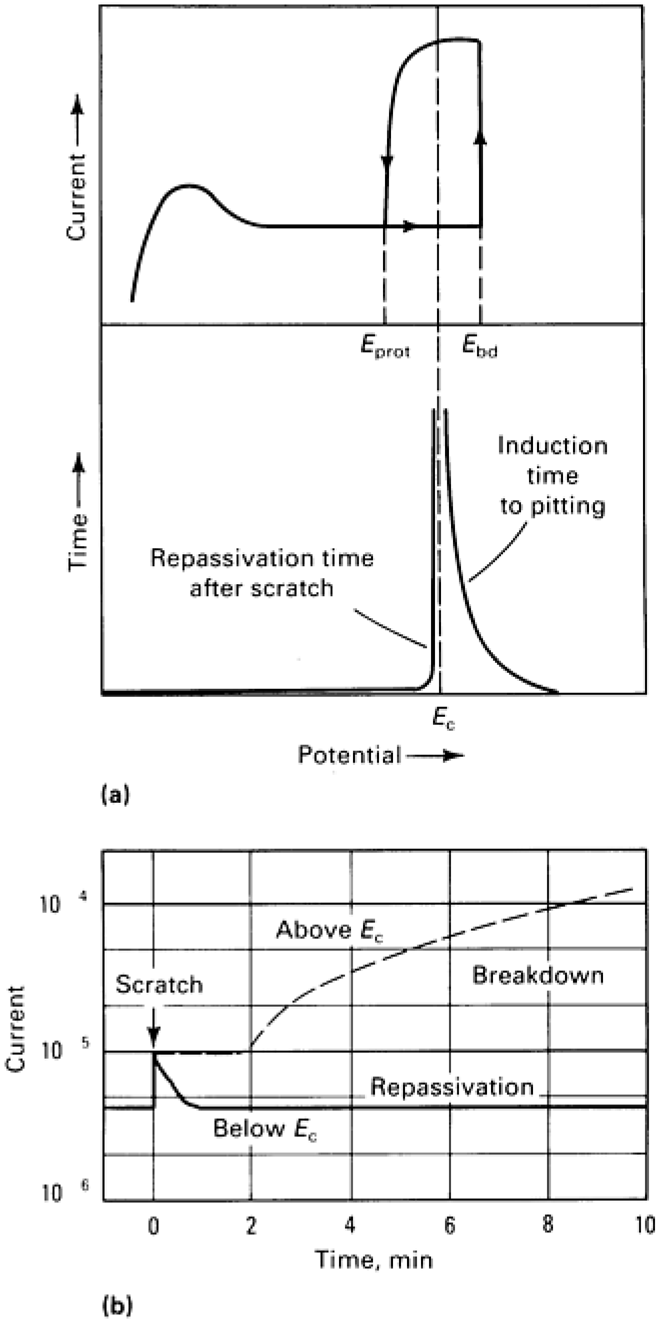

Fig. 11 Potential versus time plot of scratch test illustrating the critical potential, E_c, as it relates to the induction time (a) and the repassivation time (b). Source: Ref 48

Environmental Cracking

There are numerous electrochemical techniques in the area of environmental cracking. One of the techniques is for alloys that undergo passive film rupture and anodic dissolution, and the other is for alloys that are susceptible to hydrogen embrittlement. Both will be discussed below.

Stress Corrosion Cracking (SCC). In the area of electrochemical techniques for the study of SCC, the scratch-repassivation technique discussed above may be useful (Ref 56). This technique has been used to distinguish between the

case where an alloy is susceptible to localized corrosion, such as pitting, and whether or not the alloy is susceptible to SCC. In general, once the passive film is mechanically disturbed at some potential, an electrochemical current can be measured that will decay back to a low level when repassivation has occurred. The total current will consist of the sum of the repassivation current and the current corresponding to dissolution of the exposed bare metal.

In this case, the electrochemical test is conducted in conjunction with the optical ellipsometric method to measure the rate of film growth. This combination offers a method of separating the two currents (dissolution-repassivation) from one another because it is a means of studying the kinetics of the film growth associated with repassivation. Based on the ratio of the charge involved in dissolution and the charge associated with repassivation, a criteria for stress corrosion is established:

$$R_{SCC} = 1 + \frac{Q_d}{Q_r} \quad \textbf{(Eq 16)}$$

where Q_d is the charge involved in dissolution, and Q_r is the charge associated with repassivation. For example, a low-carbon steel was found to be nonsusceptible to SCC in a solution in which R_{SCC} was 2.8. In addition, the steel was found to be susceptible when that ratio was 26, and it was nonsusceptible again in a solution in which R_{SCC} was 75 (Ref 56). In the latter case, widespread pitting occurred instead.

Hydrogen Embrittlement. The Devanathan-Stackurski method is used to study the parameters associated with the hydrogen embrittlement tendencies of metals and alloys (Ref 57). Essentially, a thin parallel-faced wafer of the metal of interest is positioned between two separate polarization cells such that there is no electrolyte path between the two cells. Adsorbed hydrogen is electrochemically generated through cathodic polarization and hydrogen evolution on one surface of the metal. The hydrogen that diffuses through the thin piece of metal is oxidized on the opposite surface by applying anodic polarization. Special care must be taken to avoid alloy dissolution on this surface. Under steady-state conditions, Fick's first law for diffusion is satisfied (Ref 57, 58). The hydrogen oxidation current is termed the permeation current. For a known specimen thickness and a measured permeation current density, the product of the diffusion coefficient and the hydrogen concentration in the metal at the charging surface can be determined:

$$J = \frac{nFDC_H}{L} \quad \textbf{(Eq 17)}$$

where J is the permeation current, D is the diffusion coefficient, C_H is the subsurface hydrogen concentration, and L is the specimen thickness. Special transient techniques have been devised that allow individual determination of D and C_H (Ref 58).

Evaluation of Alloy Sensitization. Measurement of the quantity of coulombs generated during the electrochemical polarization of a material from the passive range to the active corrosion potential can be used to detect the susceptibility to intergranular attack associated with the precipitation of chromium carbides and chromium nitrides at grain boundaries (Ref 59, 60, 61, 62). A modification of this procedure, called the double-loop test (Ref 63, 64), involves polarizing the metal surface initially from the open-circuit potential in the active region to a potential in the passive range. Both variations of the method are illustrated in Fig. 12. This is followed by reverse polarization in the opposite direction back to the open-circuit potential. In this method, the degree of sensitization is determined by taking the ratio of the maximum current generated in the reactivation, or reverse, scan to that generated in the initial anodic scan (I_r/I_a). The rationale for this procedure is contingent on the presence of current upon the reactivation scan that results mainly from incomplete passivation of the region adjacent to the grain boundaries because of chromium depletion. For nonsensitized material, the passive film remains essentially intact during the reverse scan, and the size of the reactivation polarization peak remains small. As a result, the charge Q is small. In one study, the charge was normalized by the grain-boundary area (GBA) because this is the area from which most of the current arises in the single reactivation scan (Ref 62):

$$P = \frac{Q}{\text{GBA (coulombs/cm}^2)} \quad \textbf{(Eq 18)}$$

$$\text{GBA} = A_s \; [5.0954 \; \times \quad \textbf{(Eq 19)}$$

$$10^{-3} \cdot \exp(0.34696 \cdot X)]$$

where P is the reaction charge density associated with the sensitized area. A_s is the specimen surface area, and X is the ASTM grain size. The same procedure was used for the ratio I_r/I_a (Ref 64). That is to say, the current peak, I_r, for the reactivation scan was normalized for the grain-boundary area as shown above, while the initial anodic current peak was normalized for the wetted surface area, A_s. The resulting expression is as follows:

$$\frac{i_r}{i_a} = \frac{I_r}{I_a}[5.0954 \times 10^{-3} \cdot \exp(0.34696 \cdot X)] \quad \text{(Eq 20)}$$

A number of investigators have correlated this electrochemically derived ratio with optical metallographic evaluations of the degree of material sensitization such as those outlined in ASTM A 262 (Ref 65). This has been accomplished for several different iron-nickel-chromium alloys (Ref 66, 67, 68). The technique is nondestructive.

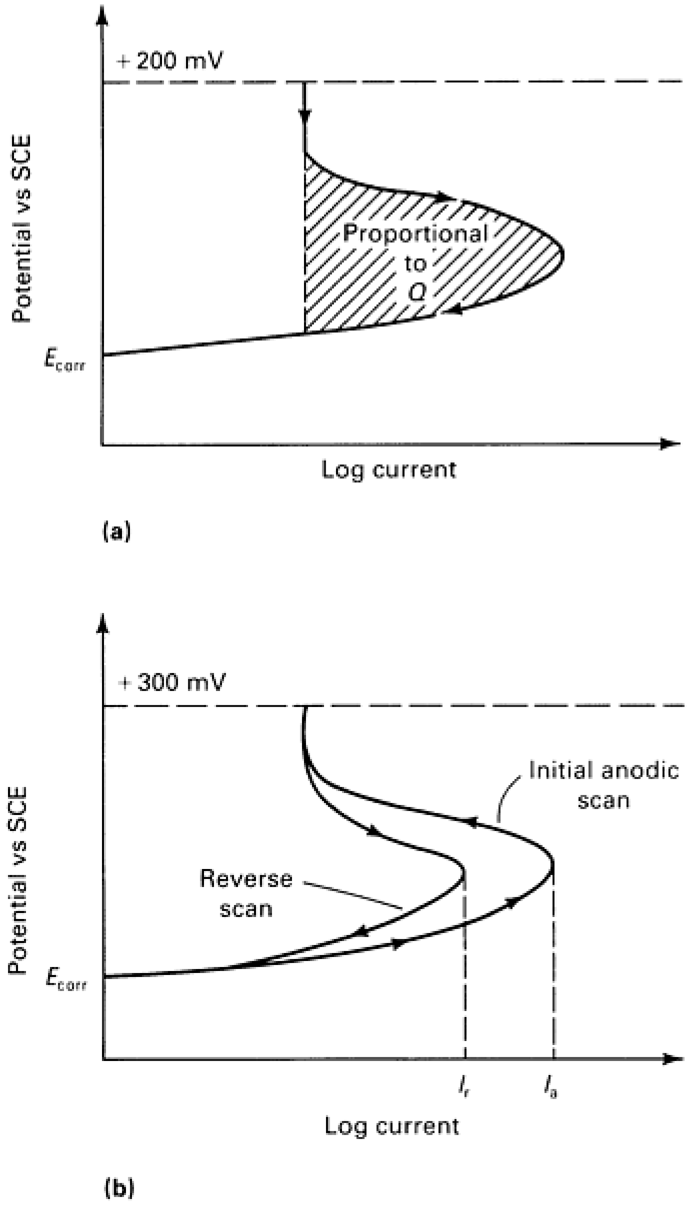

Fig. 12 Schematics of two procedures for anodic reactivation polarization testing. (a) Clarke *et al.* method (Ref 59, 60, 61, 62). (b) Akashi method (Ref 63, 64).

Electrochemical Evaluation of Protective Coatings and Films

Numerous ac and dc electrochemical methods have been used to study the performance and the quality of protective coatings, including passive films on metallic substrates, and to evaluate the effectiveness of various surface pretreatments. Several are discussed below.

Anodized Aluminum Corrosion Test. One such method is the Ford anodized aluminum corrosion test (FACT) (Ref 69, 70). This test involves the cathodic polarization of the anodized aluminum surface by using a small cylindrical glass clamp-on cell and a special 5% NaCl solution containing cupric chloride ($CuCl_2$) acidified with acetic acid. A large voltage is applied across the cell by using a platinum auxiliary electrode. The alkaline conditions created by the cathodic polarization promote dissolution at small defects in the anodized aluminum. The coating resistance is decreased, more current begins to flow, and the voltage decreases. The cell voltage (auxiliary electrode to test specimen voltage) is monitored for 3 min, and the parameter cell voltage multiplied by time is recorded. The ASTM standard B 538 describes the method in greater detail (Ref 69).

A similar test, known as the cathodic breakdown test, involves cathodic polarization to -1.6 V (versus saturated calomel electrode, SCE) for a period of 3 min in acidified NaCl. Again, the test was designed for anodized aluminum alloys because the alkali created at the large applied currents will promote the formation of corroded spots at defects in the anodized film.

The electrolytic corrosion test was designed for electrodeposits of principally nickel and chromium on less noble metals, such as zinc or steel (Ref 71, 72, 73). Special solutions are used, and the metal is polarized to +0.3 V versus the standard calomel electrode. The metal is taken through cycles of 1 min anodically polarized and 2 min unpolarized. An indicator solution is then used to detect the presence of pits that penetrate to the substrate. Each exposure cycle simulates 1 year of exposure under atmospheric-corrosion conditions. The ASTM standard B 627 describes the method in greater detail (Ref 74).

The paint adhesion on a scribed surface (PASS) test involves the cathodic polarization of a small portion of painted metal. The area exposed contains a scribed line that exposes a line of underlying bare metal. The sample is cathodically polarized for 15 min in 5% NaCl. At the end of this period, the amount of delaminated coating is determined from an adhesive tape pulling procedure.

The impedance test for anodized aluminum (ASTM B 457) is used to study the seal performance of anodized aluminum (Ref 75, 76, 77). In this sense, the test is similar to the FACT test except that this method uses a 1-V root mean square 1-kHz signal source from an impedance bridge to determine the sealed anodized aluminum impedance. The test area is again defined with a portable cell, and a platinum or stainless steel auxiliary electrode is typically used. The sample is immersed in 3.5% NaCl. The impedance is determined in ohms $\times 10^3$. The ASTM standard B 457 covers this technique (Ref 75). In contrast to the methods discussed above, this test is essentially nondestructive and does not accelerate the corrosion process.

Electrochemical impedance spectroscopy, also known as the electrochemical impedance technique, offers an advanced method of evaluating the performance of metallic coatings (passive film forming or otherwise) and organic barrier coatings (Ref 78, 79, 80, 81, 82, 83). The method does not accelerate the corrosion reaction and is nondestructive. The technique is quite sensitive to changes in the resistive-capacitive nature of coatings.

It is also possible to monitor the corrosion rate with this technique. In this respect, the electrochemical impedance technique offers several advantages over dc electrochemical techniques in that the polarization resistance related to the corrosion rate can be separated from the high dc resistance of the dielectric coating. This is not possible with the dc methods.

Because of the broad bandwidth in frequencies for the applied signal (usually from the mHz range to the kHz range), the electrochemical impedance technique also surpasses the capabilities of single-frequency impedance methods. The reason for this lies in the capability of the electrochemical impedance technique to discriminate between the resistive properties of the coating or passive film because of its weak ionic and or electronic conductance and the capacitive nature of the

passive film or coating due to its dielectric constant, area, and thickness. A single-frequency technique depends exclusively on the *a priori* assumption that the frequency of measurement provides only resistive or capacitive (in phase or out of phase) information. What is more probable, however, is that the impedance determined at the single frequency is a combined resistive-capacitive response. Although impedance circuit models may become quite complex compared to the model shown in Fig. 5, frequency regimes in which information is primarily revealed on the coating capacitance or coating resistance can be separated from one another and analyzed independently by using a broad frequency bandwidth. If the coating or passive film capacitance can be determined and if the dielectric constant is known, then the film thickness can be estimated for a given exposed area:

$$C = \frac{\epsilon \cdot \epsilon^{\circ} A}{d} \quad \textbf{(Eq 21)}$$

where *A* is the surface area, *d* is the dielectric thickness, and $\epsilon$is the electric permittivity of free space (8.854×10^{-12} F/m). In addition to this correlation, the uptake of water in an organic coating can be monitored because the dielectric constant for water is over an order of magnitude greater than the dielectric constant for the dry organic coating. The quantity of water absorbed in the organic coating can also be estimated as follows (Ref 82):

$$\text{vol\% } H_2O = \frac{100 \cdot \log\left(\frac{C_t}{C_0}\right)}{\log(79)} \quad \textbf{(Eq 22)}$$

where C_t, is the coating capacitance at time *t*, and C_0 at time zero when the exposure begins.

The coating resistance can also be monitored as a function of exposure time. Large decreases signify permeation of ionic species through the coating or the presence of defects in the coating itself.

Limitations of Electrochemical Tests

Despite this impressive range of applications, electrochemical techniques are not always successful, and it is instructive at this point to identify some of the more general reasons for this situation. First and most obvious is the requirement that the corrosion process be electrochemical. Three more specific keys to successful application of these techniques include the implementation of relevant environment, relevant alloy and surface preparation, and relevant mechanical perturbations. Without these essential features, any electrochemical test designed to simulate, for example, a chemical plant process stream will be destined for failure. More subtle but equally important is the necessity that any acceleration of the corrosion process act only upon the prevailing mechanism of corrosion under normal nonaccelerated conditions. In summary, careful application of electrochemical methods used in conjunction with other test procedures can be a tremendous aid in solving corrosion problems.

Immersion Tests

Donald O. Sprowls Consultant

Complete immersion of test specimens in a corrosive solution would appear to be a simple test indeed; however, in actuality, a number of test conditions must be controlled to ensure adequate reproducibility of test results. The actual conditions of the test will usually be determined by the nature of the problem at hand, the ingenuity of the investigator, and the budget of the test program. The following information is presented as a guide so that some of the pitfalls of such testing may be avoided.

The methods and procedures described are concerned with the basic factors that must be considered in sophisticated test procedures as well as in the simple tests that are discussed. Primary consensus standards for immersion corrosion testing of metals have been developed by ASTM (Ref 84) and the National Association of Corrosion Engineers (NACE) (Ref

85), from which must of this information has been taken. Additional details can be found in the actual standards and in the other references cited in this section.

For proper planning of the test and interpretation of the test results, the specific influences of the following variables must be considered: solution composition, temperature, aeration, volume, velocity, and waterline effects; specimen surface preparation; method of immersion of specimens; duration of test; and method of cleaning specimens at conclusion of the exposure.

Total Immersion

Composition of Solution. Test solutions should be accurately prepared from chemicals that conform to the Specifications of the Committee on Analytical Reagents of the American Chemical Society* and from distilled water, except in those cases in which naturally occurring solutions or solutions taken directly from some plant process are used. The composition of the test solutions should be controlled to the fullest extent possible. They should also be described as completely and as accurately as possible when the results are reported.

Evaporation losses can be controlled by a constant level device or by frequent addition of appropriate solution to maintain the original volume within ±1%. The use of a reflux condenser ordinarily precludes the necessity of adding to the original kettle charge.

The composition of the test solution sometimes changes as a result of catalytic decomposition or by reaction with the test coupons. These changes should be determined if possible. Where required, the exhausted constituents should be added or a fresh solution provided during the course of the test. If problems are suspected, the composition of the test solutions should be checked by analysis at the end of the test to determine the extent of change in composition, such as might result from evaporation or depletion.

Corrosion products from the coupon may influence the corrosion rate of the metal or the corrosion rate of different metals exposed at the same time. For example, the accumulation of cupric ions in the testing of copper alloys in intermediate strengths of H_2SO_4 will accelerate the corrosion of copper alloys, as compared to the rates that would be found if the corrosion products were continually removed. Cupric ions may also exhibit a passivating effect on stainless steel coupons exposed at the same time. It is generally advisable to expose only alloys of the same general type in the testing apparatus.

Temperature of Solution. Perhaps the single most important factor in corrosion is the effect of temperature. Accordingly, the temperature of the surface of the specimen must be known because this is the corroding temperature. In many cases, corrosion increases rapidly with temperature. An example is the corrosion of type 303 stainless steel by nitric acid (HNO_3), as shown in Table 1. Corrosion increased from a low rate (<0.5 mm/yr or 20 mils/yr) to several thousand mils per year as a result of increasing the temperature 65 °C (120 °F). For some corrosion systems, there can be a double effect. For example, the corrosion rate of Monel alloy in air-saturated H_2SO_4 solutions increases exponentially with rising temperature to a maximum at 80 °C (175 °F) and then decreases with further increases in temperature because of the decrease in oxygen concentration (Fig. 13).

Table 1 Effect of temperature on corrosion of type 303 stainless steel by 65% HNO_3

Temperature		Corrosion rate	
°C	**°F**	**mm/yr**	mils/yr
Up to 120	250	<0.5	**<20**
125	260	2.5	**100**
135	280	5.0	**200**

160	320	12.5	**500**
165	330	25	**1000**
185	**370**	**125**	**5000**

Source: Ref 85

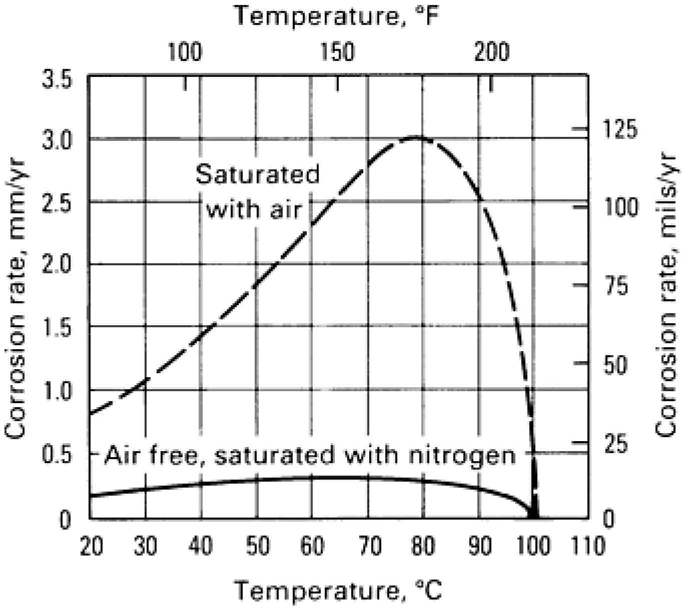

Fig. 13 Effect of temperature on the corrosion of Monel in 5 to 6% H_2SO_4. Solution velocity: 4.7 to 5 m/min (15.5 to 16.5 ft/min). Source: Ref 87 and 88

Laboratory tests are often conducted in controlled-temperature water or oil baths. The temperature of the corroding solution should be controlled within ±1 °C (±1.8 °F) and must be stated in the report of test results.

If no specific temperature, such as boiling point, is required or if a temperature range is to be investigated, the selected temperatures used in the test, as well as their respective durations, must be reported. Tests at ambient temperature should be conducted at the highest temperature anticipated. The variation in temperature should also be reported.

Accelerated corrosion tests are often conducted at temperatures above proposed operating temperatures in order to decrease the time of testing. This procedure is dangerous because the effect of temperature may be great, resulting in the elimination of more economical materials.

A common error involves the assumption that the environment temperature is the corroding temperature. This is particularly true in the case of materials for heating surfaces. The average temperature of the liquid in a tank may be 65 °C (150 °F), but the corroding or surface temperature of the steam heating coil will be considerably higher. Therefore, tests conducted at 65 °C (150 °F) may provide erroneous results. Surface temperatures can often be estimated by considering heat transfer coefficients.

Recent research has shown that dissolution of borosilicate glass vessels in distilled water at temperatures above 60 °C (140 °F) significantly lowers the corrosion rate of low-carbon steel. The method of aerating the solution is also important. A new test apparatus has been designed in which the above problems have been overcome and other parameters are capable of more precise control (Ref 89).

Aeration of Solution. Aeration or the presence of dissolved oxygen in a liquid environment can profoundly influence corrosion rates. Accordingly, this factor should be carefully considered in a corrosion test program. In general, some metals and alloys are more rapidly attacked in the presence of oxygen, but others may show better corrosion resistance. Although this discussion is primarily concerned with the oxidizing effects of aeration, these effects could also be produced by other oxidizing agents. Figure 14 shows a generalized picture of several materials in different environments.

Fig. 14 Effect of solution oxidizing capacity on corrosion rates of various metals. Source: Ref 86

Figure 13 also shows the effect of aeration and deaeration on Monel. An interesting feature is the rapid decrease in corrosion as the temperature approaches boiling. The rates at the boiling points are essentially the same under the two conditions of test. The reason for this behavior is that the solubility of oxygen in boiling water or dilute aqueous solutions

is practically nil. This feature is of interest from the practical standpoint because a boiling test is more convenient to conduct than one at, for example, 80 °C (175 °F). The operator might think that he would accelerate the test by running it at boiling, but he may actually misinterpret the results by so doing.

Unless specified, the solution should not be aerated. Most tests related to process equipment should be conducted with the natural atmosphere inherent in the process, such as the vapors of the boiling liquid. If aeration is used, the specimens should not be located in the direct air stream from the sparger. Extraneous effects can be encountered if the air stream impinges on the specimens.

The simplest and most widely used aeration method consists of bubbling air through the solution. The solution is then assumed to be saturated with air. In most practical applications, air is involved; therefore, air is used in the test. If air is not bubbled through the solution, the aeration effect depends on the air present in the solution at the start of the test and on its rate of removal or escape, if any. Air can also be absorbed from the atmosphere over the solution.

If oxygen saturation of the test solution is desired, this can best be achieved by sparging with oxygen. Appropriate precautions should be taken when oxygen-rich gases are used; many materials burn violently in pure oxygen. For other degrees of aeration, the solution should be sparged with synthetic mixtures of air or oxygen with an inert gas.

If complete exclusion of dissolved oxygen is necessary, specific techniques, such as prior heating of the solution and sparging with an inert gas (usually nitrogen), are required. A liquid atmospheric seal is often used on the test vessel to prevent air ingress.

Volume of Solution. The volume of the test solution should be large enough to avoid any appreciable change in its corrosivity during the test through exhaustion of corrosive constituents or by accumulation of corrosion products that may affect further corrosion. Two examples of a recommended minimum solution volume to specimen area ratio are 200 L/m^2 of specimen surface when detecting susceptibility to intergranular attack to austenitic stainless steel (Ref 90) and 100 L/m^2 of specimen surface when evaluating the exfoliation corrosion susceptibility of 5*xxx* aluminum alloys (Ref 91).

When the objective of the test is to determine the effect of a metal or alloy on the characteristics of the test solution (for example, to determine the effects of metals on dyes), it is desirable to reproduce the ratio of solution volume to exposed metal surface that exists in practice. The actual time of contact of the metal with the solution must also be taken into account. Any necessary distortion of the test conditions must be considered when interpreting the results.

Solution Velocity. The effect of velocity is not usually determined in normal laboratory tests, although specific tests have been designed for this purpose (Ref 87, 92). However, for the sake of reproducibility, some velocity control is desirable. Tests at the boiling point should be conducted with the least heat input possible, and boiling chips should be used to avoid excessive turbulence and bubble impingement. In tests conducted below the boiling point, thermal convection is generally the only source of liquid velocity. In test solutions with high viscosities, supplemental controlled stirring is recommended.

Method of Supporting Specimens. The supporting device and container should not be affected by or cause contamination of the test solution. The method of supporting specimens varies with the apparatus used for conducting the test, but should be designed to insulate the specimens from each other physically and electrically and to insulate the specimens from any metallic container or supporting device used within the apparatus.

The shape and form of the specimen support should ensure free contact of the specimen with the corroding solution, the liquid lines or the vapor phase (Fig. 15). If clad alloys are exposed, special procedures, such as coating of edges, will be required to ensure that only the cladding is exposed, unless the purpose is to test the ability of the cladding to protect cut edges. Common supports include glass or ceramic rods, glass saddles, glass hooks, fluorocarbon plastic strings, and various insulated or coated metallic supports.

Source: Ref 84

In aqueous solutions under 1 atm of air or oxygen, it is desirable to position all specimens so that the oxygen supply is similar. This is especially important with corrosion systems in which the corrosion rate may be fairly high, such as for iron and steel in neutral salt solutions. In such tests, totally immersed specimens at a depth less than 20 mm (0.8 in.) had markedly higher corrosion rates, but with deeper immersion, the rate was lower and variations in depth were unimportant (Ref 93). More detailed discussion of the factors that can affect corrosion behavior in immersion tests can be found in Ref 87.

Partial Immersion

Laboratory tests under conditions of partial immersion are of practical importance because such conditions are commonly found in service. Tests conducted in three locations in a resin flask, as shown in Fig. 15, can be used to determine the relative susceptibility of a material to localized corrosion at the liquid line. Partial-immersion conditions provide a very suitable accelerated test for such metals as aluminum alloys and others that develop concentrated attack at the liquid line (or splash zone in certain equipment).

Intermittent Immersion

The term intermittent immersion refers to alternate immersion and emersion in a liquid corrodent. The conditions are of practical importance because they simulate, for example, the effects of the rise and fall of tidal waters and the movements of corrosive liquids in chemical plants. Also, they may provide a relatively rapid test for the effect of aqueous solutions because a thin film of the solution, frequently renewed and almost saturated with oxygen, can be maintained on the test specimen during most of the period of exposure, even when the shape of the specimen is complex. Reference 87 contains a detailed discussion of the rather considerable research that has been done on various alternate immersion cycles and drying conditions for tests of both ferrous and nonferrous alloys.

To simulate service conditions, the specimens should be dry before reimmersion because this has an important effect on the protective character of films on the metal. For maximum corrosion, this drying should be done slowly so that the film of the corrodent on the metal can be allowed the maximum time to act during immersion. In the interest of reproducibility, it is desirable to control the humidity and temperature of the atmosphere in order to ensure a constant rate of drying in successive cycles. When more thorough drying of the specimen is desired, forced-air circulation or radiant heating can be used to accelerate the drying. Artificial heating adds to the complexity of the test conditions, however, and may reduce the reproducibility of the test if it is not very carefully controlled.

Alternate Immersion in 3.5% NaCl. The conditions of this test that have gained the most widespread acceptance, particularly in the United States, are those described in ASTM G44 (Ref 94). This practice utilizes a 1-h cycle that includes a 10-min period of immersion in an aqueous solution of 3.5% NaCl or in substitute ocean water, followed by a 50-min emersion period. This 1-h cycle is continued 24 h/day for the test duration required for the particular test material. Aluminum and steel alloys are typically exposed from 10 to 90 days or longer, depending on the resistance of the alloy to corrosion by saltwater. Although this alternate-immersion test is considered to be an accelerated test representative of certain natural conditions (particularly marine environments), it is not intended to relate to specialized chemical environments.

Air circulation is an important consideration because it affects the rate at which specimens dry and the loss of water by evaporation from the salt solution. The most important consideration consists of achieving moderate specimen drying conditions. Because various testing facilities use different immersion apparatuses and room sizes, individual experimentation is necessary to achieve adequate circulation. A mild circulation of air is recommended.

Specimen Drying. As with air circulation, no fixed procedure has been established and probably cannot be unless a standardized immersion apparatus and test chamber are adopted. The objective, however, is to ensure that all specimens dry slowly during the 50-min emersion period. Because they drain differently, specimens with different accrued corrosion films with dry at different rates. New specimens with little accumulated corrosion products become dry in about 15 min, but other specimens with an accumulation of corrosion product and salt should be allowed about 40 min to dry.

Apparatus. The usual methods of immersion involve:

- Placing specimens on a movable rack that is periodically lowered into a stationary tank containing the solution (Fig. 16)
- Placing specimens on a hexagonal Ferris wheel arrangement that rotates every 10 min through 60° and thus passes the specimens through a stationary tank of solution
- Placing specimens in a stationary tray open to the atmosphere and having the solution moved by air pressure, nonmetallic pump, or gravity drain from a reservoir to the tray

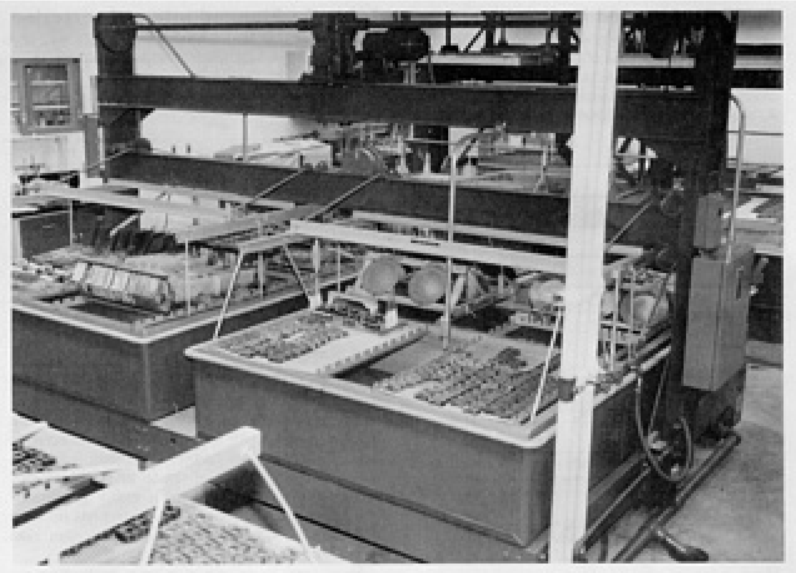

Fig. 16 Lift-type alternate-immersion apparatus. Specimens shown are in the emersion position, where they remain for 50 min. They are then lowered into the tanks of saltwater for 10 min to complete the 1-h cycle. Many shapes and sizes of specimens can be tested in this large equipment. Courtesy of the Aluminum Company of America.

Rate of Immersion. The rate of immersion and removal of the specimens from the solution should be as rapid as possible without jarring them. For purposes of standardization, an arbitrary limit shall be adopted such that no more than 2 min elapse from the time the first portion of any specimen is covered or uncovered by solution.

Materials of construction that contact the salt solution shall be such that they are not affected by the corrodent to an extent that they can cause contamination of the solution and change its corrosiveness. Use of inert plastics or glass is recommended where feasible. Metallic materials of construction should be selected from alloys that are recommended for marine use and are of the same general type as the metals being tested. Preferably, all metal parts should be protected with a suitable corrosion-resistant coating.

Specimen holders should be designed to electrically insulate the specimens from each other and from any other bare metal. When this is not possible, as with certain stressing bolts or jigs, the bare metal contacting the specimen should be isolated from the corrodent by a suitable coating. Protective coatings should be of a type that will not leach inhibiting or accelerating ions or protective oils over the noncoated portions of the specimen. Coatings containing chromates should be avoided. They should not obstruct air flow over the specimens, which retards the drying rate.

Solution Conditions. The salt solution shall be prepared by dissolving 3.5 ± 0.1 parts by weight of NaCl in 96.5 parts of water. Reagent grade NaCl shall be used for conformance to the specifications of the Committee on Analytical Reagents of the American Chemical Society. Distilled or deionized water shall be used for compliance with the purity requirements of ASTM D 1193, Type IV, reagent water (Ref 95).

When tests are to be made in substitute ocean water, it shall be prepared without heavy metals in accordance with ASTM D 1141 (Ref 96). An advantage of the substitute ocean water in the case of stress-corrosion tests of certain high-strength aluminum alloys is that it causes less severe pitting than the 3.5% NaCl solution. It may be preferred in certain other cases because the test results do (or are thought to) relate better to real marine environments.

Temperature. A freshly prepared solution should be allowed to come within 3 °C (5 °F) of the specified air temperature before being used. Thereafter, no control is required on the solution temperature. Instead, the air temperature is controlled, and the solution is allowed to reach temperature equilibrium.

Minimum Volume. The volume of the test solution should be large enough to avoid any appreciable change in its corrosiveness through exhaustion of corrosive constituents or through the accumulation of corrosion products or other constituents that might significantly affect further corrosion. An arbitrary minimum ratio between the volume of the test

solution and the surface area of the specimen(s) (including any uncoated accessories) of 320 L/m^2 (7.9 gal/ft^2) is recommended.

Air Conditions. The air temperature shall be maintained at 27 ± 1 °C (80 ± 2 °F). The percent relative humidity shall be controlled at 45 ± 6%.

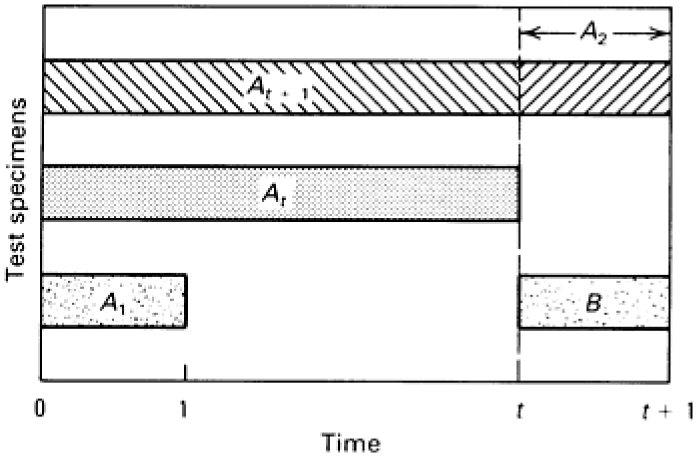
Specimen Preparation and Duration of Tests

The type, size, and shape of specimens will vary with the purpose of the test, the nature of the test materials, and the apparatus used. Standard practices for preparing, cleaning, and evaluating corrosion test specimens are provided in ASTM G 1 (Ref 97). Proper selection of appropriate lengths of exposure is important for any corrosion test, and misleading results may be obtained if the time factor is not considered. An excellent technique for investigating changes in corrosion rate with length of exposure is described below (Ref 84, 85, 86, 98).

Planned interval tests involve the accumulated effects of corrosion at several times under a given set of conditions as well as the initial rate of corrosion of fresh metal, the more or less instantaneous corrosion rate of metal after long exposure, and the initial corrosion rate of fresh metal during the same period of time as the latter. The rates, or damage in unit time interval, are shown in the diagram in Table 2 as A_1, A_2, and B, respectively. Unit time interval can often be taken conveniently as 1 day in a planned interval test extended over a total period of several days. It would be desirable to have duplicate specimens for each interval. Further time extensions of the test should be made with similar added specimens and interval spacing if no changes occurred in the corrosion rate of the metal or the corrosiveness of the liquid during the first selection of test duration.

Table 2 Planned interval test

Identical specimens are placed in the same corrosive liquid; imposed conditions of test are constant for the entire time (t + 1); A_1, A_t, A_{t+1}, B, represent the corrosion damage experienced by each test specimen; A_2 is a calculated value obtained by subtracting A_t from A_{t+1}.



Corrosivity	Observed weight changes during corrosion testing	Criteria
Liquid corrosiveness	Unchanged	$A_1 = B$
	Decreased	$B < A_1$
	Increased	$A_1 < B$
Metal corrodibility	Unchanged	$A_2 = B$

	Decreased	$A_2 < B$
	Increased	$B < A_2$

Combinations of situations		
Liquid corrosiveness	**Metal corrodibility**	Criteria
Unchanged	Unchanged	$A_1 = A_2 = B$
Unchanged	Decreased	$A_2 < A_1 = B$
Unchanged	Increased	$A_1 = B < A_2$
Decreased	Unchanged	$A_2 = B < A_1$
Decreased	Decreased	$A_2 < B < A_1$
Decreased	Increased	$A_1 > B < A_2$
Increased	Unchanged	$A_1 < A_2 = B$
Increased	Decreased	$A_1 < B > A_2$
Increased	**Increased**	$A_1 < B < A_2$

Comparison for corrosion damage A_1 for the unit time interval from 0 to 1, with corrosion damage B for the unit time interval from t to $t + 1$, shows the magnitude and direction of change in the corrosivity of the liquid that may have occurred during the total time of the test. Correspondingly, comparison of A_2 with B, where A_2 is the corrosion damage calculated by subtracting A_t from A_{t+1}, shows the magnitude and direction of change in corrodibility of the metal specimen during the test. These comparisons can be taken as criteria for the changes and are tabulated in Table 2. Also given in Table 2 are the criteria for all possible combinations of changes in the corrosivity of the liquid and corrodibility of the metal. The additional information obtained on occurrences in the course of the test justifies the additional effort involved. Table 3 lists the data obtained from a planned interval test of a carbon steel specimen in an aluminum chloride ($AlCl_3$)-antimony trichloride ($SbCl_3$) solution.

Table 3 Planned interval corrosion test

Duplicate strips of low-carbon steel (19 × 75 mm, or $\frac{3}{4}$ × 3 in.) were immersed in 200 mL of 10% $AlCl_3$-90% $SbCl_3$ mixture through which dried hydrogen chloride gas was slowly bubbled at atmospheric pressure. Temperature: 90 °C (195 °F)

Value	**Interval, days**	**Weight loss, mg**	**Penetration**		Apparent corrosion rate	
			μm	**mils**	**mm/yr**	mils/yr
A_1	0-1	1080	42.9	1.69	15.7	**620**
A_t	0-3	1430	56.9	2.24	6.8	**270**
A_{t+1}	0-4	1460	58.2	2.29	5.3	**210**
B	3-4	70	2.8	0.11	1.02	**40**
A_2	calculated 3-4	30	1.3	0.05	0.46	**18**
$A_2 < B < A_1$						
0.05 < 0.11 < 1.69						

Conclusions: Liquid markedly decreased in corrosiveness during the test, and the formation of a partially protective scale on the steel was indicated; that is, metal became less corrodible.

The causes for the changes in corrosion rate as a function of time are not given by the planned interval test criteria. The corrosivity of the liquid may decrease as a result of corrosion during the course of a test because of the reduction in concentration of the corrosive agent, the depletion of a corrosive contaminant, the formation of inhibiting products, or other metal-catalyzed changes in the liquid. The corrosivity of the liquid may increase because of the formation of autocatalytic products, the destruction of corrosion-inhibiting substances, or other catalyzed changes in the liquid. Changes in the corrosiveness of the liquid may also arise from changes in composition that would occur under the test conditions even in the absence of metal. To determine if the latter effect occurs, an identical test is run without test strips for the total time, *t*. Test strips are then added, and the test is continued for unit time interval. Comparison with A_1 of corrosion damage from this test shows if the corrosive character of the liquid changes significantly in the absence of metal.

The corrodibility of the metal in a test may decrease as a function of time because of the formation of protective scale or the removal of a less resistant surface layer of metal. Metal corrodibility may increase because of the formation of corrosion-accelerating scale or the removal of a more resistant surface layer of metal. Indications of the causes of changes in corrosion rate can often be obtained from close observation of tests and corroded specimens as well as from special supplementary tests designed to reveal effects that may be involved.

Changes in liquid corrosiveness are not a factor in most plant tests that consist of once-through runs or where large ratios of solution volume to specimen area are involved. If the effect of corrosion on the mechanical properties of the metal or alloy is under consideration, a set of unexposed specimens is needed for comparison purposes.

Lengthy corrosion tests are generally not necessary to obtain accurate corrosion rates from materials that undergo severe corrosion. However, there are cases in which this assumption is not valid. For example, lead exposed to H_2SO_4 initially corrodes at an extremely high rate while building a protective film; the rates then decrease considerably so that further corrosion is negligible. The phenomenon of the formation of a protective film is observed with many corrosion-resistant

materials. Therefore, short tests on such materials would indicate a high corrosion rate and would be completely misleading.

Short-term tests can also give misleading results on alloys that form passive films, such as stainless steels. With borderline conditions, a prolonged test may be needed to permit the breakdown of the passive film and subsequent more rapid attack. Consequently, tests conducted for long periods are considerably more realistic than those conducted for short durations. This statement must be qualified by stating that corrosion should not proceed to the point at which the original specimen size or the exposed area is drastically reduced or the metal is perforated.

If anticipated corrosion rates are moderate or low, the following equation gives the suggested tests duration:

$$\text{Hours} = \frac{2000}{(\text{corrosion rate in mils/yr})}$$

For example, where the corrosion rate is 10 mils/yr (0.25 mm/yr), the test should run for at least 200 h. This method of estimating test duration is useful as an aid in deciding, after a test has been made, whether or not it is desirable to repeat the test for a longer period.

Reporting the Data

The importance of reporting all data as completely as possible cannot be overemphasized. Expansion of the testing program in the future or correlating the results with tests of other investigators will be possible only if all pertinent information is properly recorded. The following checklist is a recommended guide for reporting all important information and data:

- Corrosive media and concentration (and any changes during test)
- Volume of test solution
- Temperature (maximum, minimum, and average)
- Aeration (describe conditions or technique)
- Agitation (describe conditions or technique)
- Type of apparatus used for test
- Duration of each test
- Chemical composition or trade name of metals tested
- Form and metallurgical conditions of specimens
- Exact size, shape, and area of specimens
- Treatment used to prepare specimens for test
- Number of specimens of each material tested, and whether specimens were tested separately or which specimens were tested in the same container
- Method used to clean specimens after exposure and the extent of any error expected by this treatment
- Initial and final masses and actual mass losses for each specimen
- Evaluation of attack if other than general, such as crevice corrosion under support rod, pit depth and distribution, and results of microscopical examination or bend tests
- Corrosion rates for each specimen
- Minor occurrences or deviations from the proposed test program often can have significant effects and should be reported if known

Salt Spray Testing

Norman B. Tipton, The Singleton Corporation

Salt spray tests have been used for over 80 years as accelerated tests for determining the corrodibility of nonferrous and ferrous metals as well as the degree of protection afforded by both inorganic and organic coatings on a metallic base (Ref 99). This procedure has been extensively discussed since its inception because of the reproducibility variances and the questionable correlation of results as related to actual service performance. The primary objective is to provide an easily performed acceptance standard for comparing the performance of materials and coatings.

Many revisions to the salt spray test procedures and many improvements to the salt spray test cabinets have been made over the years through the joint efforts of the National Bureau of Standards, ASTM, equipment manufacturers, the automotive industry, and many governmental agencies. These revisions have eliminated many of the variables that have caused much of the criticism of this test procedure, with the result being a much more reliable and useful test. Even with the newly revised test procedures and modern designs of the salt spray test cabinets, there are still variables to be further investigated (Ref 99).

Applications of Salt Spray (Fog) Testing

The salt spray (fog) test has received its widest acceptance as a tool for evaluating the uniformity of thickness and degree of porosity of metallic and nonmetallic protective coatings, and it has served this purpose with a great deal of success. The test is useful for evaluating different lots of the same product, once a standard level of performance has been established, and it is especially helpful as a screening test for revealing a particularly inferior coating. In recent years, certain cyclic acidified salt spray (fog) tests have been implemented to test the resistance of aluminum alloys to exfoliation corrosion. The salt spray (fog) test is considered to be most useful as an accelerated laboratory corrosion test that simulates the effects of marine atmospheres on different metals, with or without protective coatings.

The most commonly used and accepted salt spray test methods in the United States are the various methods outlined in ASTM standards B 117 and G 85 (Ref 100, 101). Many of the governmental agencies and automotive companies have written their own standards and procedures, but in the interest of national standardization, these standards have been revised to conform with most of the details of ASTM. However, they still incorporate several statements relating to practices that experience has shown to be desirable or beneficial for achieving reliable, reproducible results and maximum correlation among laboratories.

Types of Salt Spray (Fog) Tests

The neutral salt spray (fog) test (ASTM B 117--Method 811.1 of Federal Test Method 151b) is perhaps the most commonly used salt spray test in existence for testing inorganic and organic coatings, especially where such tests are used for material or product specifications. The duration of this test can range from 8 up to 3000 h, depending on the product or type of coating. A 5% NaCl solution that does not contain more than 200 ppm total solids and with a pH range of 6.5 to 7.2 when atomized is used, and the temperature of the salt spray cabinet is controlled to maintain 35 + 1.1 or - 1.7 °C (95 + 2 or - 3 °F) within the exposure zone of the closed cabinet.

The Acetic Acid-Salt Spray (Fog) Test (ASTM G 85, Annex A1; Former Method B 287) is also used for testing inorganic and organic coatings, but is particularly applicable to the study or testing of decorative chromium plate (nickel-chromium or copper-nickel-chromium) plating and cadmium plating on steel or zinc die-castings and for the evaluation of the quality of a product.

This test can be as brief as 16 h, although it normally ranges from 144 to 240 h or more. As in the neutral salt spray test, a 5% NaCl solution is used, but the solution is adjusted to a pH range of 3.1 to 3.3 by the addition of acetic acid, and again, the temperature of the salt spray cabinet is controlled to maintain 35 + 1.1 or - 1.7 °C (95 + 2 or - 3 °F) within the exposure zone of the closed cabinet.

The Copper-Accelerated Acetic Acid-Salt Spray (Fog) Test or CASS test, which is covered in ASTM B 368 (Ref 102), is primarily used of the rapid testing of decorative copper-nickel-chromium or nickel-chromium plating on steel and zinc die-castings. It is also useful in the testing of anodized, chromated, or phosphated aluminum. The duration of this test ranges from 6 to 720 h. A 5% NaCl solution is used, with 1 g of copper II chloride ($CuCl_2 \cdot 2H_2O$) added to

each 3.8 L of salt solution. The solution is then adjusted to a pH range of 3.1 to 3.3 by adding acetic acid. The temperature of the CASS cabinet is controlled to maintain 49 + 1.1 or - 1.7 °C (120 + 2 or - 3 °F) within the exposure zone of the closed cabinet.

Other Standard Tests. Many new salt spray test procedures have been developed in the past 20 years in order to achieve tests that are more closely aligned with a specific application. These modifications include a cyclic acidified salt spray (fog) test (ASTM G 85, Annex A2), an acidified synthetic seawater spray (fog) test (ASTM G 85, Annex A3; Former Method G 43), and a salt/sulfur dioxide (SO_2) spray (fog) test (ASTM G 85, Annex A4). The cyclic acidified salt spray (fog) test and the acidified synthetic sea water spray (fog) test are both primarily used for the production control of exfoliation-resistant heat treatments for various aluminum alloys (Ref 103). The salt/SO_2 spray (fog) test is mainly used to test for the exfoliation corrosion resistance of various aluminum alloys and a wide range of nonferrous and ferrous materials and coatings, both inorganic and organic, when exposed to an SO_2-laden salt spray (fog). As more of these cyclic-type tests are used in the near future, the development of the required sophisticated testing cabinets will be required.

Types of Salt Spray Cabinets and Their Construction

Salt spray cabinets are available from many manufacturers and range in size from extremely small bench-top cabinets to large walk-in types. The small bench-top models are not practical; they have been found to be difficult to control and should be avoided. The larger walk-in types have been developed to be controlled capably, but they are very expensive.

The most commonly used cabinet is the top-opening type (Fig. 17), which can range in size from 0.25 to 4.5 m^3 (9 to 160 ft^3) and larger. The cabinet should be large enough to test the required number of parts adequately without overcrowding. Basic cabinets are made of plastic or, more commonly, of plastic-lined steel having no exposed metals or corrodible materials in the interior testing area. The cabinets consist of an air saturation tower with automatic level control, a salt solution reservoir with automatic level control, plastic atomizing nozzles that are suitably baffled or housed in a central fog generation tower with adequate internal baffling (Fig. 18), specimen supports, and provisions for heating the cabinet and the air saturation tower along with suitable controls for maintaining temperatures.

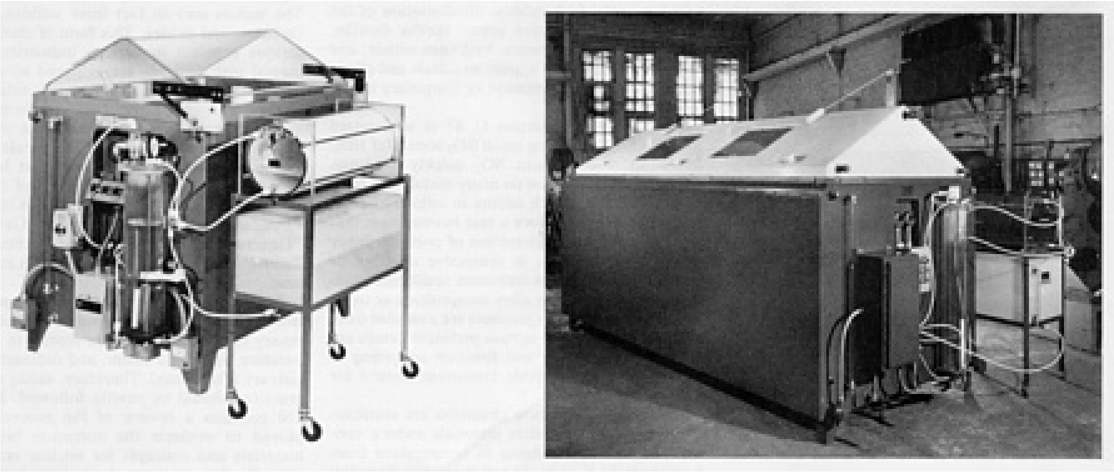


Fig. 17 Typical examples of top-opening salt spray cabinets with state-of-the-art features and pertinent accessories. Cabinets range in size from 0.25 to 4.5 m^3 (9 to 160 ft^3).

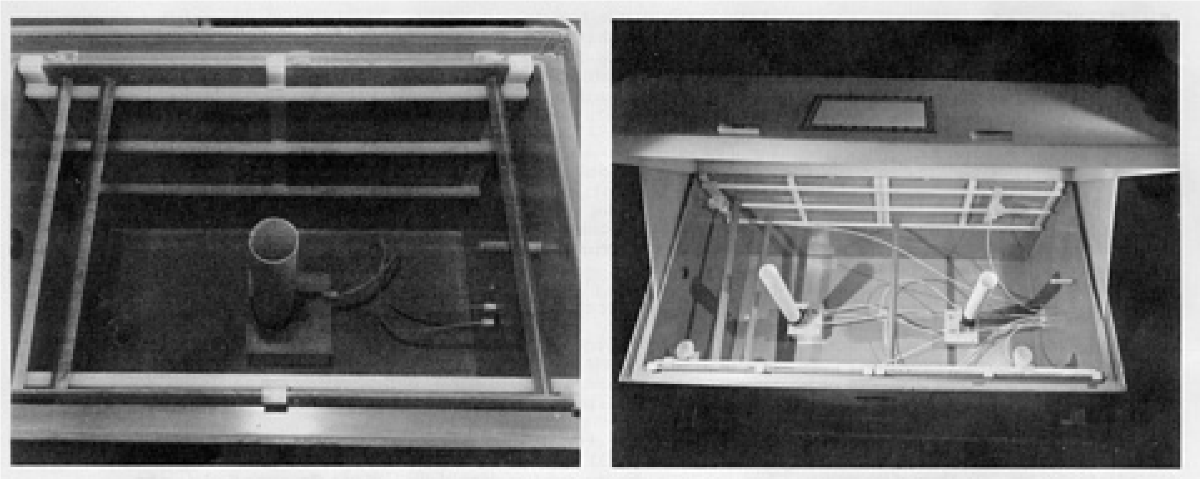

Fig. 18 Vertical-type dispersion towers are the most commonly used for ensuring an even distribution of a uniform free-falling salt mist (fog) over the test specimens. These typical dispersion towers are internally baffled and can be located in the most advantageous part of the cabinet. Single towers (left) are usually used in smaller cabinets up to 1.0 m^3, (36 ft^3), and multiple towers (right) are used in larger cabinets.

Miscellaneous Tests

Donald O. Sprowls, Consultant

There are a number of specialized corrosion tests that are very complex and can be given only brief mention in this article. These include tests in simulated atmospheres, tests in gases at elevated temperatures, aqueous corrosion tests at elevated temperatures, and tests conducted in liquid metals.

Simulated Atmospheres. Draft International Standard ISO 7384-1986 (E) describes general requirements for Corrosion Tests in artificial atmosphere (Ref 104). The corrosion processes are accelerated by intensifying such factors as temperature, relative humidity, condensation of the moisture, and corrosive agents (sulfur dioxide, chlorides, acids, ammonia, hydrogen sulfide, and so on). This standard applies to metals and alloys with and without permanent or temporary corrosion protection.

The ASTM designation G 87 is a standard practice for conducting moist SO_2 tests (Ref 105). Moist air that contains SO_2 quickly produces easily visible corrosion on many metals in a form resembling that which occurs in industrial environments. It is therefore a test environment that is well suited to the detection of pores or other sources of weakness in protective coatings as well as deficiencies in corrosion resistance associated with unsuitable alloy composition or treatments. Standard SO_2 chambers are available from several suppliers, but certain pertinent details are required before they will function according to this practice and provide consistent control for duplication of results.

Humidity-temperature chambers are commercially available for testing materials under a variety of conditions ranging in temperature from freezing to 65 °C (150 °F) and in relative humidity from 20 to 100% (Fig. 19). Such tests are commonly used for evaluating various nonmetallic materials of construction that are used in contact with metals, such as insulations and adhesives. An example is the Owens Corning Fiberglass test method C-02A (Ref 106). Versions of this test method have been used in product specifications, such as ASTM C 665 for mineral fiber blanket thermal insulation for wood frame and light construction buildings (Ref 107).

Fig. 19 Chambers for testing materials under a variety of temperature and humidity conditions. Courtesy of the Aluminum Company of America

The ASTM designation G 60 is a standard practice for conducting cyclic humidity tests (Ref 108). The procedure described is used to observe the behavior of steels under test conditions that retard the formation of a protective type of rust.

Tests in Gases at Elevated Temperatures. The deterioration of metals and alloys upon exposure to air or other gases at elevated temperatures is a specific type of corrosion that is commonly referred to as high-temperature oxidation. The metals may in fact form sulfides, nitrides, carbides, and oxides. This form of corrosion is a serious problem in various industries. Experimental test methods are required to study this phenomenon. Tests can elucidate kinetics, mechanisms, and chemistry; they can help develop more resistant alloys or qualify an alloy. The high-temperature oxidation of metals and the various oxidation test methods that have been used are extensively reviewed in Ref 109. Additional information is also available in the articles "Fundamentals of Corrosion in Gases" and "General Corrosion" (see the section "High-Temperature Oxidation/Sulfidation") in this Volume.

Aqueous Tests at Elevated Temperatures and Pressures. High-pressure equipment is necessary to conduct corrosion studies in high-temperature water and steam, and radioactive materials are often tested. Therefore, safety codes and practices should be strictly followed. Reference 110 contains a review of the procedures employed to evaluate the corrosion behavior of materials and concepts for nuclear reactor service. To date, two standards have been issued. The first is ASTM G 2, which addresses the testing of zirconium and zirconium alloys (Ref 111), and the second is NACE TM-01-71, which covers the autoclave corrosion testing of metals in high-temperature water (Ref 112). The NACE standard deals mainly with structural and pressure vessel materials, such as high-strength steel, stainless steel, and certain nickel-base alloys. Additional information on the evaluation of materials for nuclear reactor service can be found in the article "Corrosion in the Nuclear Power Industry" in this Volume.

Reference 113 describes testing in hot brine loops designed to provide quantitative information on corrosion rates that will be encountered during the desalination of seawater. The hot brine loop is essentially a device for circulating a heated 3.4% NaCl solution through tubular specimens or past flat specimens in order to determine the corrosion resistance of the alloy(s) under investigation. To accomplish this, the loop must possess certain characteristics. It must be chemically inert so as to prevent contamination of the brine by metal ions or by organic species. It must also be pressure tight, because it is usually operated above the atmospheric boiling point of water.

Liquid metals have large volumetric heat capacities, high heat transfer coefficients, and other properties that make them attractive as coolants for high-temperature nuclear reactors and in power generation systems that operate in conjunction with nuclear reactors. A comprehensive overview of the specialized test procedures required for testing the corrosiveness

of liquid metals is given in Ref 114. The ASTM standard G 68 covers the liquid sodium corrosion testing of metals and alloys (Ref 115). Additional information can be found in the articles "Fundamentals of High-Temperature Corrosion in Liquid Metals" and "General Corrosion" (see the section "Corrosion in Liquid Metals") in this Volume.

Evaluation of Uniform Corrosion

Charles A. Natalie, Department of Metallurgical Engineering, Colorado School of Mines

Introduction

TESTING FOR UNIFORM CORROSION can be broadly classified as laboratory long-term testing, laboratory accelerated testing, and service or field testing. Laboratory long-term testing usually consists of testing materials in simulated-service conditions on a relatively small scale. The advantage of this type of testing is that the tests can be controlled closely; thus, any unintentional disturbances that could occur during plant tests can be avoided. These tests usually attempt to simulate expected service conditions.

Accelerated laboratory tests, on the other hand, are short term in nature. They are designed to compare materials under severe conditions, and the test environment may not be directly related to the service environment. The environment and the test conditions must be carefully specified. The American Society for Testing and Materials (ASTM) has outlined standard methods for testing materials under accelerated conditions. These tests are usually for other modes of corrosion, such as stress-corrosion cracking, and are generally not applicable to uniform corrosion testing. Accelerated laboratory tests are described in other articles in this Section.

Service tests and plant tests involve placing test samples in actual service conditions for evaluation. The advantage of such testing is the use of the actual service environment. However, the problems involved in interrupting normal operations are also associated with this type of corrosion testing.

Uniform corrosion is one of the most common forms of corrosion; therefore, it must be designed for in many situations. The damage appears as the thickness of the metal decreases uniformly until failure occurs. Fortunately, uniform corrosion is usually easy to measure and predict; this facilitates proper design. The purposes of measuring uniform corrosion by experimental testing are:

- Evaluation and selection of materials for a specific environment or application
- Evaluation of metals and alloys to determine their effectiveness in new environments
- Routine testing to confirm the quality of materials
- Research and development

Experimental Measurements

In most cases, uniform corrosion rates are represented as a loss of metal thickness as a function of time. This value can be directly measured from experimental data, or as is often the case, it can be calculated from mass loss data. Mass loss is a measure of the difference between the original mass of the specimen and the mass when sampled after exposure. In measuring the mass after exposure it is important to remove any corrosion product adhering to the sample. This topic is discussed in more detail in the section "Sample Cleaning and Data Acquisition" in this article.

As mass loss is monitored, the reduction of thickness as a function of time can be calculated and monitored. Uniform corrosion rates are usually expressed as millimeters per year (mm/yr), mils per year (mils/yr), and/or inches per year (in./yr). A corrosion rate in mils per year can be calculated from weight loss data with the following expression:

$$\text{mils/yr} = \frac{534w}{dAt} \quad \textbf{(Eq 1)}$$

where w is weight loss in milligrams, d is metal density in grams per cubic centimeter (g/cm^3), A is area of exposure in square inches (in.^{2}), and t is exposure time in hours. Conversion factors for some common uniform corrosion rate units are given in Table 1.

Table 1 Relationships among some of the units commonly used for corrosion rates

d is metal density in grams per cubic centimeter.

Unit	Factor for conversion to					
	mdd	**g/m^2/d**	**μm/yr**	**mm/yr**	**mils/yr**	**in./yr**
Milligrams per square decimeter per day (mdd)	1	0.1	36.5/*d*	0.0365/*d*	1.144/*d*	0.00144/*d*
Grams per square meter per day (g/m^2/d)	10	1	365/*d*	0.365/*d*	14.4/*d*	0.0144/d

Other evaluations that are often included in testing for uniform corrosion include visual observations, ion concentration increase, hydrogen evolution, loss in tensile strength (according to ASTM G 50), and electrochemical testing. Initial observations in any corrosion testing should include visual observation of the corrosion activity because it is usually possible to observe the form of corrosion at low magnification. Visual evaluation can include reporting of the color or type of corrosion product as well as documentation with photographs.

In addition to the standard measurement of mass loss, the increase of metal ion in solution as the metal corrodes can be measured by analysis of samples of the corrodent removed periodically during the test (Ref 1). It may be possible to relate the increase in concentration to corrosion rate, depending on the structure of the test. In some cases, the amount of hydrogen generated in deaerated tests can be used to measure corrosion rates (Ref 2, 3).

Electrochemical tests can also be used to help evaluate corrosion rates. These methods are often successful in predicting uniform corrosion rates. Electrochemical methods include recording anodic and cathodic polarization curves, extrapolation of Tafel lines, and polarization break testing. Methods for conducting electrochemical tests include ASTM standards G 59, G 3, and G 5 (Ref 4). Reference 5 also explains some standard practices in this area, and electrochemical test methods are discussed in the article "Laboratory Testing" in this Volume.

Exposure Tests for Measuring Uniform Corrosion Rates

Sample Preparation. The first step in testing is the preparation of the samples. Clear and complete documentation of the test material is very important. This should include the chemical composition as well as the metallurgical treatment of the samples. Each sample should be clearly identified before testing.

For uniform corrosion testing, it is usually most convenient to use small test coupons. The size and shape of the test specimens are often specified in such a manner as to make them easy to handle and allow for ease of surface preparation.

Specimens that are 6.4 mm ($\frac{1}{4}$ in.) thick and a few inches square are not uncommon. For some materials, it is advisable to protect specimen edges and identification marks in order to avoid extraneous localized corrosion.

Before exposure to the corrosive medium, the test samples should be cleaned and weighed. The surface can be cleaned with a mild abrasive paper. Ideally, the surface of the test specimen should be the same as that of the metal when in service. This is not always possible, because of the variations in surface condition produced during fabrication. However, surface preparation of the test specimens ensures a standard surface condition during testing. After surface cleaning, the sample should be degreased with a solvent such as acetone, dried and weighed, and immediately put into the test medium. The standard procedures for treating test specimens of various metals are explained in detail in ASTM G 1 (Ref 4).

Testing Methods. The method and apparatus used to expose the test specimens to the test environment are very important and should meet the following guidelines:

- The corrosive medium should have easy access to samples
- The specimen should be well supported
- The sample should be electrically insulated from all other metals in the system
- The samples should be completely immersed unless other effects are being studied
- The samples should be readily accessible

An outline of standard procedures for designing these types of tests is provided in ASTM G 31 (Ref 4).

It is important to plan the experimental technique properly so that samples are removed and the weight is recorded over a proper duration of time. The corrosion rate may initially increase or decrease and may eventually remain constant with time. The intervals between samples should be selected so as to minimize misleading results. A general rule for selecting the total duration (in hours) of testing is as follows (Ref 6):

$$\text{Test duration} = \frac{2000}{\text{mils/yr}} \qquad \textbf{(Eq 2)}$$

where the mils/yr is the corrosion rate obtained in a laboratory test of short duration. The formula is based on the general rule that lower corrosion rates will require longer tests. For example, if the sample corrodes at a rate of 0.25 mm/yr (10 mils/yr), a corrosion test that is at least 200 h long should be designed (Ref 6).

In addition to the sequential removal of specimens with time, a planned interval testing schedule can be used to obtain more information on the initial corrosion rates and on accumulated effects (Ref 7). Planned interval testing involves exposing identical samples to the corrosion solution during different time intervals of the test. By evaluating the results, initial corrosion rates and changes in solution corrosivity can be determined. The planned interval testing program is an excellent example of good experimental planning.

Test Variables. Important variables that must be addressed during experimental planning include aeration, temperature, solution volume and flow, and degree of exposure. The presence of dissolved oxygen in the corrosion solution can have a dramatic effect on the rate of corrosion. If aeration is desired, the most common and simplest method consists of bubbling air or oxygen through the solution. If deaeration is required, purified nitrogen or argon can be bubbled through the solution in place of air. If a gas is not bubbled through the solution, the amount of dissolved oxygen will depend on the initial amount present and the rate of removal or adsorption from the atmosphere, which can depend on the configuration of the test apparatus.

The influence of temperature can be very complicated in that it affects oxygen solubility, pH, corrosion product formation, and other factors. Therefore, the temperature of the test should be monitored throughout the duration of the experiments and should be controlled at the desired levels.

The volume of solution to be used during laboratory testing is often a problem for practical reasons. If the volume of the solution is too small, the concentration of metal ions may increase and influence the results as well as cause a depletion of

the corrosive agent in the environment. At least 50 mL of test solution should be used per square centimeter of test area, and if the test solution is rapidly consumed, it should be periodically replenished (Ref 1).

The flow velocity of the solution also plays an important role in determining the corrosion rates. Corrosion rates may increase or decrease as the fluid velocity near the sample is increased. In any case, flow characteristics that represent the condition in service should be established during testing. This is often not a simple task, because the hydrodynamic conditions in service and their effect on the corrosion rate can be very complex. Rotating disks and cylinders are often used to study corrosion rates under controlled hydrodynamic conditions (Ref 8, 9, 10, 11) (see also the article "Evaluation of Erosion and Cavitation" in this Volume).

The degree of exposure is also important in test design; total, partial, or intermittent exposure can change the mode and rate of corrosion. If the samples are immersed, they should be immersed at the same depth in the corrosive environment. Partially immersed samples can be used to study waterline corrosion. Table 2 lists ASTM standard tests for different types of exposures that are applicable for the evaluation of resistance to uniform corrosion.

Table 2 Some ASTM standard methods and practices for corrosion testing

Designation	Test method
G 85	Modified Salt Spray (Fog) Testing
G 4	Conducting Corrosion Coupon Test in Plant Equipment
B 117	Salt Spray (Fog) Testing
G 44	Alternate Immersion Stress-Corrosion Testing in 3.5% Sodium Chloride Solution
G 16	Applying Statistics to Analysis of Corrosion Data
G 61	Conducting Cyclic Potentiodynamic Polarization Measurements for Localized Corrosion
G 52	Conducting Surface Seawater Exposure Tests on Metals and Alloys
G 31	Laboratory Immersion Corrosion Testing of Metals
D 2776	Corrosivity of Water in Absence of Heat Transfer (Electrical Methods)
D 2688	Corrosivity of Water in Absence of Heat Transfer (Weight Loss Method)
G 2	Aqueous Corrosion Testing of Samples of Zirconium and Zirconium Alloys
G 50	Conducting Atmospheric Corrosion Test on Metals
G 60	Conducting Cyclic Humidity Tests

Sample Cleaning and Data Acquisition. After a sample is removed from testing and before the final weight is recorded, the sample must be cleaned to remove any corrosion products. Also, the corrosion products must be removed

without causing additional corrosion of the specimen. Because the weight change of the specimen is used to calculate the thickness loss of the metal, any corrosion product that is weighed will provide incorrect results. A common cleaning method consists of removing the corrosion product with a brush or rubber stopper under a stream of water. In many cases, it is necessary to follow this procedure with brief chemical or electrochemical cleaning. Detailed procedures for cleaning specimens after exposure are given in ASTM G 1 (Ref 4).

Evaluation of Pitting Corrosion

Donald O. Sprowls, Consultant

Introduction

PITTING is a form of localized corrosion that is often a concern in applications involving passivating metals and alloys in aggressive environments. Pitting can also occur in nonpassivating alloys with protective coatings or in certain heterogeneous corrosive media. It is a very damaging form of corrosion that is not readily evaluated by the methods used for uniform corrosion. Therefore, special accelerated test have been devised for the evaluation of the relative resistance to pitting corrosion of passive alloys. The mechanisms of pitting corrosion are discussed in the section "Pitting" of the article "Localized Corrosion" in this Volume.

Test Methods

Method ASTM G 48 covers procedures for determining the pitting (and crevice) corrosion resistance of stainless steels and related alloys when exposed to an oxidizing chloride environment, namely 6% ferric chloride ($FeCl_3$) at 22 ± 2 or 50 ± 2 °C (70 ± 3.5 or 120 ± 3.5 °F) (Ref 1). Method A is a 72-h total-immersion test of small coupons that is designed to determine the relative pitting resistance of stainless steels and nickel-base chromium-bearing alloys. Method B is a crevice test under the same exposure conditions, and it can be used to determine both the pitting and crevice corrosion resistance of these alloys. These tests can be used for determining the effects of alloying additions, heat treatments, and surface finishes on pitting and crevice corrosion resistance.

Method ASTM F 746 covers the determination of the resistance to either pitting or crevice corrosion of passive metals and alloys from which surgical implants will be produced (Ref 2). This is a screening test that is used to rank surgical implant alloys in order of their resistance to localized corrosion in a dilute sodium chloride (NaCl) solution under the specific conditions of the test method. With this method, alloys are ranked in term of the critical potential for pitting; the higher (more noble) this potential, the more resistant the alloy is to passive film breakdown and to localized corrosion. The method was intentionally designed to cause breakdown of at least one alloy (type 316L stainless steel) that is

currently considered acceptable for surgical implant use. Those alloys that suffer pitting or crevice corrosion during the test do not necessarily suffer localized corrosion when placed within the human body as a surgical implant.

Practice ASTM G 61 describes a procedure for conducting cyclic potentiodynamic polarization measurements to determine susceptibility to localized corrosion (Ref 3). The procedure is preferably used for iron-, nickel-, and cobalt-base alloys in chloride environments. This standard practice uses both the critical potential for pitting and the protection potential in order to compare the pitting resistance of test materials. This and other electrochemical tests are described in more detail in the article "Laboratory Testing" in this Volume. In addition, a comparison of several different methods of determining the protection potential is presented in Ref 4.

Because pitting (or crevice) corrosion can perforate and destroy thin-wall industrial equipment, the protection potential, E_p, represents a limiting potential that should not be exceeded. Many authorities, however, have questioned the validity of such short-term test procedures. The most frequent criticism is that these tests may not adequately predict long-term corrosion behavior (Ref 5, 6). The lack of consistency among the protection potential results (Ref 4) and the lack of a single, most conservative test indicate a need for further research into the concept of a protection potential. At this point, no reason can be identified for the lack of consistency among the techniques reported. Therefore, conservative engineering practice would require that all three types of tests be performed and that the most conservative results be used (Ref 4).

Examination and Evaluation

ASTM G 46 provides assistance in the selection of procedures for the identification and examination of pits and in the evaluation of pitting corrosion to determine the extent of its effect (Ref 7). It is important to be able to determine the extent of pitting, either in a crevice application in which it is necessary to predict the remaining life of a metal structure or in laboratory test programs that are used to select the most pitting-resistant materials for service. The following is a summary of the procedures described in detail in Ref 7. Additional guidelines can be found in Ref 8.

Identification and Examination of Pits

Visual examination of the corroded surface can be performed with the unaided eye or a low-power microscope. The corroded surface is usually photographed, and the size, shape, and density of the pits are determined (Fig. 1 and 2).

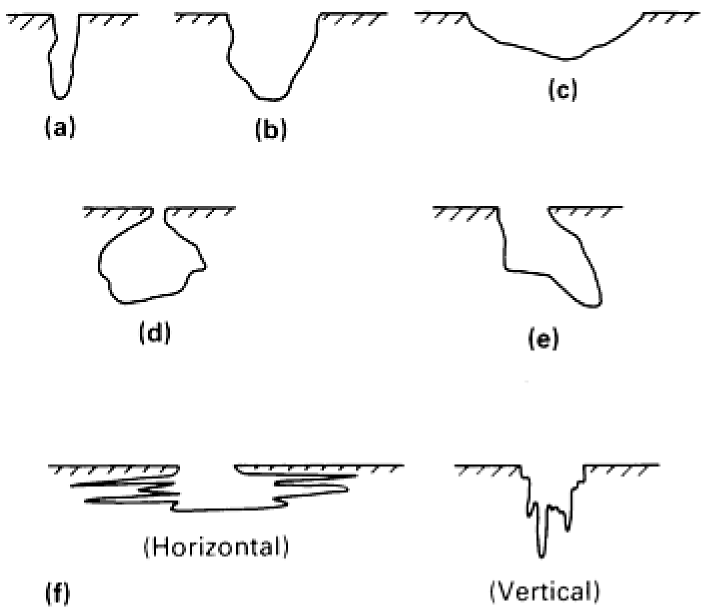

Fig. 1 Variations in the cross-sectional shape of pits. (a) Narrow and deep. (b) Elliptical. (c) Wide and shallow. (d) Subsurface. (e) Undercutting. (f) Shapes determined by microstructural orientation. Source: Ref 7

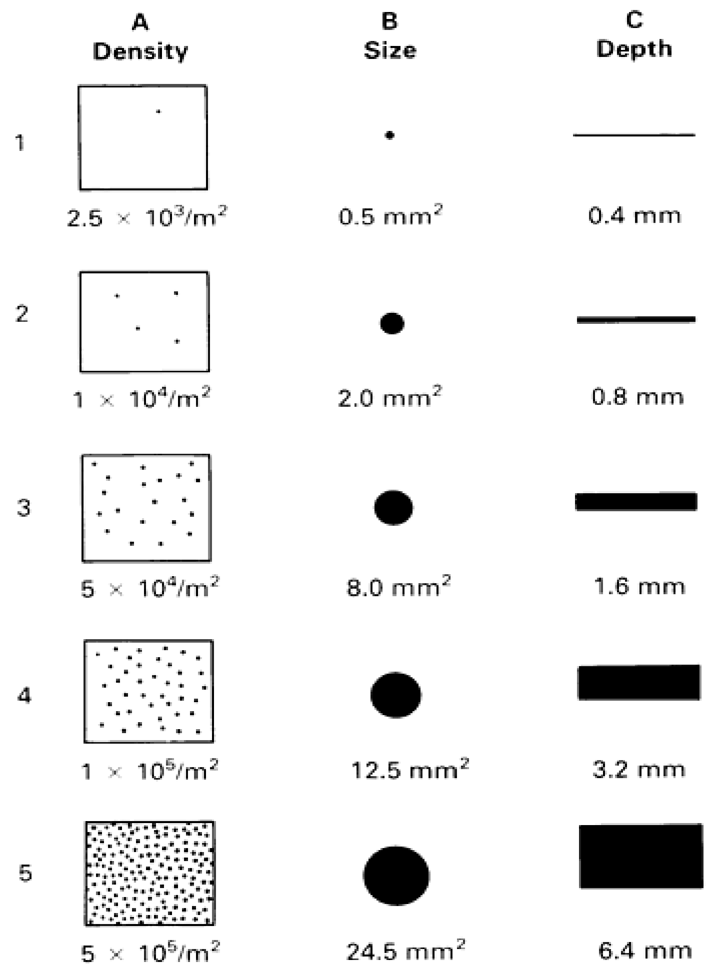

Fig. 2 Standard rating chart for pits. Source: Ref 7

Metallographic examination can be used to determine whether there is a correlation between pits and microstructure and whether the cavities are true pits or are the result of another mechanism, such as intergranular corrosion or dealloying.

Nondestructive Inspection. Reference 7 also includes procedures for the nondestructive evaluation of pitted specimens. These include radiographic, electromagnetic, ultrasonic, and dye-penetrant inspection. These methods can be used to locate pits and to provide some information on their size, but they generally cannot detect small pits or differentiate between pits and other types of surface detects.

Determination of the Extent of Pitting

Mass loss is generally not a good indication of the extent of pitting unless uniform corrosion is slight and pitting is fairly severe. If there is significant uniform corrosion, the contribution of pitting to total mass loss is small. Mass loss should not be ignored in every case, however. For example, measurement of mass loss, along with visual comparison of pitted surfaces, may be sufficient to rank the relative resistances of alloys in laboratory tests.

Pit depth measurement is generally a better indicator of the extent of pitting than mass loss. Pit depth measurement can be accomplished by several methods, including metallographic examination, machining, use of a micrometer or depth gage, and the microscopical method. In the microscopical method, a metallurgical microscope is focused on the lip of the pit and then on the bottom of the pit. The difference between the initial and final readings on the fine-focusing knob of the microscope is the pit depth.

Evaluation of Pitting

Pitting can be described in several ways. Reference 7 includes procedures for the use of standard charts, metal penetration, statistical analysis, and loss in mechanical properties to quantify the severity of pitting damage. More than one of these methods can be used. In fact, it is often found that no one method is sufficient by itself.

Standard charts such as that shown in Fig. 2 can be used to rate pits in terms of density, size, and depth. Columns A and B in Fig. 2 are used to rate the density (that is, the number of pits per unit area on the specimen surface) and the average size of the pits, respectively. Column C rates the average depth of attack. An example of a rating using Fig. 2 might be A-3, B-2, C-3; this rating indicates a density of 5×10^4 pits/m^2, an average pit size of 2.0 mm^2, and an average pit depth of 1.6 mm.

Such charts facilitate communication among those who are familiar with the standard ratings and offer a simple means of storing data for comparison with other test results. However, it can be tedious and time consuming to measure all of the pits, and the time spent doing so is usually not justified, because maximum values (for example, pit depths) are often more significant than average values.

Metal Penetration. In this method, the deepest pits are measured and metal penetration is expressed in terms of the maximum pit depth, an average of the ten deepest pits, or both. Metal penetration is especially significant when the metal is intended for service as an enclosure for gas or liquid and when a hole could result in loss of fluid.

Metal penetration can also be expressed in terms of a pitting factor, which is the ratio of the deepest metal penetration to the average metal penetration (determined from mass loss):

$$\text{Pitting factor} = \frac{\text{Deepest metal penetration}}{\text{Average metal penetration}} \quad \textbf{(Eq 1)}$$

A pitting factor of 1 represents uniform corrosion. The larger the number, the greater the depth of penetration. The pitting factor cannot be used when pitting or general corrosion is slight; values of 0 or infinity can be obtained in such situations.

The application of statistics to the analysis of corrosion data is covered in detail in ASTM G 16 (Ref 9). The subject is discussed briefly in Ref 7 to show that statistics can be used in the evaluation of pitting data.

The probability that pitting will initiate on a metal surface depends on a number of factors, including the pitting tendency of the metal, the corrosivity of the solution, the specimen area, and the duration of exposure. A pitting probability test can be used to determine the susceptibility of metals to pitting. However, this test will not provide information about the rate of propagation, and the results are applicable only to the conditions of exposure. Pitting probability P is expressed as a percentage after exposure of a number of specimens to a particular set of conditions (Ref 10, 11):

$$P = \frac{N_p}{N} \times 100 \quad \textbf{(Eq 2)}$$

where N_p is the number of specimens that pit, and N is the total number of specimens.

The relationship between pit depth and area or time of exposure may vary with such factors as the environment and the metal exposed. Equations 3 and 4 are examples that have been found to apply under certain exposure conditions.

Equation 3 was found between maximum pit depth D and the area A of a pipeline exposed to soil (Ref 12, 13, 14):

$$D = bA^a \quad \textbf{(Eq 3)}$$

where a and b > 0, and a and b are constants that were derived from the slope and the y-intercept of a straight line curve obtained when the logarithms of the mean pit depth for successively increasing areas on the pipe were plotted against the

logarithms of the corresponding areas. The dependence on area is attributed to the increased chance for the deepest pit to be found when the size of the sample of pits is increased through an increased area of corroded surface.

The maximum pit depth *D* of aluminum exposed to various waters was found to vary as the cube root of time *t*, as shown in Eq 4 (Ref 10, 15):

$$D = Kt^{1/3} \qquad \textbf{(Eq 4)}$$

where K is a constant that is dependent on the composition of the water and the alloy. Equation 4 has been found to apply to several aluminum alloys exposed to different waters.

Extreme value probability statistics (Ref 16, 17) have been successfully applied to maximum pit depth data to estimate the maximum pit depth of a large area of material on the basis of the examination of a small portion of that area (Ref 8, 10, 15). The procedure consists of measuring maximum pit depths on several replicate specimens and then arranging the pit depth values in order of increasing rank. A plotting position for each order of ranking is obtained by substitution in the relation $M/(n + 1)$, where *M* is the order of ranking of the specimen in question, and *n* is the total number of specimens or values.

For example, the plotting position for the second value out of 10 would be 2/(10 + 1) = 0.1818. These values are plotted on the ordinate of extreme value probability paper versus their respective maximum pit depths. A straight line indicates that extreme value statistics are applicable. Extrapolation of the straight line can be used to determine the probability that a specific pit depth will occur or the number of observations that must be made to find a particular pit depth.

Loss in Mechanical Properties. If pitting is the predominant form of corrosion and if the density of pitting is relatively high, the change in a mechanical property can be used to advantage for evaluation of the degree of pitting. The typical properties considered for this purpose are tensile strength, elongation, fatigue strength, impact resistance, and burst pressure (Ref 18, 19).

The precautions that must be taken in the application of these mechanical test procedures are covered in most standard methods. However, it must be stressed that the exposed and unexposed specimens should be as close to replicate as possible. Therefore, consideration should be given to such factors as edge effects, direction of rolling, and surface conditions.

Representative specimens of the metal are exposed to the same conditions except for the corrosive environment. The mechanical properties of the exposed and unexposed specimens are measured after the exposure, and the difference between the two results is attributed to corrosion damage.

Some of these methods are better suited to the evaluation of other forms of localized corrosion, such as intergranular or stress corrosion. Therefore, their limitations must be considered. The often erratic nature of pitting and the location of pits on the specimen can affect results. In some cases, the change in mechanical properties due to pitting may be too small to provide meaningful results. Perhaps one of the most difficult problems is to separate the effects due to pitting from those caused by some other form of corrosion.

Evaluation of Galvanic Corrosion

Harvey P. Hack, David Taylor Naval Ship Research and Development Center

Introduction

GALVANIC CORROSION, although listed as one of the forms of corrosion, should instead be considered as a type of corrosion mechanism, because any of the other forms of corrosion can be accelerated by galvanic effects. Therefore, any of the tests used for the more conventional forms of corrosion, such as uniform attack, pitting, or stress corrosion, can be used, with modifications, to determine galvanic-corrosion effects. The modifications can be as simple as connecting a second metal to the system or as complex as necessary to evaluate the appropriate parameters. A change in the method of data interpretation is often all that is needed to convert conventional test methods into galvanic-corrosion tests.

This article will discuss component, model, electrochemical, and specimen tests. Additional information on galvanic corrosion can be found in the article "General Corrosion" in this Volume.

Component Testing

Component testing is an especially useful technique for galvanic corrosion prediction. The materials in a system are often selected primarily for reasons other than galvanic compatibility. In complex components, such as valves or pumps, many

different materials can be used in a geometric configuration that is extremely difficult to model. In more complicated cases, even the most basic prediction, such as which materials will suffer increased corrosion due to galvanic effects, may not be possible from simple laboratory tests. Therefore, component testing becomes the best method for predicting material behavior in complex systems.

Conducting component tests for galvanic corrosion is similar to conducting component tests for any other type of corrosion. The same care must be taken to ensure that the materials, the operation of the component, and the environment are similar to those in service. However, one important difference with regard to galvanic corrosion is the relationship between the component being tested and the other elements of the system. For example, it would be a waste of effort to expose a complicated piece of machinery in order to look for galvanic corrosion when the whole device is cathodically protected as a result of being attached to a protected structure. Alternatively, incorrect results would be obtained for the exposure of an isolated bronze mixed-material valve when the ultimate use was in a piping system made of a more noble metal that could accelerate the corrosion of the entire valve galvanically. When outside interactions of this type are possible, the interacting materials must be made part of the corrosion system by exposing the appropriate surface area of those materials electrically connected to, and in the same electrolyte as, the component being tested.

The principal advantages of component testing are ease of interpretation of results and the lack of scaling or modeling uncertainties. The disadvantages include high cost and the need for extremely sensitive measures of corrosion damage to obtain results within reasonable time periods.

Modeling

Even when the galvanic behavior of panels of the materials of interest is known, the geometrical arrangement of these materials may make galvanic corrosion prediction difficult because of the effects of solution (electrolyte) resistance on the corrosion rates. An example of this is a heat-exchanger tube in a tubesheet. Assuming the tube to be anodic to the tubesheet, areas of the tube near the tubesheet will have low solution resistance to the cathode and will corrode rapidly, but areas away from the tubesheet will have a large solution resistance to the cathodic metal and will therefore corrode more slowly. In the reverse case, in which the tubesheet is anodic to the tube, the areas of the cathodic tube near the tubesheet will drive the galvanic corrosion of the tubesheet much more than distant areas will.

Computer Modeling. Geometrical effects can be modeled in computers by using such techniques as finite elements, boundary elements, and finite differences. The best computer models solve a version of the Laplace equation for the electrolyte surrounding the corroding materials and use the polarization behavior of the material in question as boundary conditions at the metal/electrolyte interface. The analysis is similar to the heat flow analysis, with potential analogous to temperature, current analogous to heat flux, and the polarization boundary condition analogous to a special nonlinear type of temperature-dependent convective flux.

The only data this type of model requires are the geometry, electrolyte conductivity, and polarization characteristics of the materials involved. The program generates potentials and current densities as a function of location, either of which can be related back to corrosion rate. The nonlinear boundary conditions make this type of computer modeling difficult to perform unless a large mainframe computer with sufficient computational capabilities is available. Computer modeling provides an excellent predictive tool for geometrical effects; however, it is still seen as less satisfying than physical scale model exposures.

Physical scale modeling must model the solution resistance effects and the relative effects of polarization resistance and solution resistance to obtain accurate geometrical predictive capability. When solution resistance is important, the best type of scale modeling is the scaled conductivity exposure. In this type of exposure, the model is reduced in size by some factor from the original. To maintain proper potential and current distribution scaling, the electrolyte conductivity must also be reduced by the same factor. Any resistive coatings, such as paints, must also have their conductivity scaled similarly. In the case of paints, this can be accomplished by applying a thinner layer, by the same scaling factor used for size, than the thickness used in practice.

For example, a one-tenth scale model of a heat exchanger designed to operate in seawater with a conductivity of 4 mho/cm should be placed in seawater diluted to a conductivity of 0.4 mho/cm. In this case, the observed potential and current distributions will be the same between the model and the full-scale heat exchanger. For physical scale modeling, measurements that can be taken include potential distribution by the use of a movable reference electrode, corrosion depth as a function of location, and, if the model design permits, current to different parts of the structure and mass loss of certain model components.

Although less expensive than full-scale component testing, physical scale modeling has many of the disadvantages of component testing. In addition, a great inaccuracy in conductivity scaling stems from the fact that the polarization resistance of the materials in the system of interest is often a function of solution conductivity. Thus, changing solution conductivity may influence polarization resistance sufficiently to make the results of the model inaccurate. There is no experimental way to avoid this shortcoming.

Laboratory Testing

Laboratory tests fall into two categories: electrochemical tests, in which the data are analyzed and reported in a way that assists galvanic-corrosion predictions, and specimen exposures, which may or may not be electrochemically monitored.

Electrochemical Tests

The use of electrochemical techniques to predict galvanic corrosion is summarized in Ref 1. The details that relate to testing techniques are discussed below.

Galvanic Series. When the only information needed is which of the materials in the system are possible candidates for galvanically accelerated corrosion and which will be unaffected or protected, the information from a galvanic series in the appropriate media is useful. Such a series is a list of freely corroding potentials of the materials of interest in the environment of interest arranged in order of potential (Fig. 1). The galvanic series is easy to use and is often all that is required to answer a simple galvanic-corrosion question. The material with the most negative, or anodic, corrosion potential has a tendency to suffer accelerated corrosion when electrically connected to a material with a more positive, or noble, potential. The disadvantages include:

- No information is available on the rate of corrosion
- Active-passive metals may display two, widely differing potentials
- Small changes in electrolyte can change the potentials significantly
- Potentials may be time dependent

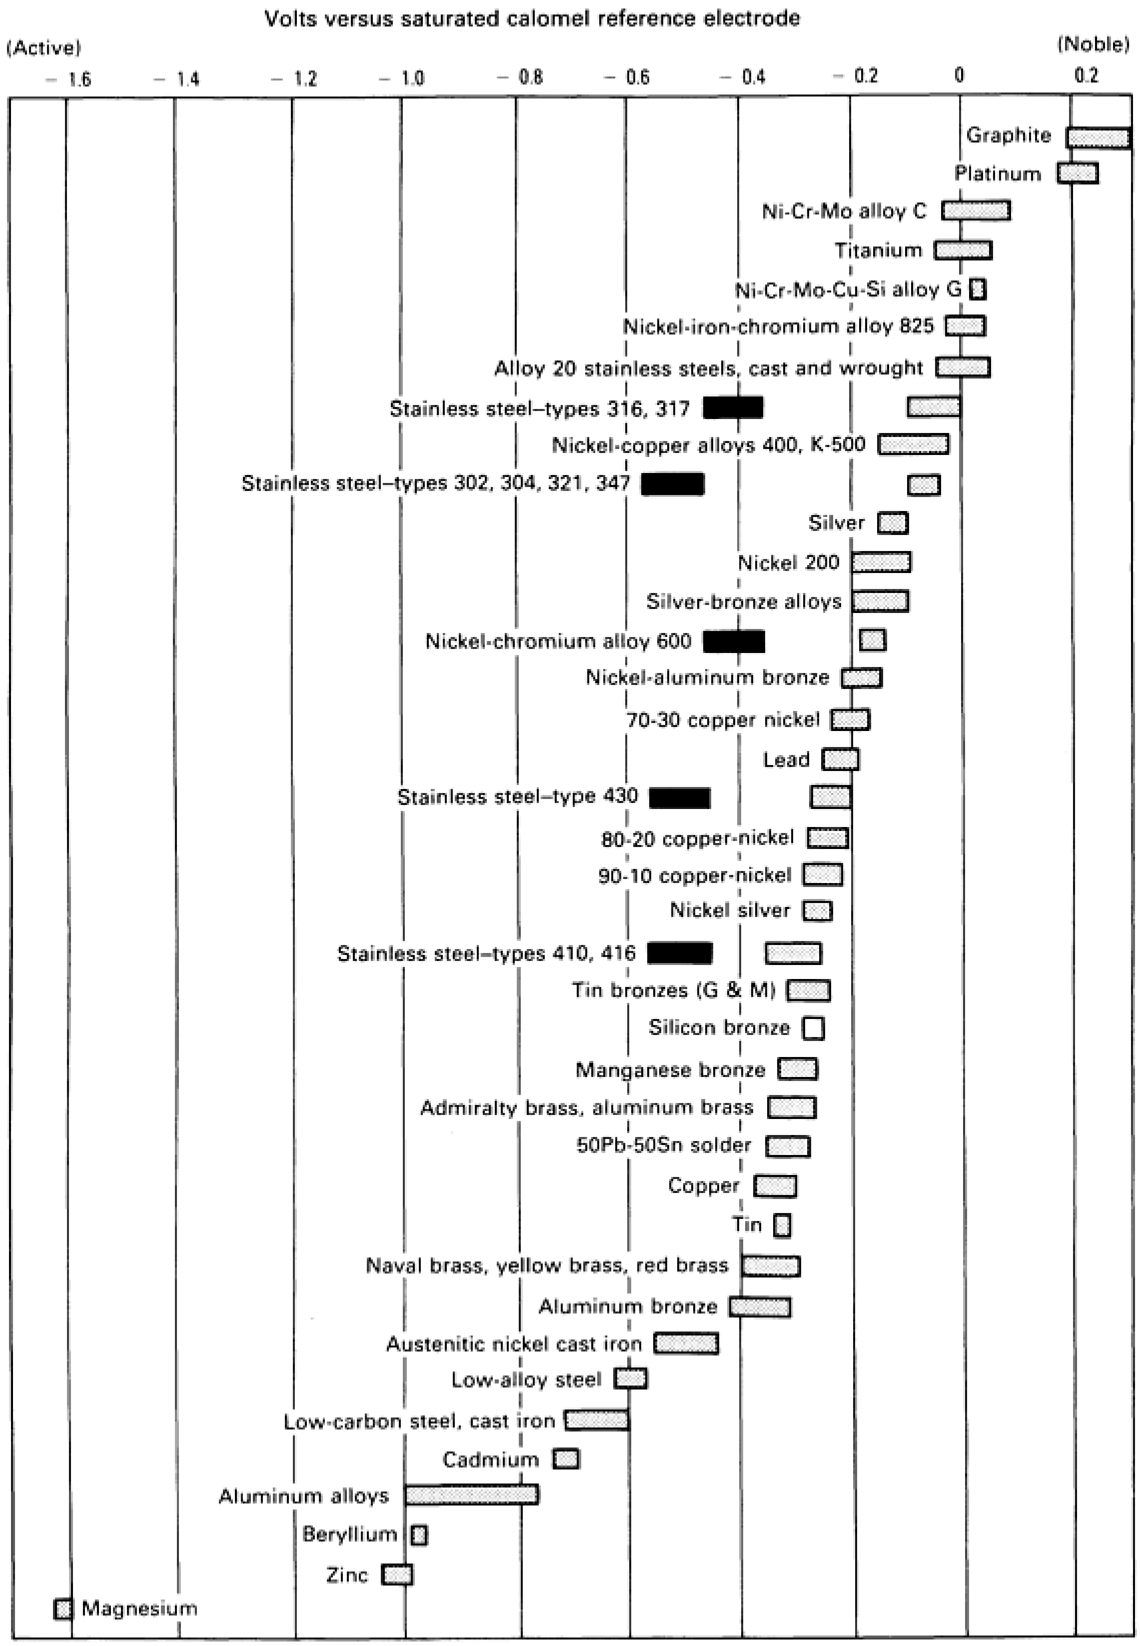

Fig. 1 Galvanic series for seawater. Dark boxes indicate active behavior of active-passive alloys.

Creating a galvanic series is a matter of measuring the corrosion potential of various materials of interest in the electrolyte of interest against a reference electrode half-cell, such as saturated calomel. This procedure is described in Ref 2. The details of such factors as meter resistance, reference cell selection, and measurement duration are also addressed in Ref 2.

There is little difference from a normal reading of corrosion potential except for the measurement duration and the creation of a list ordered by potential.

To prepare a galvanic series that will be valid for the materials and environment of interest in service, all of the factors that affect the potential of those materials in that environment must be accounted for. These factors include material composition, heat treatment, surface preparation (mill scale, coatings surface finish, etc.), environmental composition (trace contaminants, dissolved gases, etc.), temperature, and flow rate. One important effect is exposure time, particularly on materials that form corrosion product layers. All of the precautions and warnings regarding the generation and use of a galvanic series are given in Ref 2.

Polarization Curves. More useful information on the rate of galvanic corrosion can be obtained by investigating the polarization behavior of the materials involved. This can be done by generating stepped potential or potentiodynamic polarization curves or by obtaining potentiostatic information on polarization behavior. The objective is to obtain a good indication of the amount of current required to hold each material at a given potential. Because all materials in the galvanic system must be at the same potential in systems with low solution resistivity, such as seawater, and because the sum of all currents flowing between the materials must equal 0 by Kirchoff's Law, the coupled potential of all materials and the galvanic currents flowing can be uniquely determined for the system. The corrosion rate can then be related to galvanic current by Faraday's Law if the resulting potential of the anodic materials is well away from their corrosion potential, or the corrosion rate can be found as a function of potential by independent measurement.

Potentiodynamic polarization curves are generated by connecting the specimen of interest to a scanning potentiostat. This device applies whatever current is necessary between the specimen and a counter electrode to maintain that specimen at a given potential versus a reference electrode half-cell placed near the specimen. The current required is plotted as a function of potential over a range that begins at the corrosion potential and proceeds in the direction (anodic or cathodic) required by that material. Such curves would be generated for each material of interest in the system. Additional information on the method for generating these curves is available in the article "Laboratory Testing" in this Volume and in Ref 3. The scan rate for potential must be chosen such that sufficient time is allowed for completion of electrical charging at the interface.

Potentiodynamic polarization is particularly effective for materials with time-independent polarization behavior. It is fast, relatively easy, and gives a reasonable, quantitative prediction of corrosion rates in many systems. However, potentiostatic techniques are preferred for time-dependent polarization. To establish polarization characteristics for time-dependent polarization, a series of specimens is used, each held to one of a series of constant potentials with a potentiostat while the current required is monitored as a function of time. After the current has stabilized or after a pre-selected time period has elapsed, the current at each potential is recorded. Testing of each specimen results in the generation of one potential/current data pair, which gives a point on the polarization curve for that material. The data are then interpolated to trace out the full curve. This technique is very accurate for time-dependent polarization, but is expensive and time consuming. The individual specimens can be weighed before and after testing to determine corrosion rate as a function of potential, thus enabling the errors from using Faraday's Law to be easily corrected.

The process of predicting galvanic corrosion from polarization behavior can be illustrated by the example of a steel-copper system. Steel has the more negative corrosion potential and will therefore suffer increased corrosion upon coupling to copper, but the amount of this corrosion must be predicted from polarization curves. If the polarization of each material is plotted as the absolute value of the log of current density versus potential and if the current density axis of each of these curves is multiplied by the wetted surface area of that material in the service application, then the result will be a plot of the total anodic current for steel and the total cathodic current for copper in this application as a function of potential (Fig. 2).

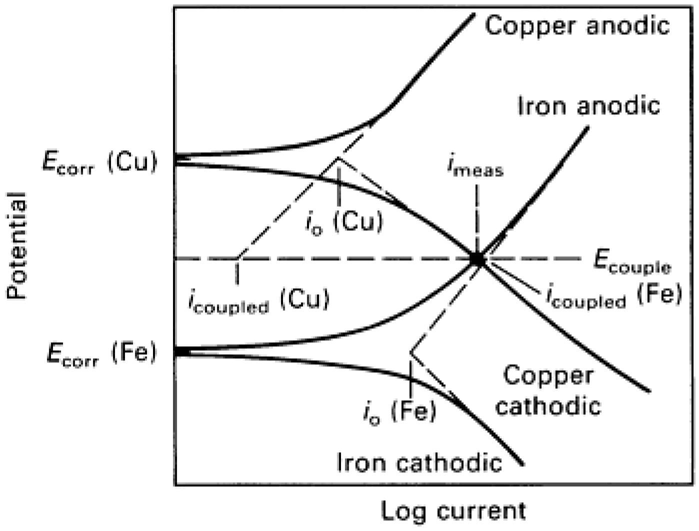

Fig. 2 Prediction of coupled potential and galvanic current from polarization diagrams, *i*, current; i_o, exchange current; E_{corr}, corrosion potential

Furthermore, when the two metals are electrically connected, the anodic current to the steel must be supplied by the copper; that is, the algebraic sum of the anodic and cathodic currents must equal 0. If the polarization curves for the two materials, normalized for surface area as above, are plotted together, this current condition is satisfied where the two curves intersect. This point of intersection allows for the prediction of the coupled potential of the materials and the galvanic current flowing between them from the intersection point. This procedure works if there is no significant electrolyte resistance between the two metals; otherwise, this resistance must be taken into account in a complex manner that is beyond the scope of this article.

Specimen Exposures

Specimens for galvanic-corrosion testing include panels, wires, pieces of actual components, and other configurations of the materials of interest that are exposed in a process stream, a simulated service environment, or the actual environment. Specimens of the materials of interest are usually exposed in the same ratios of wetted or exposed areas as in the service application. The different materials are either placed in physical contact to provide electrical connection or are wired together such that the current between the materials can be monitored, usually as a function of time. Seldom can the effects of electrolyte resistance be included in this type of test, and the resistance is usually kept extremely low by appropriate relative placement of the materials.

Immersion. There are virtually no standardized tests for galvanic corrosion under immersion conditions, partly because the type of information needed, the extent of modeling of the service situation, and the type of system studied vary widely. This makes development of a standard test difficult. However, some general guidelines for galvanic-corrosion specimen testing in liquid electrolytes are given in Ref 4.

Immersion testing always involves an electrical connection between at least two dissimilar metals. This is usually accomplished with a wire, as in Fig. 3, although threaded mounting rods have also been used successfully for electrical connection, such as the assembly shown in Fig. 4. Soldered or brazed connections have the best electrical integrity.

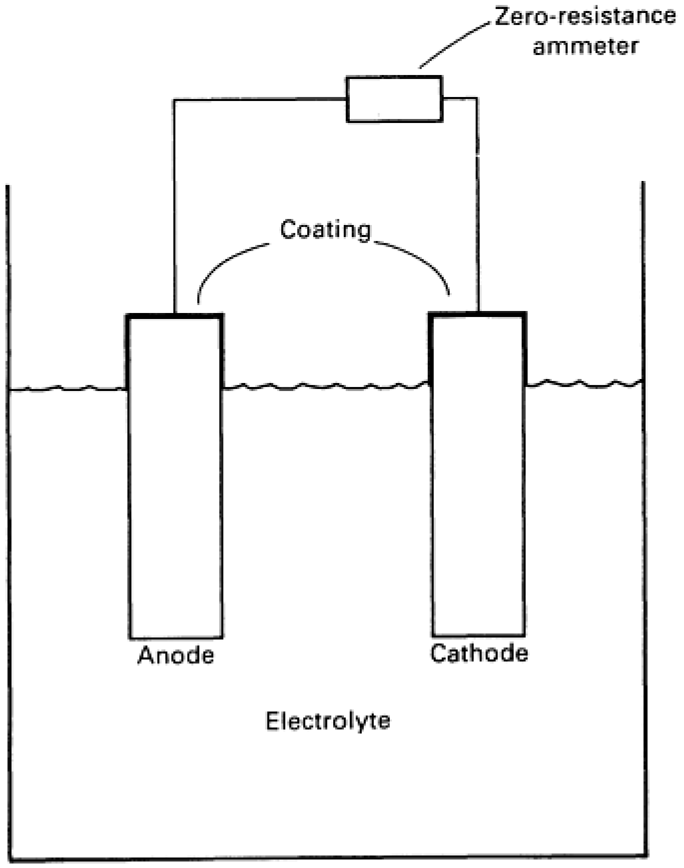

Fig. 3 Typical galvanic-corrosion immersion test setup using wire connections

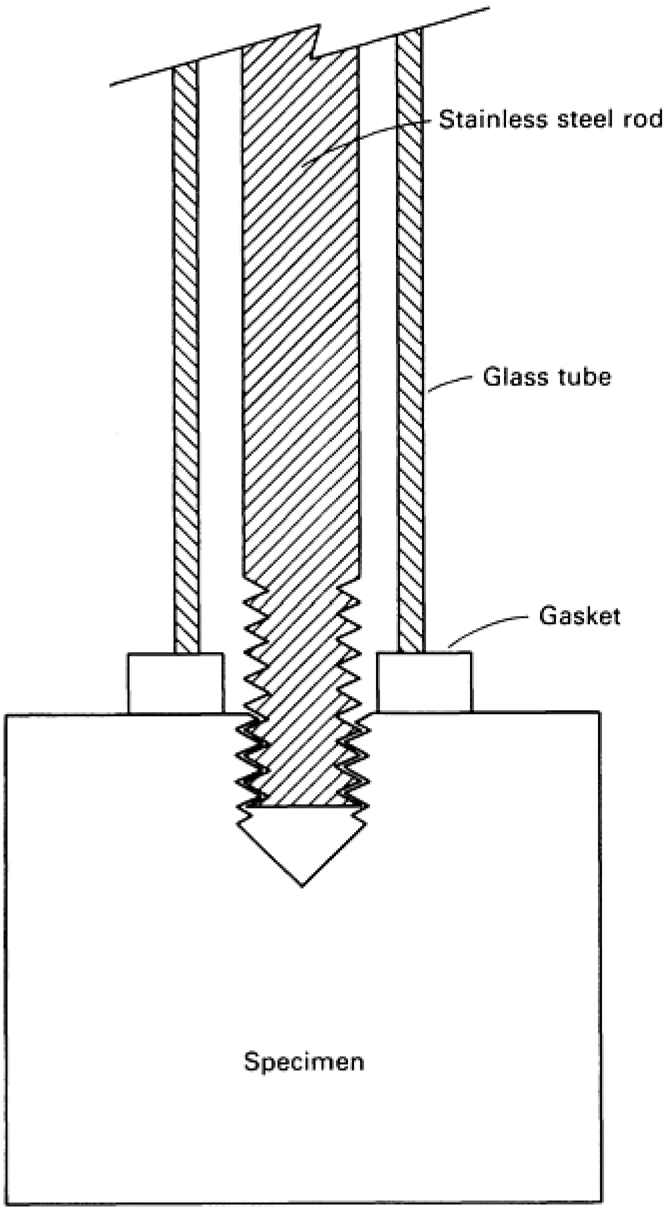

Fig. 4 Typical galvanic-corrosion test specimen using a threaded rod for mounting and electrical connection

The electrolyte must be excluded from the contact area by applying a sealant, such as silicone or epoxy; by keeping the joint area out of the electrolyte by partial immersion of the specimen, in which case a waterline area is created; or by use of a tube and gasket or O-ring seal in the case of a threaded mounting rod. Mounting the specimen in a specially formulated epoxy has been found to be effective in minimizing crevice corrosion while maintaining a dry electrical connection. However, selection of the best epoxy formulation is difficult. Care must be taken that the sealant or gasketing material is stable in the electrolyte being studied.

Almost any sealing procedure will create a potential area for crevice corrosion; thus, it is very difficult to study galvanic behavior independent of crevice corrosion behavior (see the article "Evaluation of Crevice Corrosion" in this Volume). Control specimens may be run with similar crevices and no electrical connection, but because the reproducibility of crevice corrosion behavior is not good, data scatter will be large. Under some circumstances, the galvanic effect of importance may be the acceleration of crevice corrosion attack.

The relative wetted surface areas of the materials being tested will have an important effect on the magnitude of the galvanic attack. The larger the cathode-to-anode area ratio is, the larger the attack will be; therefore, it would at first seem

reasonable to accelerate the test by using a large ratio. This should not be done, because accelerating the attack may also change the mechanism of the attack, which would lead to erroneous conclusions. It is far more appropriate to use more accurate measurement techniques to determine the extent of the attack over a short period than to accelerate the test to obtain measurable attack quickly. If soldered or brazed connections are used for electrical connection, subsequent evaluation by weight loss is difficult; therefore, if weight loss is to be used to measure attack, threaded and sealed connections are preferred.

Measurement of the electrical current flowing between the metals can give a very sensitive indication of the extent of the galvanic attack and will allow the attack to be monitored over time. Coupled potential is another parameter that is useful to follow during the course of the exposure. The effect of exposure time on the rate of attack should be properly considered. Initially high rates of galvanic attack may decay to acceptable levels in a short period of time, or initially low attack rates may increase to unacceptable levels over time.

Current can be measured by inserting a resistor of 1 to 10 Ω in the current circuit and measuring the potential decrease across this resistor with a voltmeter having a resistance of at least 1000 Ω. The resistor should be sized such that the voltage across it does not exceed 5 mV; thus, the resistor will not significantly impede the current flow. Alternatively, a zero-resistance ammeter can be used instead of the resistor. This device is an operational amplifier connected to maintain 0 V across its input terminals (Fig. 5). A current-measuring resistor, placed in the feedback circuit, may be as large as the amplifier will allow, thus enabling currents in the nanoampere range to be easily measured. One simple way of creating a zero-resistance ammeter is by using a potentiostat with the counter electrode and reference electrode leads shorted together and set to a working electrode potential of 0 V (Fig. 6).

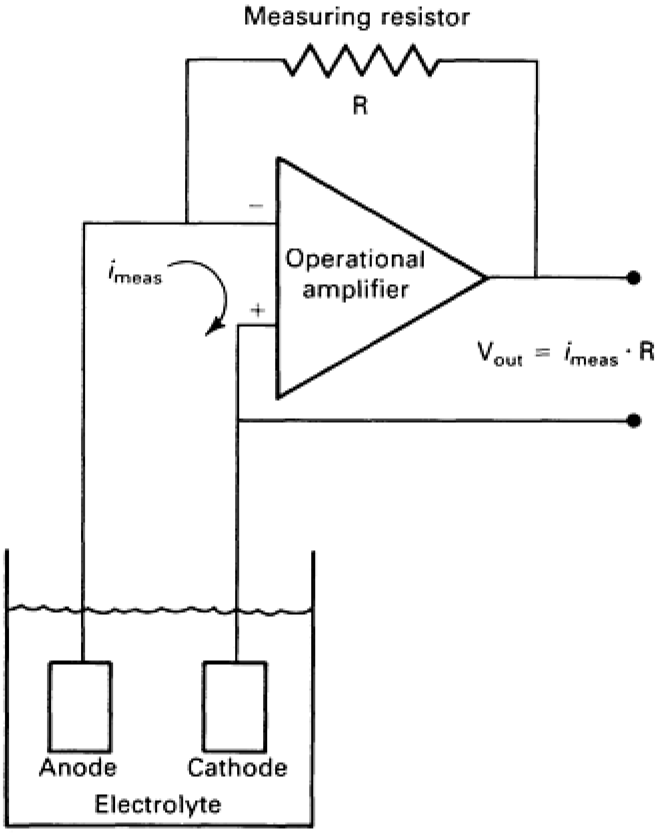

Fig. 5 Basic circuit for a zero-resistance ammeter

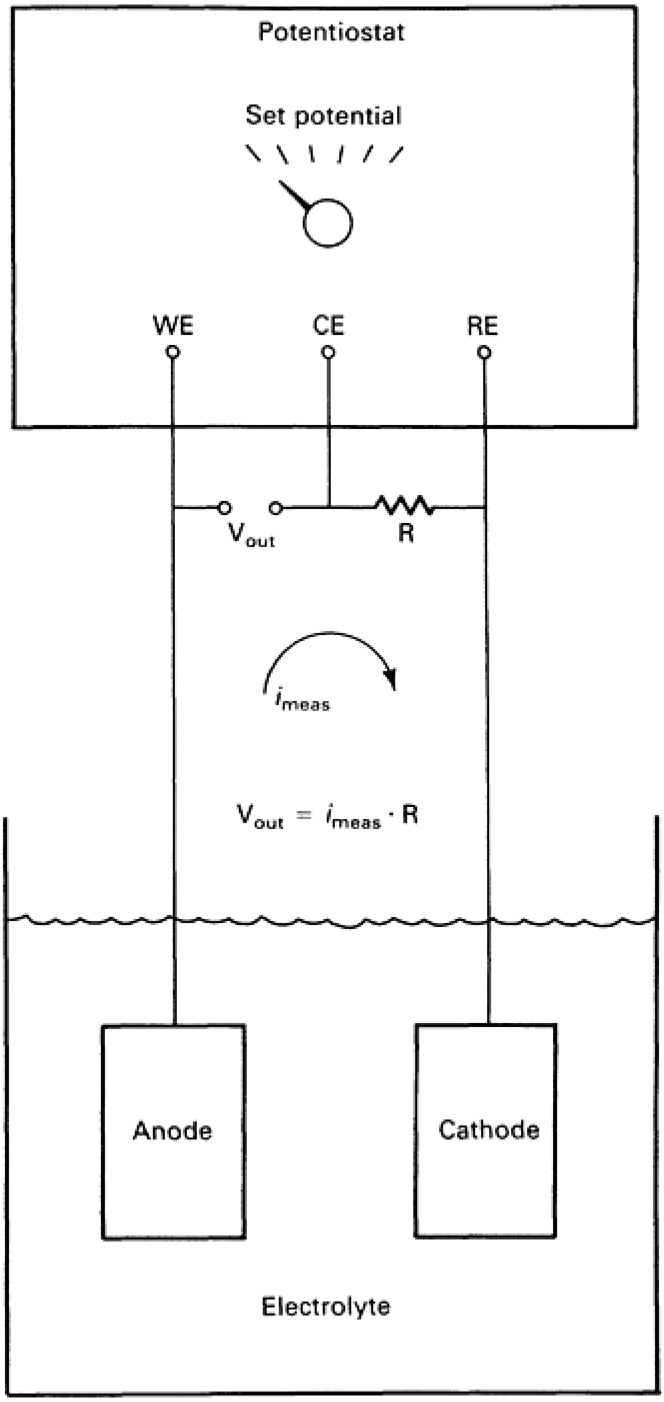

Fig. 6 Conversion of a potentiostat into a zero-resistance ammeter, WE, working electrode; CE, counter electrode; RE, reference electrode

The importance of electrolyte flow in galvanic corrosion should not be overlooked in establishing the test procedure. A test apparatus should be used that reproduces the flow under service conditions. If this is not possible and flow must be scaled, the exact scaling method will depend on the assumed corrosion processes. Cathodic reactions, such as oxygen reduction, that are controlled by diffusion through a fluid boundary layer are likely to be properly scaled by reproducing the hydrodynamic boundary layer of the service application in the test. This should reproduce the diffusion boundary layer that controls the reaction.

Alternatively, the rate of reactions controlled by films such as anodic brightening of copper alloys, other passivation-type reactions, or control by calcareous deposit formation in seawater, may depend more on the shear stress at the surface

required to strip off the film. In this case, surface shear stress may be a better hydrodynamic parameter to reproduce in the test.

Many different types of flow apparatus have been used, such as concentric tubes, in-line tubes, rotating cylinders, rotating ring-disks, rectangular flow channels with specimens mounted in the walls, and circulating foils. Each of these has its own hydrodynamic peculiarities, but one common area of concern is the leading edge of the specimen. It is difficult, even for specimens recessed in the walls of a flow channel, to avoid a step or gap that can create unexpected hydrodynamic conditions at the specimen surfaces downstream. Also, mounting to allow electrical connection must be considered, and crevice effects are essentially impossible to eliminate.

Atmospheric Tests. General testing guidelines become more complex when considering atmospheric or cabinet exposures. Testing in these environments differs markedly from immersion tests in a number of ways, most of which involve the insufficiency of electrolyte. Many of the variables that influence the behavior of specimens in the atmosphere are discussed in Ref 5.

The thinness of the electrolyte film and the normally low conductivity of the electrolyte combine to limit galvanic effects to within about 5 mm (0.2 in.) of the dissimilar-metal interface. Thus, area ratio effects become relatively unimportant. Sealing the electrical connections becomes relatively less important than in immersion testing if the connections are more than 5 mm (0.2 in.) from the area to be evaluated and if corrosion products will not interfere with the continuity of the connection. Periodic checks of electrical continuity in atmospheric galvanic-corrosion tests are recommended. Geometrical effects also become unimportant, except as they relate to the entrapment of moisture. However, specimen orientation effects must be considered. The behavior of the galvanic couples will depend on whether they are exposed on the top or the bottom of the panel, whether they are sheltered or not, or other considerations, such as the effect of specimen mass on condensation.

Because there are no standardized tests for galvanic corrosion immersed in electrolytes, it is somewhat surprising that several standard tests have emerged for atmospheric galvanic corrosion, even though less testing has been done in this area. One of these tests is an International Organization for Standardization (ISO) standard (Ref 6) and is also being developed by the American Society for Testing and Materials (ASTM). This test uses a 100- × 400-mm (4- × 16-in.) panel of the anodic material to which a 50- × 100-mm (2- × 4-in.) strip of the cathodic material is bolted (Fig. 7). After exposure, the anodic material can be evaluated for material degradation by weight loss and other corrosion measurements as well as by degradation of such mechanical properties as ultimate tensile strength.

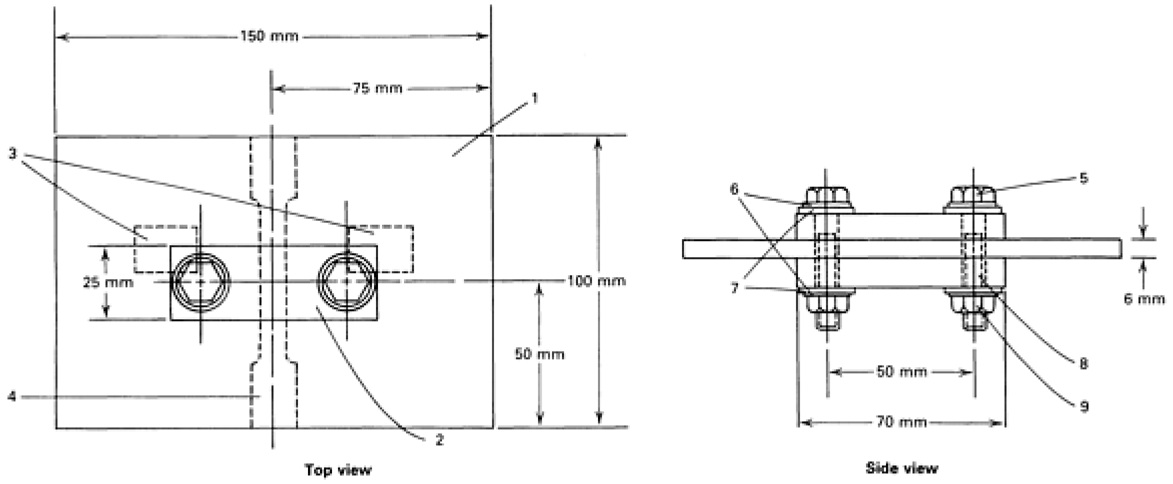

Fig. 7 Specimen configuration for the ISO test for atmospheric galvanic corrosion. 1, anodic plate, 1 piece; 2, cathodic plate, 2 pieces; 3, microsection, 2 pieces; 4, tensile test specimen; 5, bolt, 8 × 40 mm, 2 pieces; 6 washers, 1 mm thick, 16 mm diam, 4 pieces; 7, insulating washers, 1 to 3 mm thick, 18 to 20 mm diam, 4 pieces; 8, insulating sleeve, 2 pieces; 9, nut, 2 pieces. Dimensions given in millimeters

This test is relatively easy to perform, but requires the availability of plate of the materials of interest and a prior knowledge of which material is anodic. Like any atmospheric galvanic-corrosion test, crevice effects cannot be adequately separated from galvanic effects in some cases; therefore, a coating is sometimes applied between the anode and cathode plates. The disadvantage of this test is the time required to obtain results; for systems with moderate corrosion rates, exposures of 1 to 5 years are not unusual.

Another commonly used atmospheric galvanic-corrosion test is the wire-on-bolt test, sometimes referred to as the CLIMAT test (Ref 7, 8, 9). In this test, a wire of the anodic material is wrapped around a threaded rod of the cathodic material (Fig. 8). Because corrosion can be rapid in this test, exposure duration should usually be limited. This makes the test ideal for measuring atmospheric corrosivity as well as material corrosion properties. Not all materials of interest are available in the required wire and threaded rod forms, and analysis is usually restricted to weight loss measurement and observation of pitting. When the required materials are available, this test is less expensive and easier to conduct than the ISO plate test.

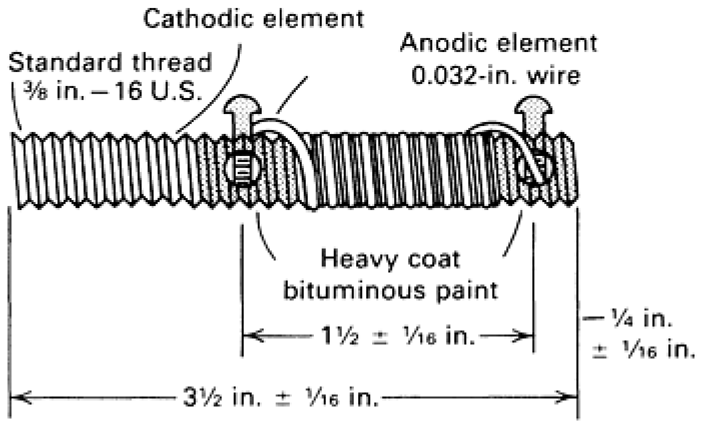

Fig. 8 Specimen configuration for the wire-on-bolt test for atmospheric galvanic corrosion

A third atmospheric galvanic-corrosion test has been used extensively by ASTM, but has not been standardized. This test (Ref 10) involves the use of 25-mm (1-in.) diam washers of the materials of interest bolted together as shown in Fig. 9. The bolt that holds the washers together can also be used to secure the assembly in position. After exposure, the washers can be disassembled for weight loss determination. The materials needed for this test are not as large as those for the ISO plate test, but it can take as long and cannot provide mechanical properties data.

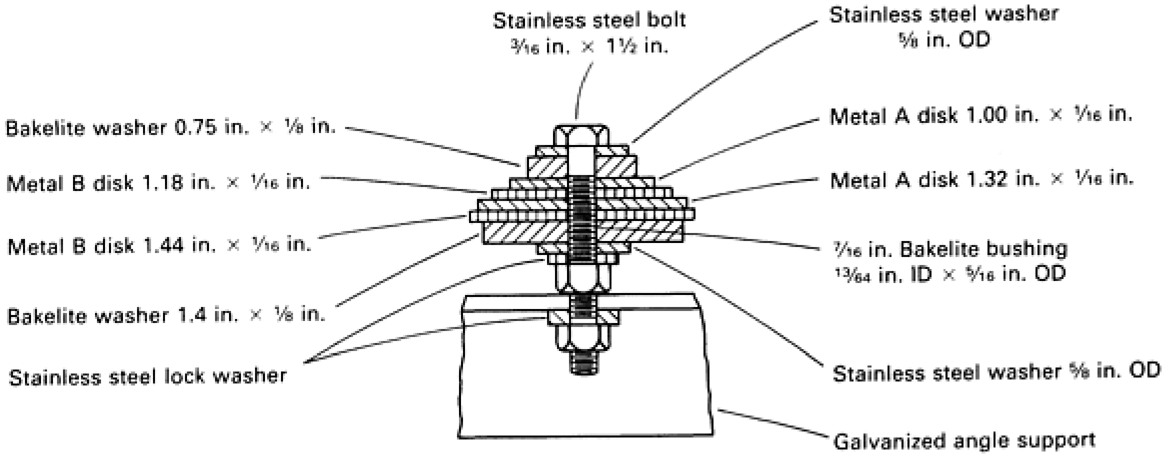

Fig. 9 Specimen configuration for the washer test for atmospheric galvanic corrosion

Evaluation of Intergranular Corrosion

Richard A. Corbett and Brian J. Saldanha, Corrosion Testing Laboratories, Inc.

Introduction

IN THE ARTICLE "Localized Corrosion" in this Volume, intergranular corrosion is defined and the mechanisms are described. It is the purpose of this article to discuss when to evaluate for susceptibility to intergranular attack and how to determine which of the various evaluation tests are applicable. However, it may first be necessary to review the methodology of intergranular corrosion and its effect on the various alloy families.

Most alloys are susceptible to intergranular attack when exposed to specific environments. This is because grain boundaries are sites for precipitation and segregation, which makes them chemically and physically different from the grains themselves. Intergranular attack is defined as the selective dissolution of grain boundaries, or closely adjacent regions, without appreciable attack of the grains themselves. This is caused by potential differences between the grain-boundary region and any precipitates, intermetallic phases, or impurities that form at the grain boundaries. The actual mechanism differs with each alloy system.

Precipitates that form as a result of the exposure of metals at elevated temperatures (for example, during production, fabrication, and welding) often nucleate and grow preferentially at grain boundaries. If these precipitates are rich in alloying elements that are essential for corrosion resistance, the regions adjacent to the grain boundary are depleted of these elements. The metal is thus sensitized and is susceptible to intergranular attack in a corrosive environment. For example, in austenitic stainless steels such as AISI type 304, the cause of intergranular attack is the precipitation of chromium-rich carbides [$(Cr, Fe)_{23}C_6$] at grain boundaries. These chromium-rich precipitates are surrounded by metal that is depleted in chromium; therefore, they are more rapidly attacked at these zones than on undepleted metal surfaces.

Impurities that segregate at grain boundaries may promote galvanic action in a corrosive environment by serving as anodic or cathodic sites. Therefore, this would affect the rate of dissolution of the alloy matrix in the vicinity of the grain boundary. An example of this is found in aluminum alloys when they contain intermetallic compounds, such as Mg_5Al_8 and $CuAl_2$, at the grain boundaries. During exposures to chloride solutions, the galvanic couples formed between these precipitates and the alloy matrix can lead to severe intergranular attack. Susceptibility to intergranular attack depends on the corrosive solution and on the extent of intergranular precipitation, which is a function of alloy composition, fabrication, and heat treatment parameters.

Corrosion tests for evaluating the susceptibility of an alloy to intergranular attack are typically classified as either simulated-service or accelerated tests. The first laboratory tests for detecting intergranular attack were simulated-service exposures. These were first observed and used in 1926 when intergranular attack was detected in an austenitic stainless steel in a copper sulfate-sulfuric acid ($CuSO_4$-H_2SO_4) pickling tank (Ref 1). Another simulated-service test for alloys intended for service in nitric acid (HNO_3) plants is described in Ref 2. In this case, for accelerated results, iron-chromium alloys were tested in a boiling 65% HNO_3 solution.

Over the years, specific tests have been developed and standardized for evaluating the susceptibility of various alloys to intergranular attack. For example, tests for the low-alloy austenitic stainless steels have been standardized by the American Society for Testing and Materials (ASTM) in Standard A 262, with its various practices (A to E). Practice A is a screening test that uses an electrolytic oxalic acid etch combined with metallographic examination. The other practices involve exposing the material (possibly after a sensitizing treatment) to boiling solutions of 65% HNO_3, acidified ferric sulfate ($Fe_2(SO_4)_3$) solution, nitric-hydrofluoric acid (HNO_3-HF) solution, or acidified $CuSO_4$ solution, depending on the specific alloy and its application. Similar ASTM tests have been developed for other higher-alloyed stainless steels, ferritic stainless steels, high nickel-base alloys, and aluminum alloys (Table 1).

Table 1 Appropriate evaluation tests and acceptance criteria for wrought alloys

UNS number	Alloy name	Applicable tests (ASTM standards)	Sensitizing treatment	Exposure time, h	Criteria for passing, appearance or maximum allowable corrosion rate, mm/month (mils/month)
S43000	Type 430	Ferric sulfate (A 763-X)	None	24	1.14 (45)
S44600	Type 446	Ferric sulfate (A 763-X)	None	72	0.25 (10)
S44625	26-1	Ferric sulfate (A 763-X)	None	120	0.05 (2) and no significant grain dropping

The Purpose of Testing

There is a perception in much of the industry that testing for susceptibility to intergranular attack is equivalent to evaluating the resistance of the alloy to general and localized corrosion. Although the tests used for evaluating susceptibility to intergranular attack are severe, they are not intended to duplicate conditions for the wide range of chemical exposures present in an industrial plant, even though some of these tests simulate service conditions.

Testing for susceptibility to intergranular attack, however, is useful for determining whether the correct material, in the proper metallurgical condition, has been supplied by a vendor. There are some problems associated with quality assurance programs for purchased materials. Such programs are sometimes based on faith in what is supplied by a vendor or production mill and what is certified in the documentation sent along with the material. However, such confidence may be misplaced. For example, there have been a number of accounts in which alloys have been substituted, resulting in premature failure. In one case, this occurred when Hastelloy B valves were substituted for the Hastelloy C-276 valves that were ordered to handle a hypochlorite solution. The Hastelloy B valves failed in about 3 months.

In addition, there are many examples in which the material supplied does not conform to its certified analysis. The problem of getting reliable certified analyses increases when documentation goes from a mill to an alloy supplier. In one case, for example, AISI type 304L stainless steel valves were ordered, but the vendor, having few orders for this alloy, substituted type 316L stainless steel valves and sent certifications that purposely omitted the molybdenum analysis. Normally, this would have been a good substitution for improved corrosion resistance at a bargain price, but these valves were destined for hot, concentrated HNO_3 service and failed prematurely.

These are just two examples of using a material that is incorrect or is not in the proper metallurgical condition; such problems, of course, are not limited to stainless steels. It should be realized that errors do occur and that for critical service the specified alloys must be in optimum metallurgical condition to resist intergranular attack and other forms of corrosion associated with precipitates at the grain boundaries.

Tests for Stainless Steels and Nickel-Base Alloys

The austenitic and ferritic stainless steels, as well as most nickel-base alloys, are generally supplied in a heat-treated condition such that they are free of carbide precipitates that are detrimental to corrosion resistance. However, these alloys are susceptible to sensitization from welding, improper heat treatment, and service in the sensitizing temperature range. The phenomenon of sensitization of these alloys is discussed further in the article "Corrosion of Stainless Steels," "Corrosion of Weldments," and "Corrosion of Nickel-Base Alloys" in this Volume.

The theory and application of acceptance tests for detecting the susceptibility of stainless steels and nickel-base alloys to intergranular attack are extensively reviewed in Ref 3 and 4. It would be repetitive to review this work other than to

discuss why and when it is necessary to evaluate the susceptibility of alloys to this form of attackand to discuss acceptable criteria for the tests used.

Because sensitized alloys may inadvertently be used, acceptance tests are implemented as a quality control check to evaluate stainless steels and nickel-base alloys when:

- Different alloys, or regular carbon types of the specified alloy, are submitted for the low-carbon grades (for example, type 316 substituted for type 316L) and are involved in welding or heat treating
- An improper heat treatment during fabrication results in the formation of intermetallic phases
- The specified limits for carbon and/or nitrogen contents of an alloy are inadvertently exceeded

Some standard tests include acceptance criteria, but others do not (Ref 3). Some type of criterion in needed that can clearly separate material susceptible to intergranular attack from that resistant to attack. Table 1 lists evaluation tests and acceptance criteria for various stainless steels and nickel-base alloys that have been used by the DuPont Company, the U.S. Department of Energy, and others in the chemical-processing industry. Identifying such rates still leaves the buyer and seller free to agree on a rate that meets their particular needs.

Tests for Aluminum Alloys

The electrochemically active paths at the grain boundaries of aluminum alloy materials can be either the solid solution or closely spaced anodic second-phase particles. The identities of the specific active paths vary with the alloy composition and metallurgical condition of the product, as discussed in the article "Corrosion of Aluminum and Aluminum Alloys" in this Volume and in Ref 5 and 6. The most serious forms of such structure-dependent corrosion are stress-corrosion cracking (SCC) and exfoliation. Stress-corrosion cracking requires the presence of a sustained tensile stress, and exfoliation occurs only in wrought products with a directional grain structure. Not all materials that are susceptible to intergranular attack, however, are susceptible to SCC or exfoliation. Therefore, specific tests are required for the latter (see the article "Evaluation of Exfoliation Corrosion" in this Volume).

Strain-Hardened 5*xxx* Alloys. Alloys in this series that contain more than about 3% Mg are rendered susceptible to intergranular attack (sensitized) by certain manufacturing conditions or after being subjected to elevated temperatures up to about 175 °C (350 °F). This is the result of the continuous grain-boundary precipitation of the highly anodic Mg_2Al_3 phase, which corrodes preferentially in most corrosive environments.

The ASTM standard G 67 is a method that provides a quantitative measure of the susceptibility to intergranular attack of these alloys (Ref 7). This method consists of immersing test specimens in concentrated HNO_3 at 30 °C (85 °F) for 24 h and determining the mass loss per unit area as the measure of intergranular susceptibility. When this second phase is precipitated in a relatively continuous network along grain boundaries, the preferential attack of the network causes whole grains to drop out of the specimens. Such dropping out causes relatively large mass losses of the order of 25 to 75 mg/cm_2, although specimens of intergranular-resistant materials lose only about 1 to 15 mg/cm^2. Intermediate mass losses occur when the precipitate is randomly distributed. The parallel relationship between the susceptibility to intergranular attack and to SCC and exfoliation of these particular alloys makes ASTM G 67 a useful screening test for alloy and process development studies. A problem arises, however, in selecting a pass-or-fail value in relation to the performance of intermediate materials in environments other than HNO_3.

Heat-Treated High-Strength Alloys. Materials problems caused by SCC, exfoliation, or corrosion fatigue of the early 2*xxx* (aluminum-copper) alloys were identified with intergranular corrosion, and the blame came to be associated with improper heat treatment. In 1944, an accelerated test for detecting susceptibility to intergranular corrosion was incorporated into a U.S. Government specification for the heat treatment of aluminum alloys. This specification has been superseded by the current Military Specification MIL-H-6088F. Tests are required for periodic monitoring of 2*xxx* and 7*xxx* series alloys in all rivets and fastener components as well as sheet, bar, rod, wire, and shapes under 6.4 mm (0.25 in.) thick. Specimen preparation, test procedure, and evaluation criteria are detailed in Ref 8.

Other Tests for Aluminum Alloys. The volume of hydrogen evolved upon immersion of etched 2*xxx* series (aluminum-copper-magnesium) aluminum alloys in a solution containing 3% sodium chloride (NaCl) and 1% hydrochloric acid (HCl) for a stipulated time has been used as a quantitative measure of the severity of intergranular

attack. A problem with this approach (which is quite valid) was that the correlation between the amount (or the rate) of hydrogen evolved is influenced by a number of factors, including alloy composition, temper, and grain size (Ref 9, 10).

Applied current or potential in neutral chloride solutions (for example, 0.1 *N* NaCl) provides another direct method of assessing the degree of susceptibility to intergranular attack when accompanied by a microscopic examination of metallographic sections (Ref 9, 11, 12). More sophisticated electrochemical approaches for studying systems involving active-path corrosion use potentiodynamic methods. Tests for SCC are discussed in the article "Evaluation of Stress-Corrosion Cracking" in this Volume.

Tests for Other Alloys

Although intergranular corrosion is present to some extent in alloys other than stainless and aluminum alloys, incidences of attack associated with this form of corrosion are few and are generally not of practical importance. Therefore, no attempts have been made to develop and standardize specific tests for detecting susceptibility to intergranular corrosion in these alloys. However, certain media have been commonly used for evaluating the susceptibility to intergranular corrosion of magnesium, copper, lead, and zinc alloys (Ref 13). These media are listed in Table 2. The presence or absence of attack in these tests is not necessarily a measure of the performance of the material in other corrosive environments.

Table 2 Media for testing susceptibility to intergranular corrosion

Alloy	Medium	Concentration, %	Temperature, °C (°F)
Magnesium alloys	Sodium chloride plus hydrochloric acid	. . .	Room
Copper alloys	Sodium chloride plus sulfuric or nitric acid	1 NaCl, 0.3 acid	40-50 (105-120)
Lead alloys	Acetic acid or hydrochloric acid	. . .	Room Room
Zinc alloys	Humid air	100% relative humidity	95 (205)

Source: Ref 13

Magnesium Alloys. There are rare instances of reported intergranular corrosion of magnesium alloys, as in the case of chronic acid contaminated with chlorides or sulfates.

The copper alloys that appear to be the most susceptible to intergranular corrosion are Muntz metal, admiralty metal, aluminum brasses, and silicon bronzes. Admiralty alloys have been observed to suffer intergranular corrosion upon exposure to saline cooling waters, although the incidence of attack is very low. The antimonial grades are reportedly superior to the arsenical grades in this respect. Similarly, arsenical and phosphorized grades of aluminum brass have been observed to suffer intergranular corrosion in seawater-type exposures.

Zinc die casting alloys have reportedly suffered intergranular corrosion in certain steam atmospheres. A laboratory test for simulating service failures, and particularly for alloy development work, has been is use for testing the susceptibility of zinc-base die castings to intergranular corrosion (Ref 14). The test consists of exposing samples to air at 95 °C (205 °F) and 100% relative humidity for 10 days under conditions permitting condensation of hot water on the metal. Susceptibility to intergranular corrosion is assessed by the effect on mechanical properties, such as impact strength. Experience has shown that castings with mechanical properties and dimensions that are not significantly altered by the 10-day exposure in this test will not suffer intergranular attack in atmospheric service.

Evaluation of Exfoliation Corrosion

Donald O. Sprowls, Consultant

Introduction

EXFOLIATION is a structure-dependent form of localized (usually) intergranular corrosion that is most familiar in certain alloys and tempers of aluminum. The mechanism of exfoliation is described in the article "Corrosion of Aluminum and Aluminum Alloys" in this Volume.

The occurrence of exfoliation in susceptible materials is influenced to a marked degree by environmental conditions. Figure 1 illustrates the broad range of behavior in different types of atmospheres. For example, forged truck wheels made of an aluminum-copper alloy (2024-T4) give corrosion-free service for many years in the warm climates of the southern and western United States, but they exfoliate severely in only 1 or 2 years in the northern states, where deicing salts are used on the highways during the winter months.

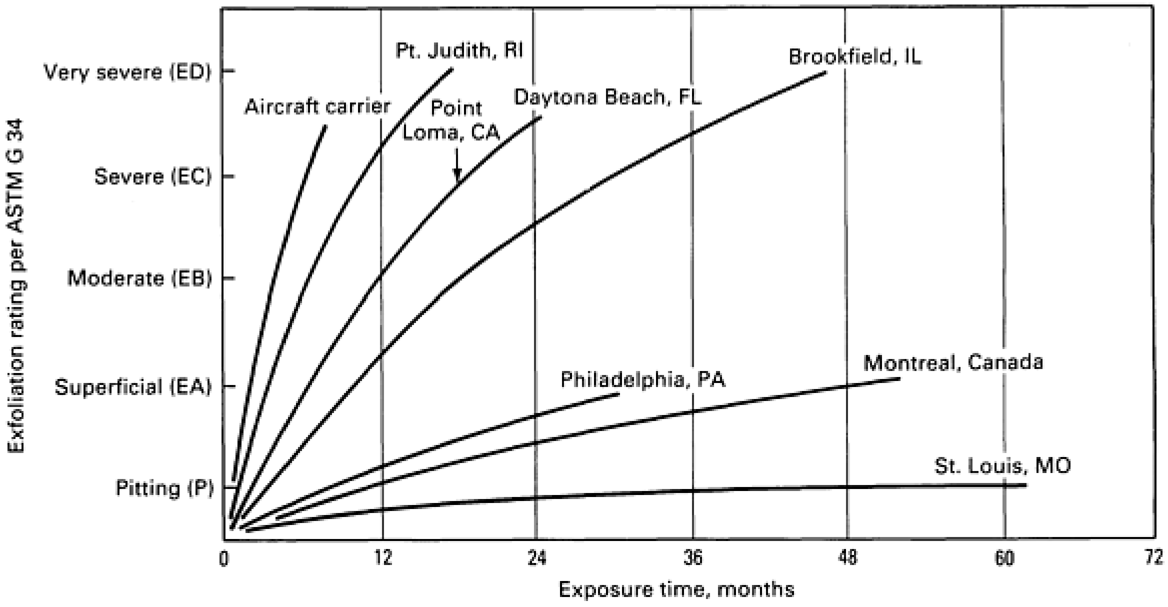

Fig. 1 Comparison of exfoliation of aluminum alloy 2124 (heat treated to be susceptible; EXCO ED rating) in various seacoast and industrial environments. Specimens were 13-mm ($\frac{1}{2}$-in.) plate. Source: Ref 1

Accelerated laboratory tests do not precisely predict long-term corrosion behavior; however, answers are needed quickly in the development of new materials. For this reason, accelerated tests are used to screen candidate alloys before conducting atmospheric exposures or other field tests. They are also sometimes used for quality control tests. Several new laboratory tests for exfoliation corrosion have been standardized in recent years under the jurisdiction of American Society for Testing and Materials (ASTM) Committee G-1 on the Corrosion of Metals.

Spray Tests

Three cyclic acidified salt spray tests have been widely used in the aluminum and aircraft industries. These are covered by the procedures described in Annexes A2, A3, and A4 of ASTM G 85 (Ref 2). This standard does not prescribe the particular practice, test specimen, or exposure period to be used for a specific product, nor does it define the interpretation to be given to the test results. These considerations are prescribed by specifications covering the material or product being tested or by agreement between the purchaser and the seller.

Annex A2 describes a cyclic salt spray test that uses a 5% sodium chloride (NaCl) solution acidified to pH 3 with acetic acid in a spray chamber at a temperature of 49 °C (120 °F). This test is applicable for exfoliation testing of 2*xxx* (dry-bottom operation) and 7*xxx* (wet-bottom operation; that is, with approximately 25 mm, or 1 in., of water present in the bottom of the test chamber) aluminum alloys with a test duration of 1 to 2 weeks. Results with 7075 and 7178 alloys in various metallurgical conditions have been shown to correlate well with results obtained in a seacoast atmosphere (4-year exposure at Point Judith, RI) (Ref 3).

Annex A3 describes another cyclic-salt spray test that uses a 5% synthetic sea salt solution acidified to pH 3 with acetic acid in a spray chamber at a temperature of 49 °C (120 °F). The test is applicable to the production control of exfoliation-resistant tempers of the 2*xxx*, 5*xxx*, and 7*xxx* aluminum alloys (Ref 4, 5). Wet-bottom operating conditions are recommended with test durations of 1 to 2 weeks.

Annex A4 describes a salt-sulfur dioxide (SO_2) spray test that uses either 5% NaCl or 5% synthetic sea salt solution in a spray chamber at a temperature of 35 °C (95 °F). The spray may be either cyclic or constant; this, along with the type of salt solution and the test duration, is subject to agreement between the purchaser and the seller. The test is applicable for 2*xxx* and 7*xxx* aluminum alloys. Test duration is 2 to 4 weeks (Ref 1).

Spray Tests

Three cyclic acidified salt spray tests have been widely used in the aluminum and aircraft industries. These are covered by the procedures described in Annexes A2, A3, and A4 of ASTM G 85 (Ref 2). This standard does not prescribe the particular practice, test specimen, or exposure period to be used for a specific product, nor does it define the interpretation to be given to the test results. These considerations are prescribed by specifications covering the material or product being tested or by agreement between the purchaser and the seller.

Annex A2 describes a cyclic salt spray test that uses a 5% sodium chloride (NaCl) solution acidified to pH 3 with acetic acid in a spray chamber at a temperature of 49 °C (120 °F). This test is applicable for exfoliation testing of 2*xxx* (dry-bottom operation) and 7*xxx* (wet-bottom operation; that is, with approximately 25 mm, or 1 in., of water present in the bottom of the test chamber) aluminum alloys with a test duration of 1 to 2 weeks. Results with 7075 and 7178 alloys in various metallurgical conditions have been shown to correlate well with results obtained in a seacoast atmosphere (4-year exposure at Point Judith, RI) (Ref 3).

Annex A3 describes another cyclic-salt spray test that uses a 5% synthetic sea salt solution acidified to pH 3 with acetic acid in a spray chamber at a temperature of 49 °C (120 °F). The test is applicable to the production control of exfoliation-resistant tempers of the 2*xxx,* 5*xxx,* and 7*xxx* aluminum alloys (Ref 4, 5). Wet-bottom operating conditions are recommended with test durations of 1 to 2 weeks.

Annex A4 describes a salt-sulfur dioxide (SO_2) spray test that uses either 5% NaCl or 5% synthetic sea salt solution in a spray chamber at a temperature of 35 °C (95 °F). The spray may be either cyclic or constant; this, along with the type of salt solution and the test duration, is subject to agreement between the purchaser and the seller. The test is applicable for 2*xxx* and 7*xxx* aluminum alloys. Test duration is 2 to 4 weeks (Ref 1).

Visual Assessment of Exfoliation

One of the problems in evaluating the extent of damage due to exfoliation corrosion is the lack of a generally acceptable numerical measure of the corrosion. Therefore, the usual practice, as noted above for ASTM G 34 and G 66, is to assign visual ratings reference to standard photographs, as shown in Fig. 2, 3, 4, and 5. The use of such ratings requires the inspector to make a judgment; because of this, the ratings are subject to variation among different inspectors.

Further, the lack of numerical measures of the corrosion damage hampers analysis of test results when a number of test materials must be compared. One approach is to assign numbers as substitutes for the letters. It is proposed for this purpose that a geometric scale (such as EA = 1, EB = 2, EC = 4, ED = 8) would be more consistent with the differences in damage illustrated by the standard photos than successive numbers would be (that is, 1, 2, 3, 4).

Evaluation of Stress-Corrosion Cracking

Donald O. Sprowls, Consultant

Introduction

THERE ARE A NUMBER of corrosion-related causes of the premature fracture of structural components. The most common of these are compared in Fig. 1. Cracking due to corrosion fatigue occurs only under cyclic or fluctuating operating loads, while failure resulting from the other processes shown occurs under static or slowly rising loads. With certain alloy systems, hydrogen embrittlement (see the articles "Environmentally Induced Cracking" and "Evaluation of Hydrogen Embrittlement" in this Volume) may have a contributory role in each of these failure processes. Appropriate tests for the different failure modes are discussed in other articles in this Section.

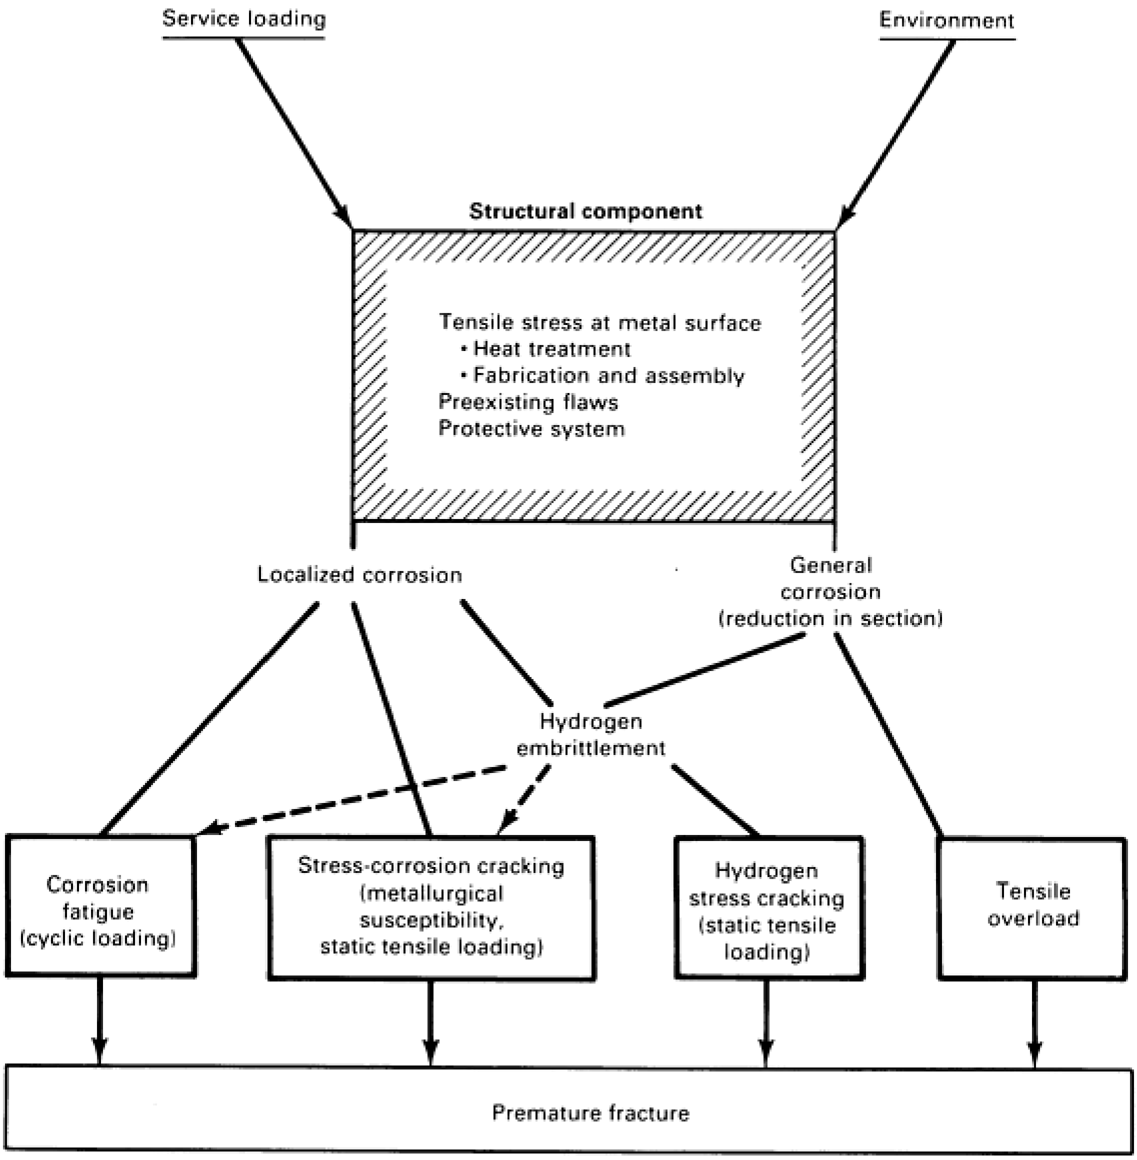

Fig. 1 Causes of premature fracture influenced by the corrosion of a structural component

This article will follow the broad outline listed below:

- General state of the art
- Static loading of smooth specimens
- Static loading of precracked specimens
- Dynamic loading: slow strain rate testing
- Selection of test environments
- Appropriate tests for various alloy systems
- Interpretation of test results

General State of the Art

Most stress-corrosion cracking (SCC) testing is performed either to determine the best material for a specific application or to compare the relative behaviors of material and environmental variations. Test conditions for the former should be representative of the most severe conditions anticipated in the intended service. For the latter, test conditions are usually chosen to produce various degrees of cracking in a reasonable time (Ref 1). The primary challenge in both cases is expressed well in the following statement, which was written a generation ago: "While it is relatively easy to determine if a product is susceptible to SCC, it is far more difficult to determine if it possesses a `degree of susceptibility' which will restrict its general usefulness" (Ref 2).

Historically, service failures due to SCC have been identified with sustained tensile stress; thus, SCC testing has developed around the use of static loading. In some situations, it is advantageous to use an actual structural component for testing. However, this is usually not practical; more often, it is necessary to select smaller specimens that afford the required predictive capability. Before about 1965, only constant-load or constant-strain test of smooth and notched test specimens of various configurations were used to assess SCC. More test methods are currently available than ever before.

During the 1960s, two accelerated testing techniques based on different mechanical approaches emerged. One technique tests and analyzes statically loaded, mechanically precracked test specimens by using linear elastic fracture mechanics concepts. The second technique consists of constant (slow) strain rate tests on smooth or precracked specimens. Laboratory testing with these techniques has frequently produced SCC, when the older, traditional tests have not.

Initiation and Propagation of SCC

The process of SCC is frequently discussed in terms of initiation (incubation and nucleation and propagation, and illustrations similar to Fig. 2 can be found in the literature. However, an accepted model has not been established. There may be a gradual transition from localized corrosion to crack initiation and growth with no separation of stages, or there may be a repeated succession of short steps of initiation and growth. In any event, from an engineering standpoint, it is convenient to hypothesize the process in two generic stages: initiation and propagation. This terminology will be used throughout this article.

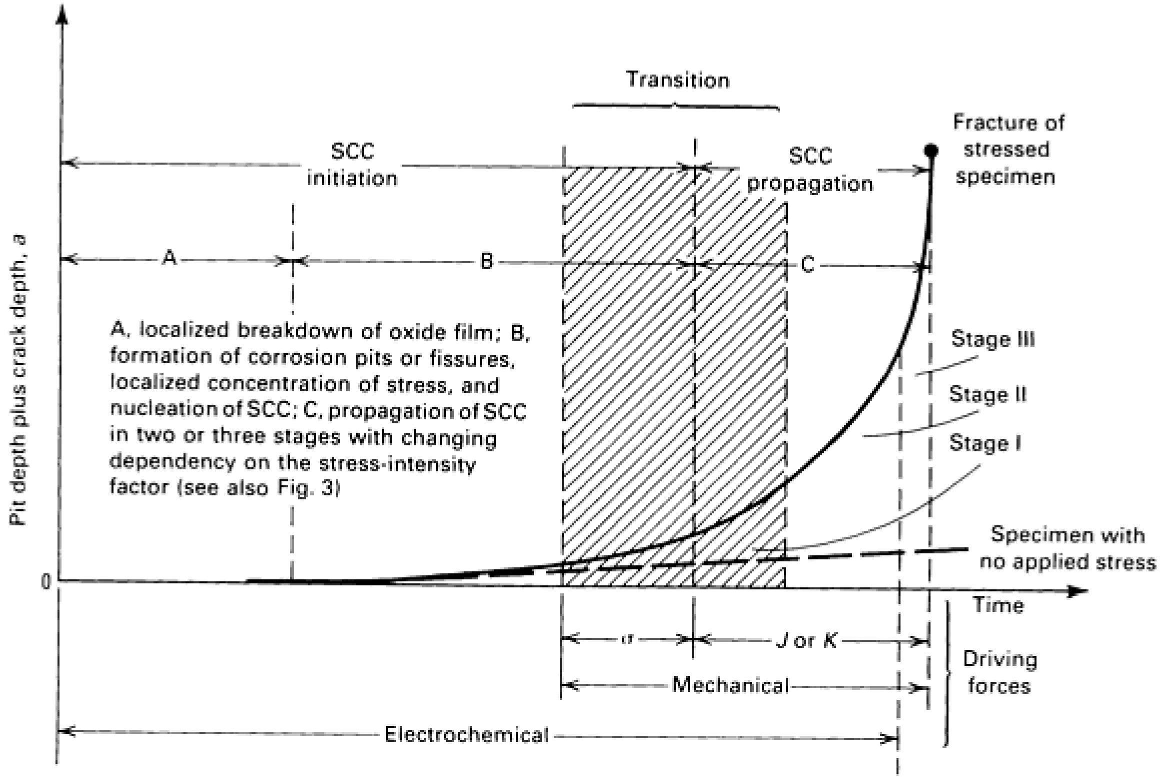

Fig. 2 The relative influences of electrochemical and mechanical factors in the corrosion and SCC damage of a

susceptible material. The shaded area represents the transition of driving force from dominance by electrochemical factors to chiefly mechanical factors. Precise separation of initiation and propagation stages is experimentally difficult. Stimulation of cracking by atomic hydrogen may also become involved in this transition region.

Two basic corrosion reactions, anodic and cathodic, dominate the SCC process in conjunction with mechanical stress. The chemical composition of the environment, including pH and the presence of hydrogen recombination poisons that affect the cathode reaction product, and the composition and metallurgical condition of the metal determine which of the two partial corrosion reactions is dominant. Anodic SCC (active path corrosion) involves the dissolution of metal during the initiation and propagation of cracks. Cathodic SCC (embrittlement by corrosion product hydrogen) involves the deposition of hydrogen at cathodic sites on the metal surface or on the walls of a fissure or crack and its subsequent absorption into the metal lattice. More information on the mechanisms of SCC is availablein the article "Environmentally Induced Cracking" in this Volume.

Figure 2 also suggests the relative influences of the electrochemical and mechanical driving forces in the SCC process. Figure 2 indicates a change as SCC proceeds, with the role of stress being negligible at first and then becoming dominant as subcritical cracking advances. Environmental action must always be involved, although it may be dominant only at first. The preexistence of a mechanical flaw or crack in the stressed metal may of course alter the initiation stage. Application of the fracture mechanics based stress intensity factor (*J* for elastic-plastic fracture mechanics; *K* for linear elastic fracture mechanics) as a driving force for the propagation of SCC is illustrated schematically in Fig. 2 and 3 (Ref 3, 4).

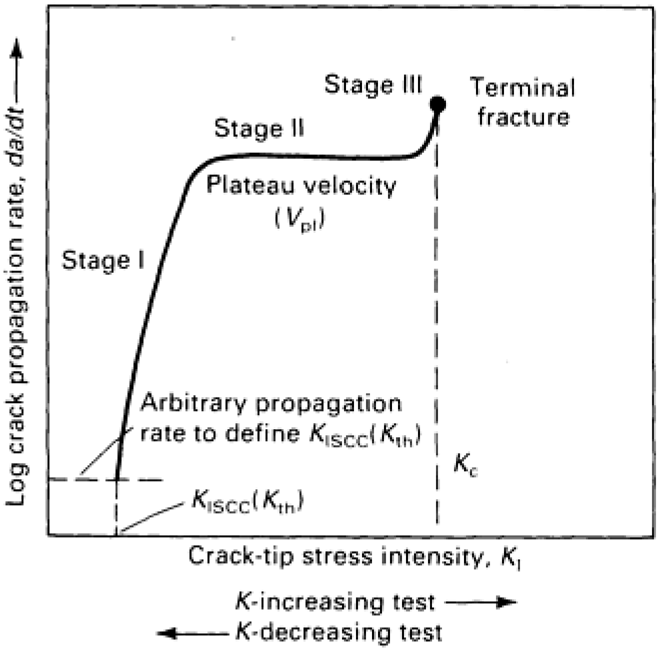

Fig. 3 Effect of stress intensity on the kinetics of SCC. Stages I and II may not always be straight lines but may be strongly curved, and one or the other may be absent in some systems. Stage III is of little interest and is generally absent in *K*-decreasing tests.

Standardization of Tests

Standardization of SCC test methods in the United States was initiated in the 1960s by the American Society for Testing and Materials (ASTM), the National Association of Corrosion Engineers (NACE), and the federal government. Standard tests have also been developed in Europe (Ref 5), and uniform testing methods are currently under development on a broader basis through the International Organization for Standardization (ISO). Reference will be made throughout this article to available standards and to useful publications for details on the test methods.

There are several essential factors that must be given carefully consideration in the design of all types of SCC tests:

- The composition of the test environment must remain constant throughout the test, unless changes are a part of the corrosion system of interest
- The materials used for SCC test fixtures must resist attack
- Stressing fixtures must remain dimensionally stable so as not to affect the stress placed on specimens during the test
- Galvanic action between the test specimens and ancillary equipment must be avoided; such action, if present, can either accelerate or retard SCC, depending on whether there is anodic or cathodic control

Static Loading of Smooth Specimens

Tests for predicting the stress-corrosion performance of an alloy in a particular service application should be conducted with a stress system similar to that anticipated in service. Table 1 lists the numerous sources of sustained tension that are known to have initiated SCC in service and the applicable methods of stressing. Most of the SCC service problems involve tensile stresses of unknown magnitude that are usually very high. The tests that incorporate a high total strain are usually the most realistic in terms of duplicating service.

Table 1 Stressing methods applicable to various sources of sustained tension in service

Source of sustained tension in service	Constant strain	Constant load
Residual stress		
Quenching after heat treatment	X	. . .
Forming	X	. . .
Welding	X	. . .
Misalignment (fit-up stresses)	X	. . .
Interference fasteners	X	. . .
Interference bushings		
Rigid	X	. . .
Flexible	. . .	X
Flareless fittings	X	. . .
Clamps	X	. . .

Hydraulic pressure	X	X
Dead weight	. . .	X
Faying surface corrosion	X	X

Note: The greatest hazard arises when residual, assembly, and operating stresses are additive.

The results are strongly influenced by the mechanical aspects of the tests, such as method of loading and specimen size. These mechanical aspects can have variable effects on the initiation and propagation lifetimes and can influence estimates of a threshold stress. Therefore, an apparent threshold stress for SCC is not a material property, and threshold estimates must be qualified with regard to the test conditions and the significance level.

Constant-Strain Versus Constant-Load Tests

Constant-strain (fixed-displacement) tests are widely used, primarily because a variety of simple and inexpensive stressing jigs can be devised. However, there is poor reproducibility of the exposure stress with some of these techniques. Therefore, sophisticated procedures have been developed to improve this facet of testing.

Constant-strain tests are sometimes called decreasing-load tests, because after the onset of SCC in small test specimens the gross section exposure stress decreases. This results from the opening of the crack (or cracks) under the high stress concentration at the crack tip (or tips) and causes some of the applied elastic strain to change to plastic strain, with an attendant reduction in the initial load (Ref 6, 7). Such trends in changing stress during crack growth are shown in Fig. 4.

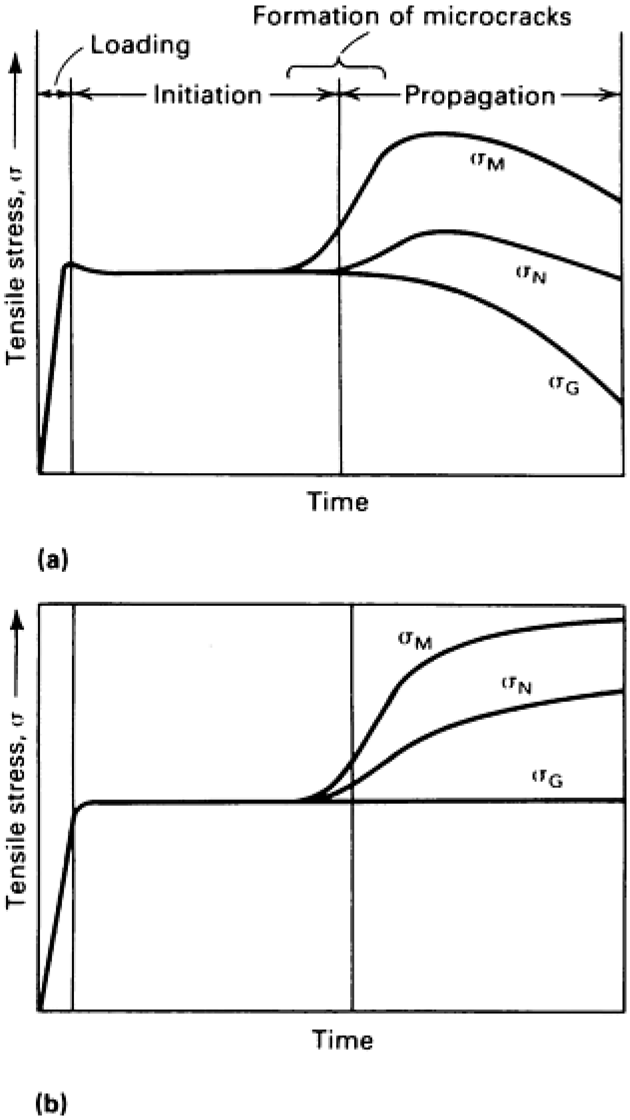

Fig. 4 Schematic comparison of changing stress during initiation and growth of isolated SCC in constant-strain and constant-load tests of a uniaxially loaded tension specimen. (a) Constant-strain test. (b) Constant-load test. σ_M is the maximum stress at crack tip, σ_N is the average stress in the net section, and σ_G is the applied stress to the gross section. Source: Ref 7

Comparison of the stress trends for a constant-strain test (Fig. 4a) with those for a constant-load test (Fig. 4b) reveals that neither method of loading provides a constant-stress test after growth of microcracks has occurred. True constant-load (dead-load) tests result in increasing stress levels as cracking progresses, and are more likely to lead to earlier failure with complete fracture and lower estimates of a threshold stress than constant-strain tests. Figures 4(a) and 4(b) illustrate basic trends that may be applied to all types of test specimens, including precracked specimens. Specific curves, however, will differ depending on other test conditions.

The stiffness of the combined stressing frame/test specimen system can have a significant effect on materials evaluation if identical test procedures are not used (Ref 6). Many so-called constant-strain tests, particularly if a spring is included in the stressing system, are not actually constant-strain tests, because a significant amount of elastic strain energy may be contained in the stressing system. Depending on the "softness" of the spring or the elasticity of the stressing jig, the stiffness (compliance) of the stressing system can be varied greatly between zero stiffness (dead load) and infinite stiffness (true constant total strain). Figure 5 shows the typical change in net section stress with the onset of SCC in an intermediate-stiffness stressing frame.

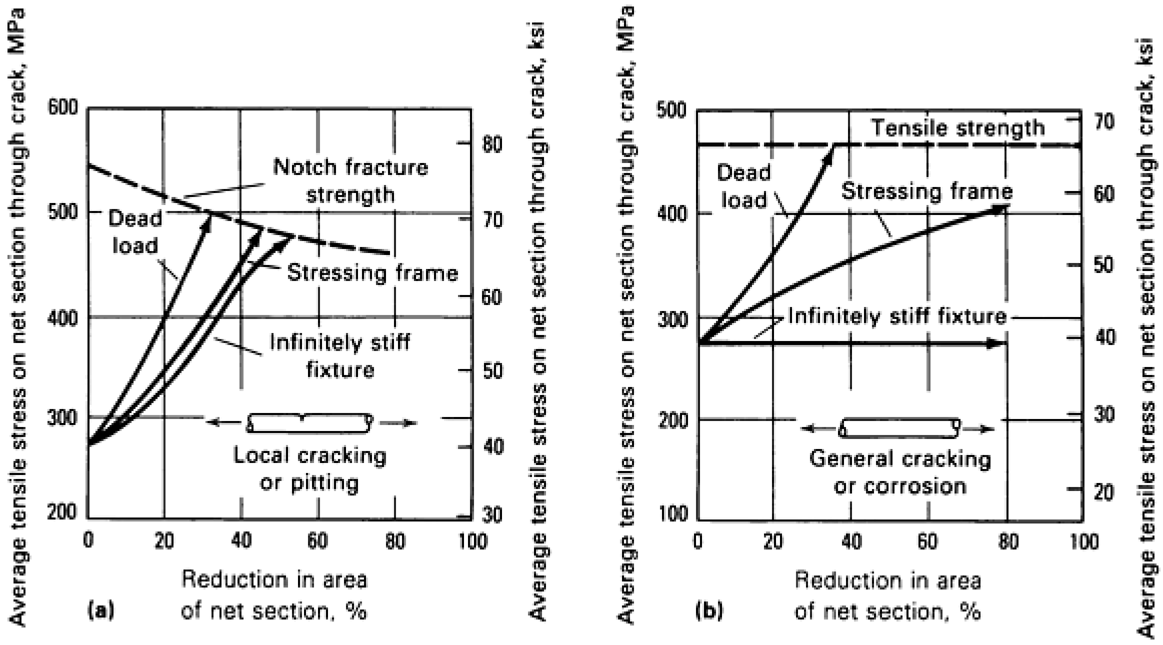

Fig. 5 Effect of loading method and extent of cracking or corrosion pattern on average net section stress in a uniaxially loaded tension specimen. Behavior is generally representative, but curves will vary with specific alloys and tempers. (a) Localized cracking. (b) General cracking. Source: Ref 8 (ASTM G 49)

The corrosion pattern on the test specimen, particularly the number and distribution of cracks, can impair the precision of results obtained by either constant-strain or constant-load tests. When isolated stress-corrosion cracks propagate in a specimen stressed by either method, the average tensile stress on the net section increases rapidly until the notch fracture strength is reached and the specimen breaks (Fig. 5a). Less penetration is required for fracture of specimens under dead load; this indicates that specimen life is shorter with lower-stiffness stressing frames. When microcracks initiate close to one another, their individual stress concentrations interact and are relaxed. Consequently, there may not be a sufficient stress concentration in the true constant-strain test to propagate further SCC, and the specimen will not break (Fig. 5b). Under a constant load, however, the growth of many cracks continues, and the specimen ultimately breaks.

With general cracking, crack propagation can be strongly influenced by frame stiffness. Therefore, SCC comparison of specimens tested at stress levels just above their thresholds is complicated by random variations in the cracking pattern, particularly when tested with relatively stiff stressing system.

Although constant-load stressing appears to be advantageous for testing materials with relatively high resistance to SCC, difficulties arise when small-diameter specimens are utilized to avoid the use of massive loads or lever systems. In some test environments, highly stressed specimens may fail from general or pitting corrosion and an attendant increase in the effective stress. Such non-SCC failures complicate interpretation of test results, unless failure by SCC is confirmed by metallographic examination. Such extraneous failures are less likely to occur with specimens loaded under constant strain.

Therefore, small test specimens, which are generally preferred for laboratory screening tests and research studies, must be used with caution when estimates of serviceability are required. To determine serviceability, larger specimens should be used, and a stressing system should be selected that best duplicates the anticipated service conditions.

Bending Versus Uniaxial Tension

Historically, the most extensively used stressing systems have incorporated constant-deformation specimens stressed by bending. This method is versatile because of the variety of simple techniques that can be used to test most metal products in all types of corrosive environments. The state of stress in a bend specimen, however, is much more complex than in a tension specimen. Theoretically, tensile stress is uniform throughout the cross section in the tension specimen, except at corners in rectangular sections, but the tensile stress in bend specimens varies through the specimen thickness.

Tensile stress is at a maximum on the convex surface and decreases steeply to zero at the neutral axis. It then changes to a compressive stress, which reaches a maximum on the concave surface. Thus, only about 50% of the metal surface is under tension, and stress can vary from maximum to zero, depending on the stressing system. As SCC penetrates the metal, the stress gradient through the section thickness produces changes in stresses and strains that are different from those in a uniaxial tension specimen. This tendency yields significantly different SCC responses for the two types of stressing (Fig. 6).

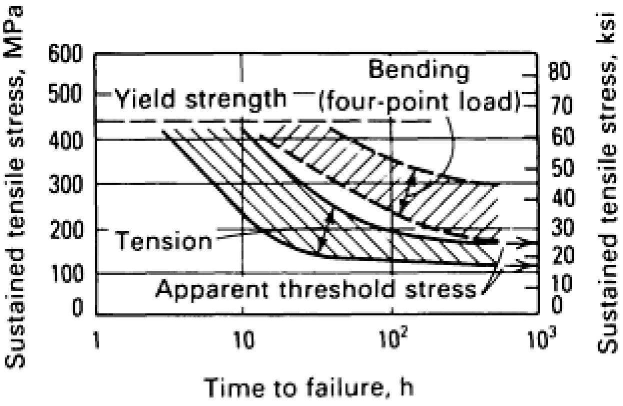

Fig. 6 Comparison of the SCC response with bending versus direct tension stressing under constant load for Al-5.3Zn-3.7Mg-0.3Mn-0.1Cr T6 temper alloy steel. Tested to failure in 3% sodium chloride plus 0.1% hydrogen peroxide. Source: Ref 9

Bending stress specimens experience other sources of variability in stress that are not present with direct tension stressing. Variations occur in the principal longitudinal stress across the width of the specimen as well as with the presence of biaxial stresses, both of which are influenced by the design of the specimen. Therefore, just as in the case of constant-load stressing, optimal control of stress and more severe testing conditions are provided by uniaxial tension stressing.

Statically loaded, smooth test specimens for SCC tests can be divided into three general categories: elastic strain specimens, plastic strain specimens, and residual stress specimens. The commonly used specimen geometries for each of these categories are discussed below.

Elastic Strain Specimens

To control the surface tensile stress applied by deformation loading, strain is usually restricted to the elastic range for the test material. The magnitude of the applied stress can then be calculated from the measured strain and modulus of elasticity. In constant-load stressing, the load typically is measured directly, and the stress is calculated by using the appropriate formula for the specimen configuration and the method of loading. Load cells or calibrated springs may be useful for applying and monitoring possible changes in load during the test. The commonly used types of specimens for tests under elastic-range stress are described below.

Bent-beam specimens can be used to test a variety of product forms. The bent-beam configuration is primarily used for sheet, plate, or flat extruded sections, which conveniently provide flat specimens of rectangular cross section, but it is also used for cast materials, rod, pipe, or machined specimens of circular cross section. This method is applicable to specimens of any metal that are stressed to levels less than the elastic limit of the material; therefore, the applied stress can be calculated or measured accurately (ASTM G 39) (Ref 8).

Stress calculations by this method are not applicable to plastically stressed specimens. Bent-beam specimens are usually tested under constant-strain conditions, but constant-load conditions can also be used. In either case, local changes in the curvature of the specimen when cracking occurs result in changes in stress and strain during crack propagation. The "test stress" is taken as the highest surface tensile stress existing at the start of the test, that is, before the initiation of SCC.

Several configurations of bent-beam specimens and stressing systems are illustrated in Fig. 7 and are described in detail in ASTM G 39 (Ref 8). When specimens are tested at elevated temperatures, the possibility of stress relaxation should be

investigated. More information on stress relaxation is available in the article "Creep, Stress-Rupture, and Stress-Relaxation Testing" in *Mechanical Testing,* Volume 8 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Fig. 7 Schematic specimen and holder configurations for bent-beam stressing. (a) Two-point loaded specimen. (b) Three-point loaded specimen. (c) Four-point loaded specimen. (d) Welded double-beam specimen. (e) Bolt-loaded double-beam specimen. Formula for stressing specimen (e): $\Delta d = 2fa/3Et(3L - 4a)$, where Δd is deflection (in inches), *f* is nominal stress (in pounds per square inch), and *E* is modulus of elasticity (in pounds per square inch). Source: Ref 10

Two-point loaded specimens can be used for materials that do not deform plastically when bent to $(L - H)/H = 0.01$. The specimens should be approximately 25- × 250-mm (1- × 10-in.) flat strips cut to appropriate lengths to produce the

desired stress after bending, as shown in Fig. 7(a). The maximum stress occurs at the midlength of the specimen and decreases to zero at specimen ends.

Three-point loaded specimens are flat strips that are typically 25 to 51 mm (1 to 2 in.) wide and 127 to 254 mm (5 to 10 in.) long. The thickness of a specimen is usually dictated by the mechanical properties of the material and the available product form. The specimen should be supported at the ends and bent by forcing a screw (equipped with a ball or knife-edge tip) against it at a point halfway between the end supports, as shown in Fig. 7(b). In a three-point loaded specimen, the maximum stress occurs at the midlength of the specimen and decreases linearly to zero at the outer supports.

Two- and four-point loaded specimens are often preferred over the three-point loaded specimen, because crevice corrosion often occurs at the central support of the three-point loaded specimen. Because this corrosion site is very close to the point of highest tensile stress, it may cathodically protect the specimen and prevent possible crack formation, or it may cause hydrogen embrittlement. Furthermore, the pressure of the central support at the point of highest load introduces biaxial stresses at the area of contact and can introduce tensile stresses where compressive stresses are normally present.

Four-point loaded specimens are flat strips that are typically 25 to 51 mm (1 to 2 in.) wide and 127 to 254 mm (5 to 10 in.) long. The thickness of a specimen is usually dictated by the mechanical properties of the material and the available product form. The specimen is supported at the ends and is bent by forcing two inner supports against it, as shown in Fig. 7(c). The two inner supports are located symmetrically around the midpoint of the specimen.

In a four-point loaded specimen, the maximum stress occurs between the contact points of the inner supports; the stress is uniform in this area. From the inner supports, the stress decreases linearly toward zero at the outer supports. The four-point loaded specimen is preferred over the three-point and two-point loaded specimens, because it provides a large area of uniform stress.

Welded double-beam specimens consist of two flat strips 25 to 51 mm (1 to 2 in.) wide and 127 to 254 mm (5 to 10 in.) long. The strips are bent against each other over a centrally located spacer until both ends touch. The strips are held in position by welding the ends together, as shown in Fig. 7(d).

In a welded double-beam specimen, the maximum stress occurs between the contact points of the spacer; the stress is uniform in this area. From contact with the spacer, the stress decreases linearly toward zero at the ends of the specimen.

A bolt-loaded double-beam specimen is shown in Fig. 7(e), along with suggested specimen dimensions for various thicknesses of plate and the formula for stressing such specimens (Ref 10). The beam deflections required to develop the intended tensile stress are calculated with the formula and are then applied by bolting the ends of the beams together. The deflections are measured with a dial gage to within ±0.0127 mm (±0.0005 in.). Thus, the error in stress application--if the beams are of homogeneous material and if the cross sections are uniform--is within 2%. The precision of the deflection measurement is within 0.5%, and the error in determining the modulus of elasticity, *E*, is within 1%.

Constant-moment beam specimens are designed such that a constant moment exists from one end to the other when the specimen is bent in the manner shown in Fig. 8. This bending produces equal stress along the length of the specimen. The width-to-thickness ratio is less than 4 so that biaxial stresses are eliminated.

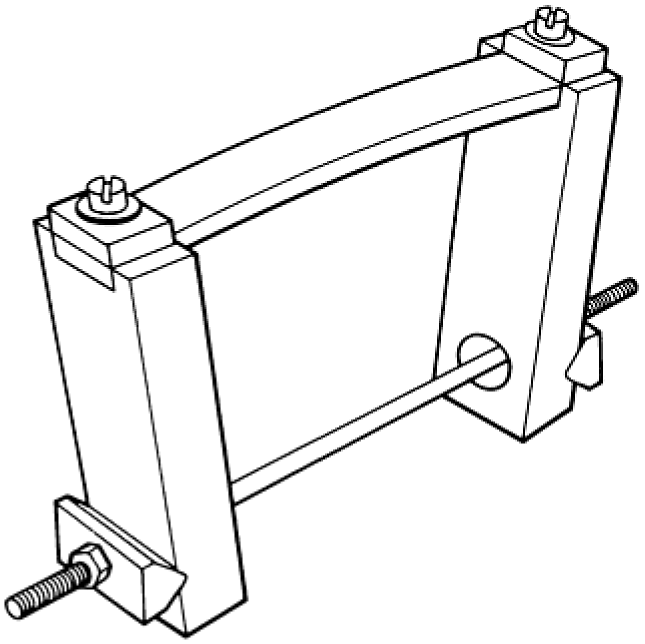

Fig. 8 Bent beam designed to produce pure bending. Source: Ref 11

This type of specimen offers the advantage of a relatively large area of material under a uniform stress. Such specimens can be used when the dimensions of the specimen are too small for other bent-beam specimens--for example, when specimens are taken in the short-transverse direction in plate (see Fig. 18c). The elastic stress σ in the convex surface is calculated by using:

$$\sigma = \frac{4Ety}{h^2} \quad \textbf{(Eq 1)}$$

where *h* is the distance between inner edges of the supports, *y* is the maximum deflection between inner edges of the supports, *t* is the thickness of the specimen, and *E* is the modulus of elasticity.

C-Ring Specimens. As discussed in ASTM G 38, (Ref 8), the C-ring is a versatile, economical specimen for quantitatively determining the susceptibility to SCC of all types of alloys in a wide variety of product forms. It is particularly well suited for testing tubing and for making short-transverse tests on various product forms, as shown in Fig. 9. The sizes of C-rings can be varied over a wide range, but rings with outside diameters less than about 16 mm ($\frac{5}{8}$ in.) are not recommended because of increased difficulties in machining and decreased precision in stressing.

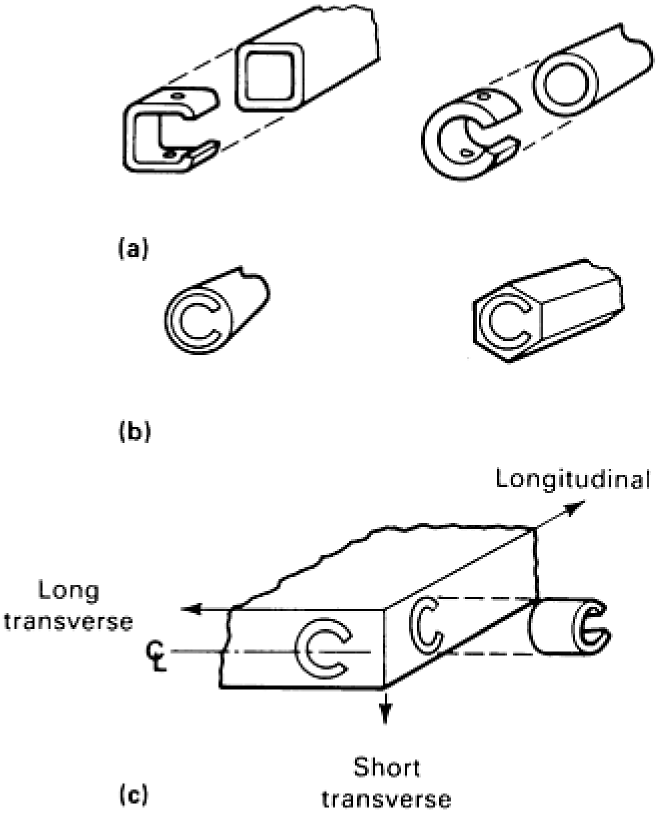

Fig. 9 Sampling procedure for testing various products with C-rings. (a) Tube. (b) Rod and bar. (c) Plate

The C-ring is typically a constant-strain specimen with tensile stress produced on the exterior of the ring by the tightening of a bolt centered on the diameter of the ring. However, an almost constant load can be developed by placing a calibrated spring on the loading bolt. C-rings can also be stressed in the reverse direction by spreading the ring and creating a tensile stress on the inside surface. These methods of stressing are illustrated in Fig. 10.

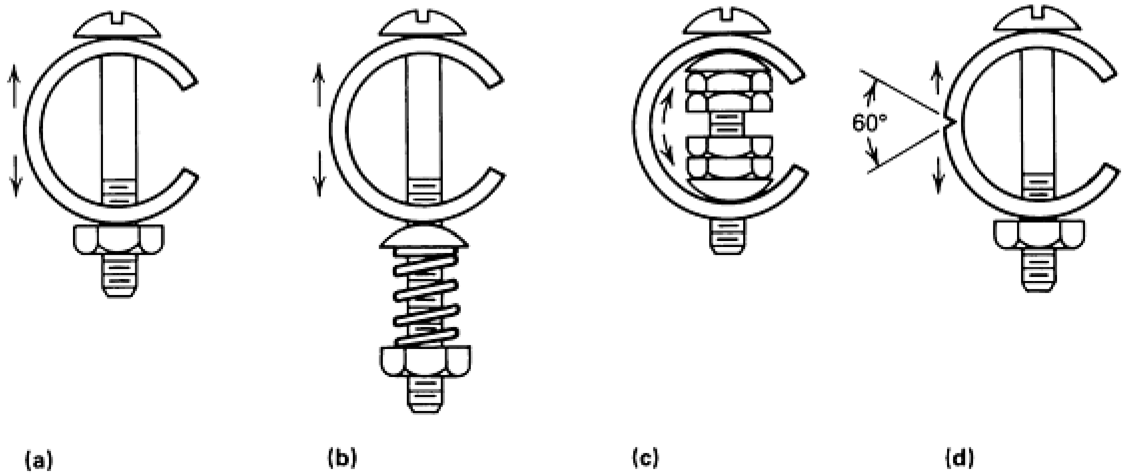

Fig. 10 Methods of stressing C-rings. (a) Constant strain. (b) Constant load. (c) Constant strain. (d) Notched C-ring; a similar notch could be used on the side of (a), (b), or (c).

Circumferential stress is of principal interest in the C-ring specimen. This stress is not uniform (Ref 12), as discussed previously in the section "Elastic Strain Specimens" in this article. The stress varies around the circumference of the C-ring from zero at each bolt hole to a maximum at the middle of the arc opposite the stressing bolt. In a notched C-ring, a triaxial stress state is present adjacent to the root of the notch (Ref 13). For all notches, the circumferential stress at the root of the notch is greater than the nominal stress and can generally be expected to be in the plastic range.

Generally, the C-ring can be stressed with high precision. The most accurate stressing procedure consists of attaching circumferential and transverse electrical strain gages to the surface stressed in tension, followed by tightening the bolt until the strain measurements indicate the desired circumferential stress.

The amount of compression required on the C-ring to produce elastic straining and the degree of elastic strain can be predicted theoretically. Therefore, C-rings can be stressed by calculating the deflection required to develop a desired elastic stress (ASTM G 38) (Ref 8). In notched specimens, a nominal stress is estimated using a ring outside diameter measured at the root of the notch and by taking into consideration the stress-concentration factor, K_t, for the specific notch.

O-ring specimens (Fig. 11) are used to develop a hoop stress in a particular part--for example, a cylindrical die forging in which a critical end-grain structure associated with the parting plane of the forging exists only at the surface of the forging. A relatively large surface area of metal is placed under a uniform tensile stress, and the O-ring stressing plug assembly simulates service conditions in structures containing interference-fit components. Stressed O-rings have also been used to evaluate protective treatments for the prevention of SCC (Ref 14).

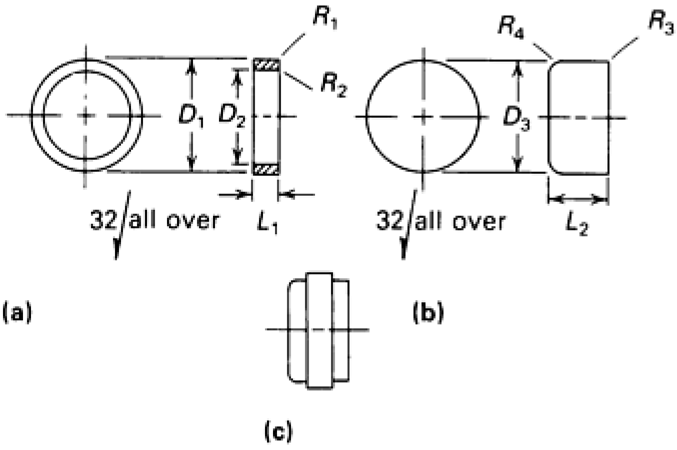

Fig. 11 O-ring SCC test specimen (a) and stressing plug (b). The O-ring is stressed by pressing it onto the plug, as shown in (c).

An O-ring is stressed by pressing it onto an oversized plug that is machined to a predetermined diameter to develop the desired stress at the outside surface of the ring. The nominal dimensions of this specimen can be varied to suit the part being tested, but certain characteristics should be observed to achieve adequate control of the stresses. The ring width should not be more than four times the wall thickness in order to ensure maximum uniformity of the hoop stress from the centerline to the edges of the ring. The tensile stress varies through the thickness of the ring and is highest at the inside surface. Interference required for stressing an O-ring can be calculated by using:

$$I = \frac{F(\text{OD})^2}{E(\text{ID})} \quad \textbf{(Eq 2)}$$

where *I* is the interference (on the diameter) between the O-ring and the plug, *E* is the modulus of elasticity, ID is the inside diameter, OD is the outside diameter, and *F* is the circumferential stress desired on the outside surface. Additional information regarding the design and stressing of O-ring specimens is given in Ref 15.

Tension Specimens. Specimens used to determine tensile properties in air are well suited and easily adapted to SCC, as discussed in ASTM G 49 (Ref 8). When uniaxially loaded in tension, the stress pattern is simple and uniform, and the magnitude of the applied stress can be accurately determined. Specimens can be quantitatively stressed by using equipment for application of either a constant load, a constant strain, or an increasing load or strain.

This type of test is one of the most versatile methods of SCC testing because of the flexibility permitted in the type and size of the test specimen, the stressing procedures, and the range of stress level. It allows the simultaneous exposure of unstressed specimens (no applied load) with stressed specimens and subsequent tension testing to distinguish between the effects of true SCC and mechanical overload.

A wide range of test specimen sizes can be used, depending primarily on the dimensions of the product to be tested. Stress-corrosion test results can be significantly influenced by the cross section of the test specimen. Although large specimens may be more representative of most structures, they often cannot be prepared from the available product forms being evaluated. They also present more difficulties in stressing and handling in laboratory testing.

Smaller cross-sectional specimens are widely used. They have a greater sensitivity to SCC initiation, usually yield test results rapidly, and permit greater convenience in testing. However, the smaller specimens are more difficult to machine, and test results are more likely to be influenced by extraneous stress concentrations resulting from nonaxial loading, corrosion pits, and so on. Therefore, use of specimens less than about 10 mm (0.4 in.) in gage length and 3 mm (0.12 in.) in diameter is not recommended, except when testing wire specimens.

Tension specimens containing machined notches can be used to study SCC and hydrogen embrittlement. The presence of a notch induces a triaxial stress state at the root of the notch, in which the actual stress will be greater by a concentration factor that is dependent on the notch geometry. The advantages of such specimens include the localization of cracking to the notch region and acceleration of failure. However, unless directly related to practical service conditions, the results may not be relevant.

Tension specimens can be subjected to a wide range of stress levels associated with either elastic or plastic strain. Because the stress system is intended to be essentially uniaxial (except in the case of notched specimens), great care must be exercised in the construction of stressing frames to prevent or minimize bending or torsional stresses.

The simplest method of providing a constant load consists of a dead weight hung on one end of the specimen. This method is particularly useful for wire specimens. For specimens of larger cross section, however, lever systems such as those used in creep-testing machines are more practical. The primary advantage of any dead-weight loading device is the constancy of the applied load.

A constant-load system can be modified by the use of a calibrated spring, such as that shown in Fig. 12. The proving ring, as used in the calibration of tension testing machines, has also been adapted to SCC testing to provide a simple, compact, easily operated device for applying axial load (Fig. 13). The load is applied by tightening a nut on one of the bolts and is determined by carefully measuring the change in ring diameter.

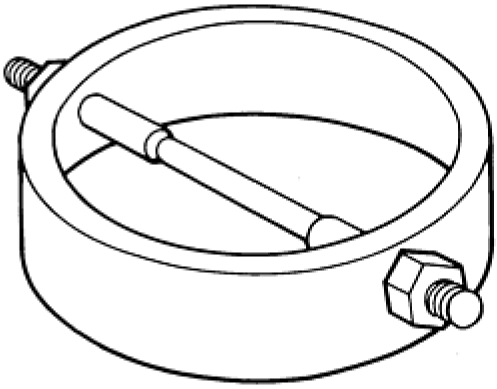

Fig. 13 Ring-stressed tension specimen for field testing. Source: Ref 1

Constant-strain SCC tests are performed in low-compliance tension-testing machines. The specimen is loaded to the required stress level, and the moving beam is then locked in position. Other laboratory stressing frames have been used, generally for testing specimens of smaller cross section. Figure 14(a) shows an exploded view of such a stressing frame, and Fig. 14(b) illustrates a special loading device developed to ensure axial loading with minimal torsion and bending of the specimen.

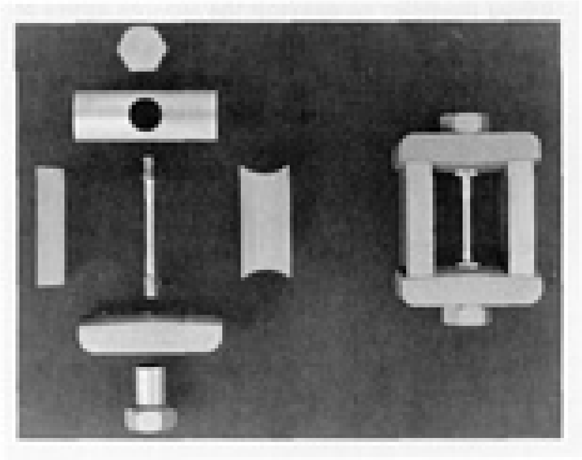

Fig. 14(a) Constant-strain SCC testing frame. Exploded view (left) showing the 3.2-mm (0.125-in.) diam tension specimen and various parts of the stressing frame. Final stressed assembly (right). Source: Ref 16

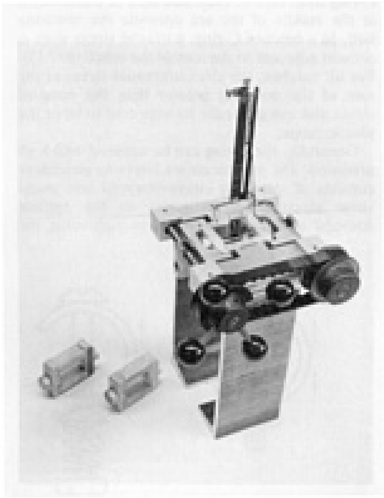

Fig. 14(b) Synchronous loading device used to stress specimens. The specimen is loaded to a prescribed strain value determined from a clip-on gage. The applied stress is given by the product of the strain and the material elastic modulus. A stressed assembly and one assembled finger-tight ready for stressing are shown.

For stressing frames that do not contain any mechanism for the measurement of load, the stress level can be determined from measurement of the strain. However, only when the intended stress is below the elastic limit of the test material is the average linear stress (σ) proportional to the average linear strain (ϵ), $\sigma/\epsilon = E$, where E is the modulus of elasticity.

When tests are conducted at elevated temperatures with constant-strain loaded specimens, consideration should be given to the possibility of stress relaxation. When stress relaxation or creep occurs in the test specimen, some of the elastic strain is converted to plastic strain and the nominal applied test stress is reduced. This effect is particularly important when the coefficients of thermal expansion are different for the specimen and stressing frame. Frequently, nonmetallic (plastic) insulators are used between the specimen and stressing frame to avoid galvanic action. If such plastic insulators are part of the stress-bearing system, creep (even at room temperature) can significantly alter the applied load on the specimen.

Even though eccentricity in loading can be minimized to levels acceptable for tension-testing machines, tensile stress around the circumference of round specimens and at the corners of sheet-type specimens varies to some extent. Several factors may introduce bending moments on specimens, such as longitudinal curvature and misalignment of threads on threaded-end round specimens. These factors have a greater effect on specimens with smaller cross sections. Tests should

be made on specimens with strain gages affixed to the specimen surface around the circumference of 90° or 120° intervals to verify strain and stress uniformity and to determine if machining practices and stressing jigs are of adequate tolerance and quality.

When SCC occurs, it generally results in complete fracture of the specimen, which is easy to detect. However, when testing relatively ductile materials at stress levels close to the threshold of susceptibility, fracture may not occur during the period of exposure. The presence of SCC in such cases must be determined by mechanical tests or by metallographic examination, as discussed previously.

To study trends in SCC susceptibility, such as in alloy development research, it is often necessary to detect small differences in susceptibility. For this purpose, it is advantageous to use replicate sets of specimens stressed at several levels, including zero applied stress. The sets are then removed for metallographic examination or tension tests after appropriate periods of exposure.

Figure 15 illustrates the use of this procedure with samples of 7075 aluminum alloy that have been given different thermal treatments to decrease susceptibility to SCC. Analysis of these breaking stress data by extreme value statistics enables calculation of survival probabilities and the estimation of a threshold stress, without depending on failures during exposure. By using an elastic-plastic fracture mechanics model, an effective flaw size is calculated from the mean breaking stress, the strength, and the fracture toughness of the test material. The effective flaw size corresponds to the weakest link in the specimen at the time of the tension test, and it therefore represents the maximum penetration of the SCC. An advantage to using flaw depth to examine SCC performance is that the effects of specimen size and alloy strength and toughness can be normalized. In contrast, the specimen lifetime and breaking strength are biased by those mechanical (non-SCC) factors.

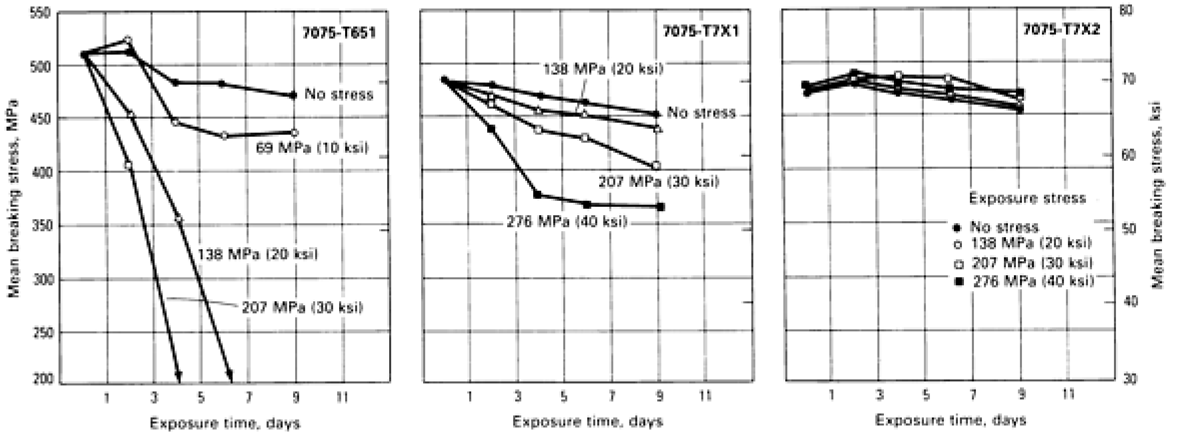

Fig. 15 Mean breaking stress versus exposure time for short-transverse 3.2-mm (0.125-in.) diam aluminum alloy 7075 tension specimens tested according to ASTM G 44 at various exposure stress levels. Each point represents an average of five specimens. Source: Ref 3

Mean trends in the 207-MPa (30-ksi) exposure data for the three temper variants of aluminum alloy 7075 examined in Fig. 15 are shown in Fig. 16. These results clearly illustrate that the thermal treatments used to reduce the SCC susceptibility of the 7075-T651 decreased the SCC penetration (Ref 17). The equivalent performance of the 7075-T7X1 3.2- and 5.7-mm (0.125- and 0.225-in.) diam specimens is evident. In contrast, Fig. 17 shows the specimen biases in SCC ratings obtained by traditional pass-fail methods (Ref 18).

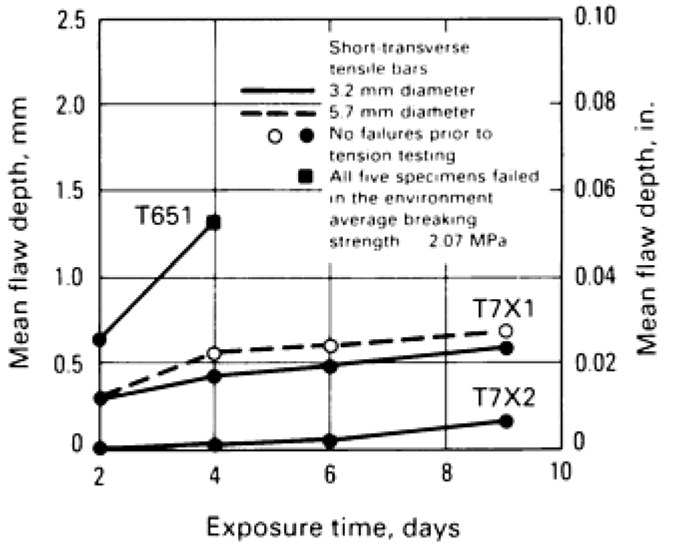

Fig. 16 Effect of temper on SCC performance of aluminum alloy 7075 subjected to alternate immersion in 3.5% NaCl solution at a stress of 207 MPa (30 ksi). Mean flow depth was calculated from the average breaking strength of five specimens subjected to identical conditions. Source: Ref 17

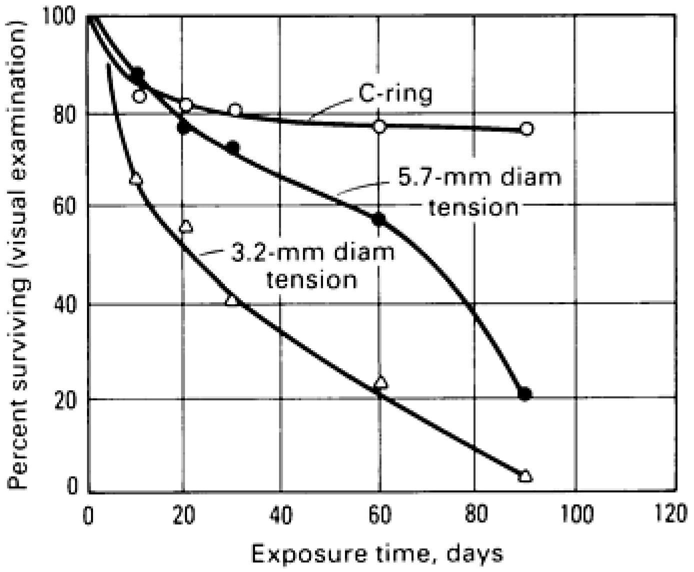

Fig. 17 Influence of specimen configuration on SCC test performance (alternate immersion in 3.5% sodium chloride per ASTM G 44). Aluminum alloy 7075-T7X51 specimens stressed 310 MPa (45 ksi); each point represents 60 to 90 specimens. Source: Ref 18

Tuning fork specimens are special-purpose specimens with numerous modifications (Fig. 18). In Europe, the metal is strained into the plastic range, and stresses and strains are usually not measured (Ref 19, 21). In the United States, however, these specimens have been used with measured strains in the elastic and plastic ranges. Specimens of the type shown in Fig. 18(b) are convenient when a small self-contained specimen is required that will afford some insight into the applied stresses. Such a specimen is particularly well suited for testing thin plate material in the longitudinal or long-transverse direction while keeping the original mill-finished surface intact.

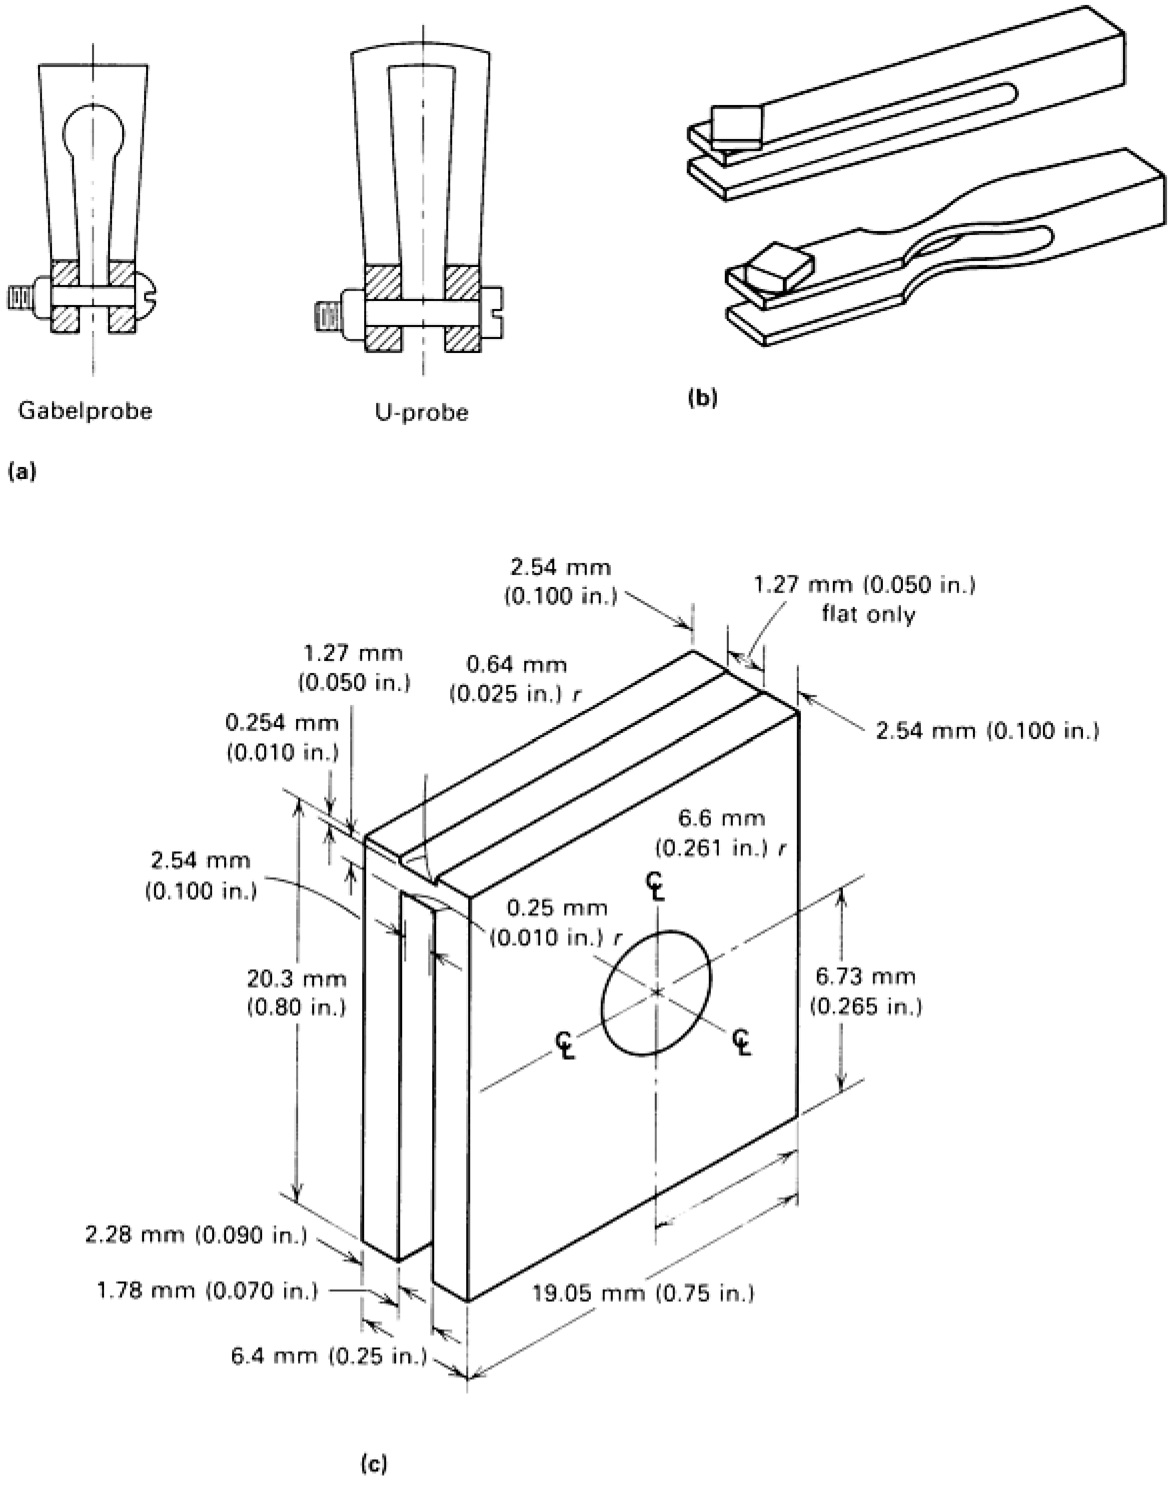

Fig. 18 Typical tuning fork SCC test specimens. (a) Source: Ref 19. (b) Source: Ref 1. (c) Source: Ref 20

Tuning fork specimens are stressed by closing the specimen tines and restraining them in the closed position with a bolt placed at the tine ends. The amount of closures is determined from Eq 3, which was derived from the data obtained with strain gages placed at the base of the tines on calibration specimens (Ref 1):

$$S = A\Delta t \quad \textbf{(Eq 3)}$$

where S is the maximum tension stress in the outer fiber of either tine, A is the calibration constant, Δ is the total amount of closure at the tine ends, and t is the thickness of the tines.

The stress on tuning forks with straight tines is greatest in a small area at the base of the tines. In tuning forks with tapered tines, the maximum stress extends uniformly along the tapered section. Tuning forks must be given the same consideration with regard to biaxial stresses as other flexurally loaded specimens.

The miniature tuning fork shown in Fig. 18(c) was devised to conduct short-transverse tests on sections that are too thin for tensile specimens or C-rings to be obtain (Ref 20). As with other tuning fork specimens, the relationship between strain on the grooved surface and the deflection at the ends of the legs can be determined through the use of strain gages.

Plastic Strain Specimens

Many accelerated SCC tests are performed with plastically deformed specimens, because these specimens are simple and economical to manufacture and use. These specimens are convenient for multiple replication tests of self-stressed (fixed-deflection) specimens in all environments. Because they usually contain large amounts of elastic and plastic strain, they provide one of the most severe tests available for smooth SCC test specimens.

Generally, the stress conditions are not known precisely. However, the anticipated high level of stress can be obtained consistently only if the precautions described for each type of specimen are observed. Another consideration is that the cold work required to form the test specimen can change the metallurgical condition and the SCC behavior of certain alloys.

Tests of this type are primarily used as screening tests to detect large differences between the SCC resistance of one alloy in several environments, one alloy in several metallurgical conditions in a given environment, and different alloys in the same environment. These tests are sometimes claimed to be too severe and therefore unsuitable for many applications, but the stress conditions are nevertheless representative of the high locked-in fabrication and assembly stresses frequently responsible for SCC in service.

U-bend specimens are rectangular strips bent approximately 180° around a predetermined radius and maintained in this plastically (and elastically) deformed condition during the test. Standardized test methods for this type of specimen are described in ASTM G 30 (Ref 8). Bends slightly less than or greater than 180° are also used, but the term U-bend is generally applied to test specimens that are bent beyond their elastic limits. Figure 19 illustrates typical U-bend configurations showing several different methods of maintaining the applied stress.

Fig. 19 Typical U-bend SCC specimens. (a) Various methods of stressing U-bends. (b) Typical U-bend specimen dimensions

U-bend specimens can be used for all materials sufficiently ductile to be formed into a U-configuration without cracking. A U-bend specimen is most easily made from strips of sheet, but specimens can be machined from plat, bar, wire, castings, and weldments. Of primary interest in U-bend specimens is circumferential stress, which is not uniform, as discussed previously in the section on "Bent-Beam Specimens" in this article. Stress distribution in the U-bend specimen is discussed in detail in Ref 22.

A good approximation of applied strain ϵcan be obtained by:

$$\epsilon = \frac{t}{2R} \text{ when } t < R \quad \textbf{(Eq 4)}$$

where *t* is the specimen thickness, and *R* is the radius of curvature at the point of interest. Knowledge of the stress-strain curve is necessary to determine the stress. When a U-bend specimen is formed, the material in the outer fibers of the bend is strained into the plastic portion of the true stress/true strain curve, such as in section AB in Fig. 20(a). Several other stress-strain relationships that can exist in the outer fibers of a stressed U-bend test specimen are shown in Fig. 20(b) through (e). The actual relationship obtained depends on the method of stressing used.

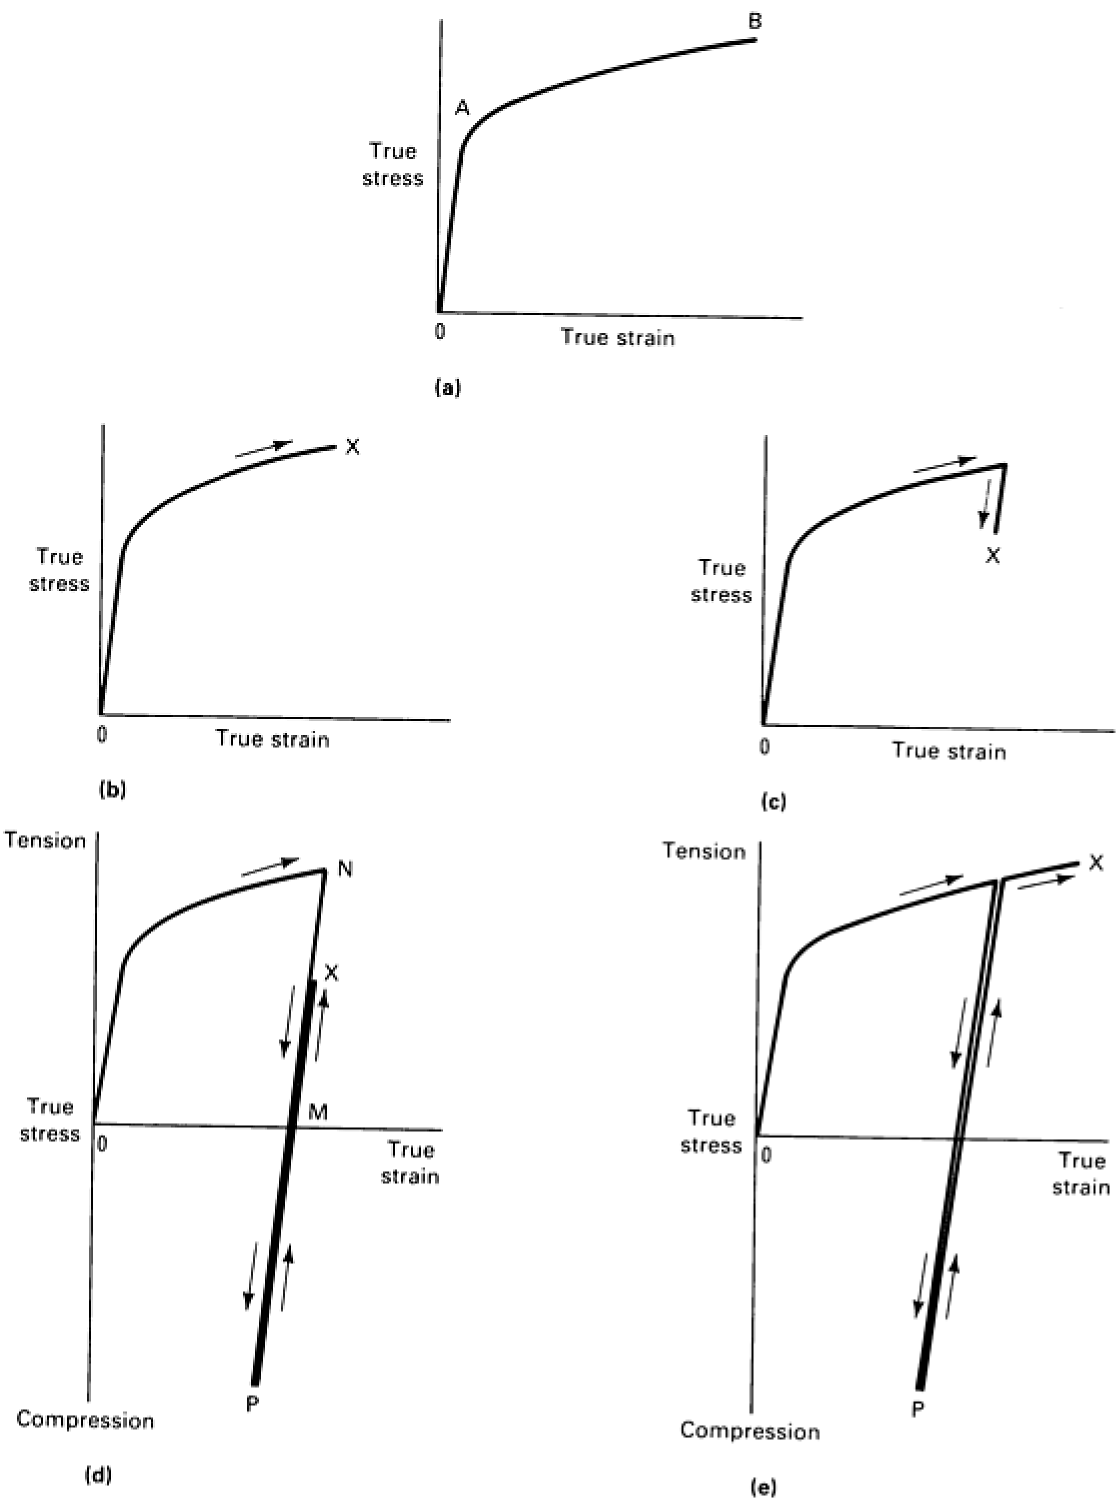

Fig. 20 True stress/true strain relationships for stressed U-bends. See text for discussion of (a) to (e).

Stressing is usually achieved by a one- or two-stage operation. Single-stage stressing is accomplished by bending the specimen into shape and maintaining it in that shape. The two types of stress conditions that can be obtained by single-stage stressing are defined by point X in Fig. 20(b) and 20(c). In Fig. 20(c), some elastic strain relaxation has occured by allowing the U-bend legs to spring back slightly at the end of the stressing sequence.

Two-stage stressing involves forming the approximate U-shape and then allowing the elastic strain to relax completely before the second stage of applying the test stress. The applied test strain can be a percentage (from 0 to 100%) of the

tensile elastic strain that occurred during preforming (Fig. 20d) or can involve additional plastic strain (Fig. 20e). The convex specimen surface is stressed in tension in the region 0NM (Fig. 20d), and the concave surface is in compression. In the region MP, the situation is reversed; that is, compression is on the convex surface, and tension is on the concave surface.

The slope MN of the curve shown in Fig. 20(d) is steep. Therefore, it is often difficult to apply reproducibly a constant percentage of the total elastic prestrain, and the specimen surface may remain under compressive stress. Therefore, because they result in a more severe test (that is, higher applied stress), the stress conditions in Fig. 20(b) and 20(e) are recommended. Thus, the final applied strain prior to testing consists of plastic and elastic strain. To achieve the conditions illustrated in Fig. 20(b) and 20(e), springback of the U-bend legs after achieving the final plastic strain must be avoided. For materials with relatively low creep resistance, there will be some strain relaxation.

Residual Stress Specimens

Most industrial SCC problems are associated with residual stresses developed in the metal during such processes as heat treatment, fabrication, and welding. Therefore, residual stress specimens simulating anticipated service conditions are useful for assessing the SCC performance of some materials in particular structures and in specific environments.

Plastic Deformation Specimens. Residual stresses resulting from such fabricating operations as forming, straightening, and swaging that involve localized plastic deformation at room temperature can exceed the elastic limit of the material. Examples of specimens of this type that have been used are shown in Fig. 21 and 22. Other specimen types used include panels with sheared edges, punched holes, or stamped identification numbers and specimens that show evidence of other practical fabricating operations.

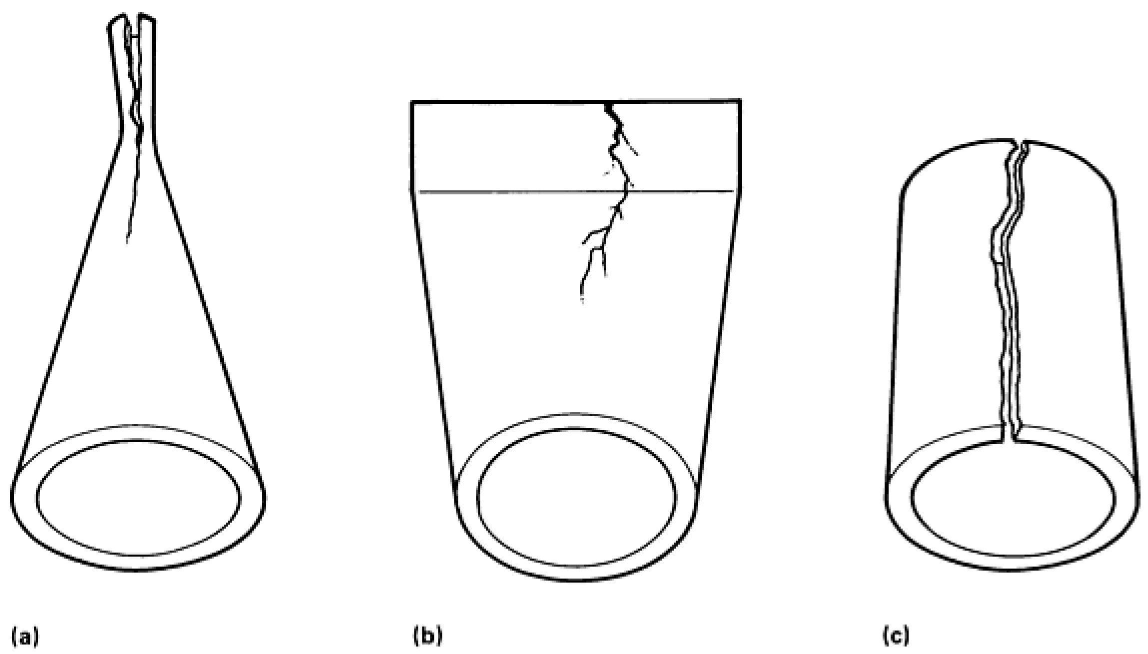

Fig. 22 SCC test specimens containing residual stresses from plastic deformation. Shown are 12.7-mm (0.5-in.) diam stainless steel tubular specimens after SCC testing. (a) and (b) Annealed tubing that was cold-formed before testing. (c) Cold worked tubing tested in the as-received condition. Source: Ref 1

Weld Specimens. Residual stresses developed in and adjacent to welds are frequently a source of SCC in service. Longitudinal stresses in the vicinity of a single weld are unlikely to be as large as stresses developed in plastically deformed weldments, because stress in the weld metal is limited by the yield strength of the hot metal that shrinks as it cools. High stresses can be built up, however, when two or more weldments are joined into a more complex structure.

Test specimens containing residual welding stresses are shown in Fig. 23. In fillet welds, residual tensile stress transverse to the weld can be critical, as indicated in Fig. 23(a) for a situation in which the tension stress acts in the short-transverse direction in an aluminum-zinc-magnesium alloy plate.

Static Loading of Precracked (Fracture Mechanics) Specimens

The use of precracked (fracture mechanics) specimens is based on the concept that large structures with thick components are apt to contain cracklike defects. After a stress-corrosion crack begins to grow, or if the specimen is provided with a mechanical precrack, classical stress analysis is inadequate for determining the response of the material subjected to stress in the presence of a corrodent.

The mechanical driving force for cracks can be measured with linear elastic fracture mechanics theory in terms of the crack-tip stress intensity factor, K, which is expressed in terms of the remotely applied loads, crack depth, and test specimen geometry. At or above a certain level of K, SCC in a susceptible material will initiate and grow in certain environments, but below that level no measurable propagation is observed (Ref 23).

The apparent threshold stress intensity for the propagation of SCC (assuming that crack nuclei form in a manner that cannot be described by fracture mechanics, such as localized corrosion) is designated K_{ISCC} (or K_{th}). Therefore, in terms of linear elastic fracture mechanics theory, for a surface crack in a large plat remotely loaded in tension, the shallowest crack (of a shape that is long compared to its depth) that will propagate as a stress-corrosion crack is $a_{cr} = 0.2(K_{ISCC}/TYS)^2$, where TYS is tensile yield strength. Thus, a crack that is shallower than this critical value will not propagate under the given environmental conditions.

The value of a_{cr} incorporates the SCC resistance, K_{ISCC}, and the contribution of stress levels (of the order of the yield strength) to SCC due to residual or assembly stresses in thick component sections (Ref 4). Therefore, the application of fracture mechanics does not provide independent information about SCC; it simply provides a usable method for treating the stress factor in the presence of a crack.

When the rate of SCC propagation is determined and plotted as a function of K_t (the crack opening mode), the test results for a highly susceptible alloy will exhibit the general trend shown in Fig. 3. Actual curves vary depending on the SCC resistance and fracture toughness of the alloy.

Although precracking may shorten or modify the initiation period, it does not circumvent it. Therefore, this method of testing also requires arbitrary and sometimes long exposure periods.

Test Specimen Selection

Almost all standard plane-strain fracture toughness test specimens can be adapted to SCC testing. These standard configurations should be used to ensure valid fracture analyses. Comprehensive discussions on SCC testing with precracked specimens can be found in Ref 24, 25, 26. Precracked specimens are illustrated schematically in Fig. 24 where they are classified with respect to loading methods and the relationship with the stress intensity factor as stress-corrosion cracking propagates. Proportional dimensions and tolerances per ASTM E 399 (Ref 27) for the more commonly used specimens are given in 25(a), 25(b), Fig. 25(c). Minor modifications to accommodate different loading arrangements and to facilitate mechanical precracking can be made to these configurations without invalidating the plane-strain constraints on the specimens. Figure 26 illustrates alternative chevron-notch and face-groove designs.

Bolt of material similar to specimen where practical; fine threaded, square or Allen head. Half height = *H*; thickness (*B*) = 2*H*; net width (*W*) = 10*H* minimum; total width (*C*) = *W* + *T*; thread diameter (*T*) = 0.75*H* minimum; notch width (*N*) = 0.14*H* maximum; effective notch length (*M*) = 2*H*

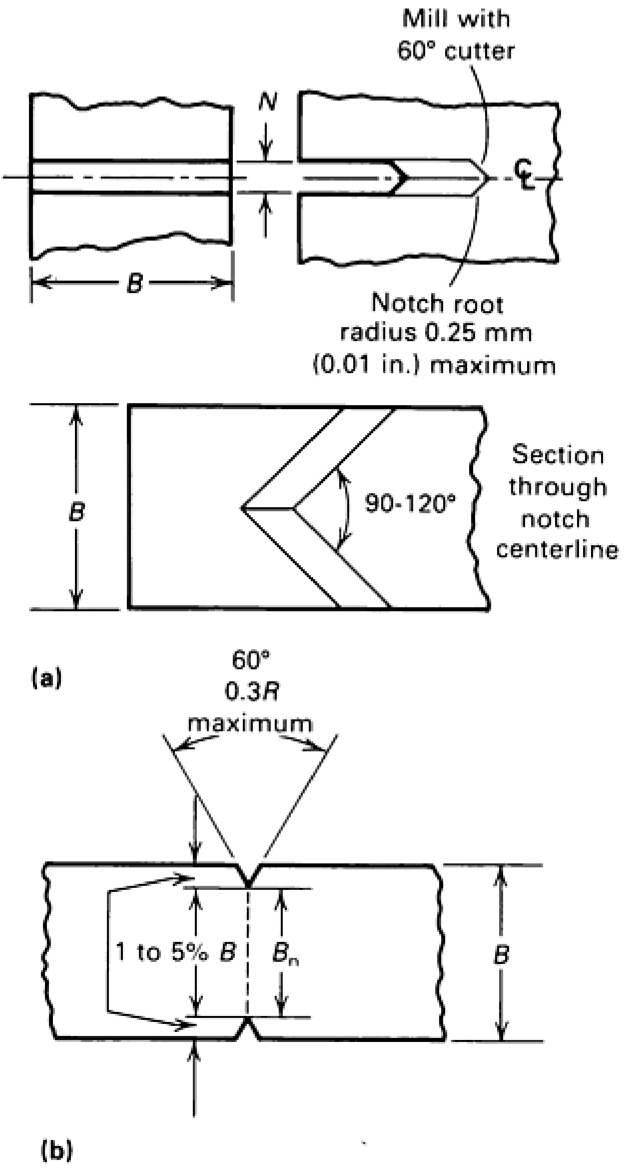

Fig. 26 Alternative chevron notch (a) and face grooves (b) for single-edge cracked specimens

Standards for SCC tests using precracked specimens have not yet been developed, although recommended test procedures have been published for certain uses (Ref 28). The best state-of-the-art stress intensity and compliance calibration relationships and guidelines for testing the specimens illustrated in 25(a), 25(b), and Fig. 25(c) are discussed below. Standard names for these specimens and methods of loading per ASTM E 616, "Standard Terminology Relating to Fracture Testing," are used in 25(a), 25(b), and Fig. 25(c) and in paragraph headings for the following discussion. Reference is also made to familiar names used in the literature that may appear elsewhere in this article.

Cantilever bend specimens (Fig. 25(a), sometimes referred to as single-edge-notched cantilever bend specimens, have been used in constant-load tests (*K*-increasing) for characterizing high-strength steels and titanium alloys (Ref 28). Equations 5, 6, and 7 are recommended (Ref 29, 30):

$$K = \frac{6M}{BW^2}\left(\frac{2W}{\pi a}\tan\frac{\pi a}{2W}\right)^{1/2} \times \left[\frac{0.923 + 0.199\left(1 - \sin\frac{\pi a}{2W}\right)^4}{\cos\frac{\pi a}{2W}}\right] \quad \textbf{(Eq 5)}$$

$$\frac{EBW\,(2V_0)}{M} = e^x \quad \textbf{(Eq 6)}$$

$$\frac{EBW\,V_{LL}}{M} = e^y \quad \textbf{(Eq 7)}$$

where e is the base of natural logarithm (2.718), $x = [0.1426 + 11.92(a/W) - 17.42(a/W)^2 + 15.84(a/W)^3 - 2.235(a/W)^4]$, $y = [6.188 + 12.98(a/W) - 41.19(a/W)^2 + 54.98(a/W)^3 - 22.28(a/W)^4]$. M is the applied bending moment, B is the specimen thickness (face grooves, when present, may be accounted for by replacing B with $\sqrt{BB_n}$, where B_n is the net thickness at the base of the face grooves; see Fig. 26b), W is the depth of the specimen, a is the depth of the notch plus crack, E is the modulus of elasticity, $2V_0$ is the total crack mouth opening displacement at the top face of the specimen, and V_{LL} is the total crack mouth opening displacement measured at the point of load application, which will vary depending on the load arm length.

Equation 5 is an expression for the stress intensity of a rectangular beam in pure bending and is valid over a wide range of a/W values. It applies to Mode I loading only, however, and the usual tests include a Mode II component from resulting shear stresses.

Equations 6 and 7 were determined by fitting experimental compliance data for cantilever bend specimens with a polynomial equation expressing the natural log of the normalized compliance as a function of a/W. These experimental values are in excellent agreement with those determined from Eq 5 for pure bending, even though the stress state at the crack tip will differ for cantilever bending. It has been suggested that analyses using pure bending expressions related to compliance measurement are suitable for testing with the cantilever bend configuration (Ref 29).

Crack growth measurements can be made with clip gage readings in conjunction with the crack opening displacement calibrations given above or by any other method that can be verified within ±0.127 mm (±0.005 in.). Examples of various methods are given in Ref 29 and 31.

Modified compact specimens (*K*-decreasing or *K*-increasing), as shown in Fig. 25(b), are frequently referred to as 1*T*-WOL (wedge-opening loaded) or modified WOL specimens. Although most frequently used with constant-displacement (bolt) loading (Ref 28, 32), these specimens have also been used with constant load (Ref 3, 33, 34). The specimen configuration shown in Fig. 25(b) is similar to that adopted by the Navy (Ref 28), except that it does not incorporate face grooves.

Equations 8, 9, 10, and 11 can be used to calculate stress intensity levels and normalized crack opening displacements for fatigue precracking, for initiation of stress-corrosion testing, and for subsequent intervals during the test. These equations are based on boundary colocation values determined for this type of specimen configuration with face grooves and bolt loading (threaded bolt against a rigid loading tip) (Ref 29). The polynomial regression equation agrees with experimentally determined colocation values within 1% for $0.2 \leq a/W \leq 0.95$:

$$K_{Io} = \frac{P\left(2 + \frac{a_0}{W}\right)}{B\sqrt{W}\left(1 - \frac{a_0}{W}\right)^{3/2}} \times \left[1.308 + 5.278\left(\frac{a_0}{W}\right) - 19.67\left(\frac{a_0}{W}\right)^2 + 24.57\left(\frac{a_0}{W}\right)^3 - 10.27\left(\frac{a_0}{W}\right)^4\right] \quad \text{(Eq 8)}$$

$$2V_0 = \frac{P}{EB} \times e^x \quad \text{(Eq 9)}$$

where $x = [1.830 + 4.307(a/W) + 5.871\,(a_0/W)^2 - 17.53(a_0/W)^3 + 14.57(a_0/W)^4]$

$$2V_{LL} = 2V_0 \times \frac{e^y}{e^x} \quad \text{(Eq 10)}$$

where $y = [1.623 + 3.352(a_0/W) + 8.205(a_0/W)^2 - 19.59(a_0/W)^3 + 15.23(a_0/W)^4]$

$$K_{Ii} = \frac{E(2V_{LL})\left(2 + \frac{a_i}{W}\right)}{\sqrt{W}\left(1 - \frac{a_i}{W}\right)^{3/2}} \times \left\{\left[1.308 + 5.278\left(\frac{a_i}{W}\right) - 19.67\left(\frac{a_i}{W}\right)^2 + 24.57\left(\frac{a_i}{W}\right)^3 - 10.27\left(\frac{a_i}{W}\right)^4\right] \div e^z\right\} \quad \text{(Eq 11)}$$

where $z = [1.623 + 3.352(a_i/W) + 8.205(a_i/W)^2 - 19.59(a_i/W)^3 + 15.23(a_i/W)^4]$. In Eq 8, 9, 10, and 11, K_{Io} is the desired starting stress intensity, a_0 is the starting crack length, P is the load calculated to develop K_{Io} with measured a_0, W is the net width of the specimen measured from the load line, K_{Ii} is the stress intensity after time interval i, a_i is the crack length after time interval i, and $2V_{LL}$ is the total crack mouth opening displacement at the load line. All other quantities are as defined previously.

Double-beam specimens (*K*-decreasing or *K*-increasing), which are also referred to as double-cantilever beam specimens, are similar to modified compact specimens, but because of their greater width or length, they are well suited for studying SCC growth rates over a greater range of K_I values. The smaller height of these specimens (Fig. 25(c)) allows more versatility in performing short-transverse tests from moderate thicknesses of material. Like compact specimens, double-beam specimens are generally used with constant-displacement (bolt) loading for convenience, but they can also be used with constant load.

Bolt-loaded specimens used with a test procedure similar to that described in Ref 35 have been extensively employed for short-transverse tests of aluminum alloy products (Ref 34, 36, 37).

Equations 12, 13, 14, and 15 are recommended for general use with double-beam specimens:

$$K_{\mathrm{I}o} = \frac{P\sqrt{12}}{B\sqrt{H}} \times \left[\frac{a_0}{H} + 0.6728 + 0.0377\left(\frac{H}{a_0}\right)^2\right] \quad \textbf{(Eq 12)}$$

$$2V_0 = \frac{4K_{\mathrm{I}o}\sqrt{H}}{\sqrt{3}\,E}\left(\frac{a_0}{H} + 0.6728\right)^2 \times \left[1 + 1.5\left(\frac{C_0}{a_0}\right) - 1.15\left(\frac{C_0}{a_0}\right)^2\right] \quad \textbf{(Eq 13)}$$

$$2V_{\mathrm{LL}} = \frac{2V_0}{1 + 1.5\left(\frac{C_0}{a_0}\right) - 1.15\left(\frac{C_0}{a_0}\right)^2} \quad \textbf{(Eq 14)}$$

$$K_{\mathrm{i}} = \frac{\sqrt{3}\,E(2V_{\mathrm{LL}})}{4\sqrt{H}\left(\frac{a_{\mathrm{i}}}{H} + 0.6728\right)^2} \quad \textbf{(Eq 15)}$$

Equation 12 is an expression reported in Ref 38. The simplified Eq 15 provides more versatility with high accuracy for a wider range of specimen configurations and *K* values (crack growth) than equations previously published (Ref 35).

Two early K_I calibrations based on stress analysis (Ref 39) and compliance (Ref 40) are illustrated in Fig. 27 and are in excellent agreement. The shape of these curves can also be used as a design guide for preparing specimens. If the test must be completed in the shortest possible time, a_0 should be short to capitalize on the fact that the rate of decrease of K_I with crack extension is maximum for shallow cracks. However, if maximum accuracy is desired, a deeper crack (effective notch length *M*, Fig. 25(c) should be chosen so that errors in crack length measurement do not cause significant errors in K_I.

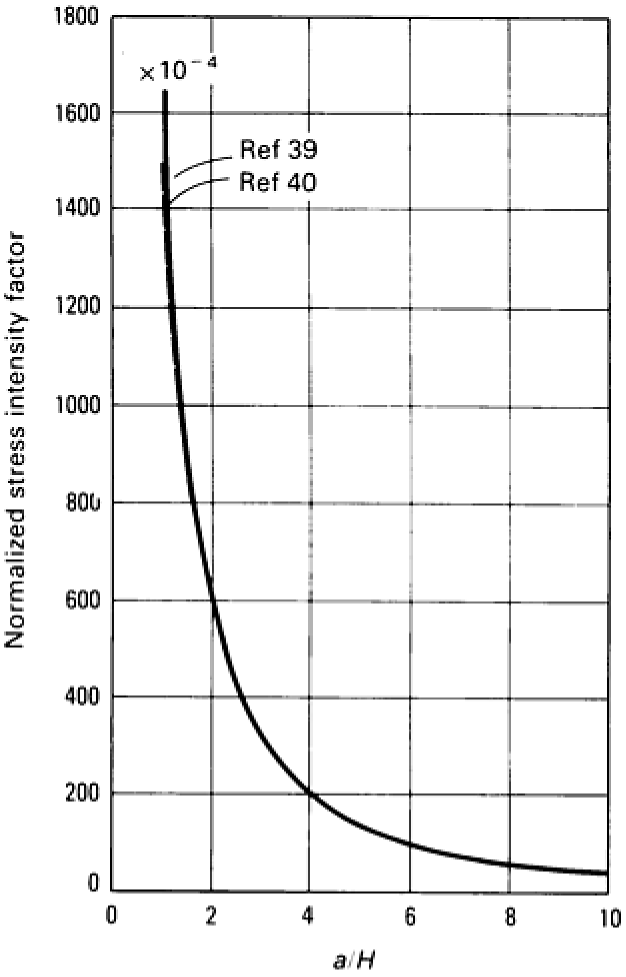

Fig. 27 Configuration and K_I calibration of a double-beam plate specimen. Normalized stress intensity K_I plotted against *a*/*H* ratio. (*W* - *a*) indifferent, crackline-loaded, single-edge cracked specimen. Source: Ref 26

Although in early work with aluminum alloys (Ref 35, 36) a relatively short effective notch length was used ($a_0/H \simeq 0.9$), deeper notches have been used recently ($a_0/H \simeq 1.2$ to 2.2), all with a 2*H* value of 25.4 mm (1.0 in.) (Ref 3, 34, 36, 37). The recommended starting *a*/*H* value shown in Fig. 25(c) is about 2 to 2.2, depending on the length of the precrack. Limited tests of a smaller beam height of 2*H* = 12.7 mm (0.5 in.) have shown little effect on the amount and rate of crack growth in aluminum alloy 7075 plate (Ref 41); however, additional study is needed in this area.

An alternative double-cantilever beam specimen has been developed for testing relatively thin sections (typically 6.4 mm, or $\frac{1}{4}$ in., thick) of low-alloy steels (Ref 42). The specimen is stressed by forcing an appropriately dimensioned wedge into the slot. These specimens have been used to determine the effect of hardness of low-alloy steels on their resistance to SCC in environments containing hydrogen sulfide.

Constant K_I specimens are well suited for studying the mechanisms of SCC, because the stress intensity. K_I, is not dependent on crack depth and can be neglected in kinetic studies. Other attractive features are the relatively simple expressions for stress intensity and compliance and the apparent retention of plane-strain conditions in thin plate and sheet specimens. The cost of specimen preparation and instrumentation, however, prohibits its use for extensive SCC characterizations.

Reference 26 provides equations for the analysis of two types of constant K_I specimens: the tapered double-beam specimen and the double-torsion loaded single-edge cracked specimen. A recent evaluation of the double-torsion method (Ref 43) used Al-Zn-Mg alloy sheet 3.2 mm (0.125 in.) thick. By using the double-torsion specimen, *V*-*K* curves were produced for aluminum alloy 7075-T651 sheet with conventional two-stage growth and plateau velocities that were only slightly higher than those for conventional double-cantilever beam tests of plate.

Other precracked specimen configurations, such as those shown in Fig. 24, can be used for special testing conditions. Information on the preparation and use of these specimens and the related fracture mechanics equations are given in Ref 26 and 44, 45, 46.

Preparation of Precracked Specimens

When using precracked SCC test specimens, the investigator must consider the dimensional (size) requirements of the specimen, its crack configuration and orientation, and machining and precracking of the specimen. These considerations are discussed below. Additional guidelines and recommendations on specimen preparation in conjunction with fracture toughness testing are given in Ref 26, 27 and 44, 45, 46.

Dimensional Requirements. A basic requirement of all precracked specimen configurations is that the dimensions be sufficient to maintain predominantly triaxial stress (plane-strain) conditions, in which plastic deformation is limited to a very small region in the vicinity of the crack tip. Experience with fracture toughness testing has shown that for a valid K_{Ic} measurement neither the crack depth a nor the thickness B should be less than $2.5(K_{Ic}/YS)^2$, where YS is the yield strength of the material (Ref 28). Because of the uncertainty regarding a minimum thickness for which an invariant value of K_{ISCC} can be obtained, guidelines for designing fracture mechanics test specimens should be tentatively followed for SCC test specimens. The threshold stress intensity value should be substituted for K_{Ic} in the above expression as a test of its validity.

If specimens are to be used for determination of K_{ISCC}, the initial specimen size should be based on an estimate of the K_{ISCC} of the material. Overestimation of the K_{ISCC} value is recommended; therefore, a larger specimen should be used than may eventually be necessary. When determining stress-corrosion crack growth behavior as a function of stress intensity, specimen size should be based on the highest stress intensity at which crack growth rates are to be measured (substitute K_{Io} in the $2.5(K_{Ic}/YS)^2$ expression).

Notch Configuration and Orientation. For SCC testing, the depth of the initial crack-starter notch--that is, the machined slot with a fatigue or mechanical pop-in crack at its apex--can be as short as 0.2W. Guidelines for the depth of the notch depend on the limits of accurate K_I calibration with respect to the range of a/W or a/H and the considerations discussed previously for double-beam specimens.

Several designs of crack-starter notches are available for most plate specimens. The machined slot is used to simulate a crack, because it is impractical to produce plane cracks of sufficient size and accuracy in plate specimens. ASTM E 399 (Ref 27) recommends that the notch root radius should not be greater than 0.127 mm (0.005 in.), unless the chevron form is used, in which case it may be 0.25 mm (0.01 in.) or less (Fig. 26). This tolerance can be easily achieved with conventional milling and grinding equipment.

A significant factor in the SCC testing of thick sections of some metals, such as aluminum and titanium, is the direction of applied stress relative to the grain structure. A standardized plan for identifying the loading direction, the fracture plane, and the direction of crack propagation is shown in Fig. 28.

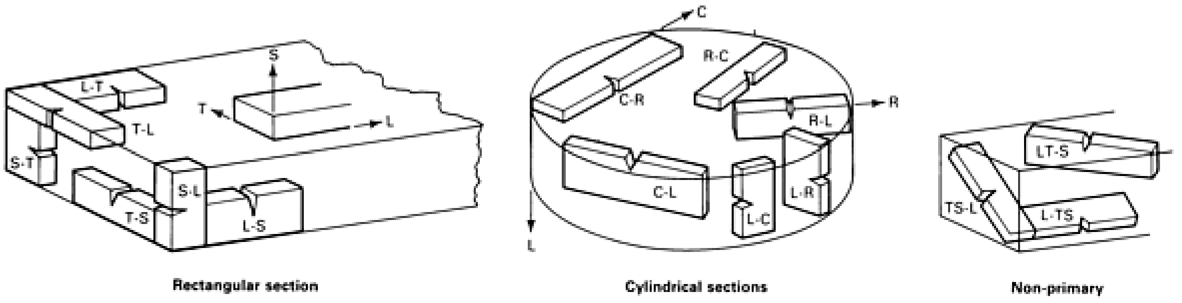

Fig. 28 Specimen orientation and fracture plane identification. L, length, longitudinal, principal direction of metal working (rolling, extrusion, axis of forging); T, width, long-transverse grain direction; S, thickness, short-transverse grain direction; C, chord of cylindrical cross section; R, radius of cylindrical cross section. First letter: normal to the fracture plane (loading direction); second letter: direction of crack propagation in fracture plane.

Source: Ref 27

Machining. Specimens of the required orientation should be machined from products in the fully heat-treated and stress-relieved condition to avoid complications due to residual stresses in the finished specimens. Safeguards against the presence of residual stresses are especially important for precracked specimens because these specimens are usually bulky and contain notches that are machined deep into the metal. For specimens of material that cannot easily be completely machined in the fully heat-treated condition, the final thermal treatment can be given before the notching and finishing operations. However, fully machined specimens should be heat treated only when the heat treatment will not result in distortion, residual stress, quench cracking, or detrimental surface conditions.

Precracking. Fatigue precracking should be done in accordance with ASTM E 399 (Ref 27). The *K* level used for precracking each specimen should not exceed about two thirds of the intended starting *K*-value for the environmental exposure. This prevents fatigue damage or residual compressive stress at the crack tip, which may alter the SCC behavior, particularly when testing at a *K* level near the threshold stress intensity for the specimen.

Aluminum alloy specimens can also be precracked by pop-in methods (wedge-opening loaded to the point of tensile overload), but steel and titanium alloys are usually too strong and tough to pop in without breaking off one of the specimen arms. Chevron notches are usually used to facilitate starting such mechanical precracks, and face grooves are sometimes necessary to produce straight precracks in tougher alloys (Fig. 26). These modifications may also be necessary to control fatigue precracking of some materials.

When a specimen is mechanically precracked by pop in, the load should be maintained and should not be reduced for testing at a lower initial *K*-value. Reducing the load (crack mouth opening displacement) required for pop in will result in residual compressive stress at the crack tip, which could interfere with SCC initiation. When testing specimens at a relatively low fraction of K_{Ic}, fatigue precracking is recommended.

Testing Procedure

For all methods using precracked specimens, the primary objective is usually to determine K_{ISCC} or K_{th}, threshold stress intensity for SCC for the alloy and environment combination. One procedure, similar to that used with smooth specimens, depends on the initiation of SCC at various levels of applied K_{Io} values. Both constant load (*K*-increasing) and constant-displacement (*K*-decreasing) tests can be used. The latter procedure, which is unique to precracked specimens, involves crack arrest. This technique requires a *K*-decreasing constant-displacement test. These methods are compared in Fig. 29, which illustrates the shift in the stress intensity factor as SCC growth occurs.

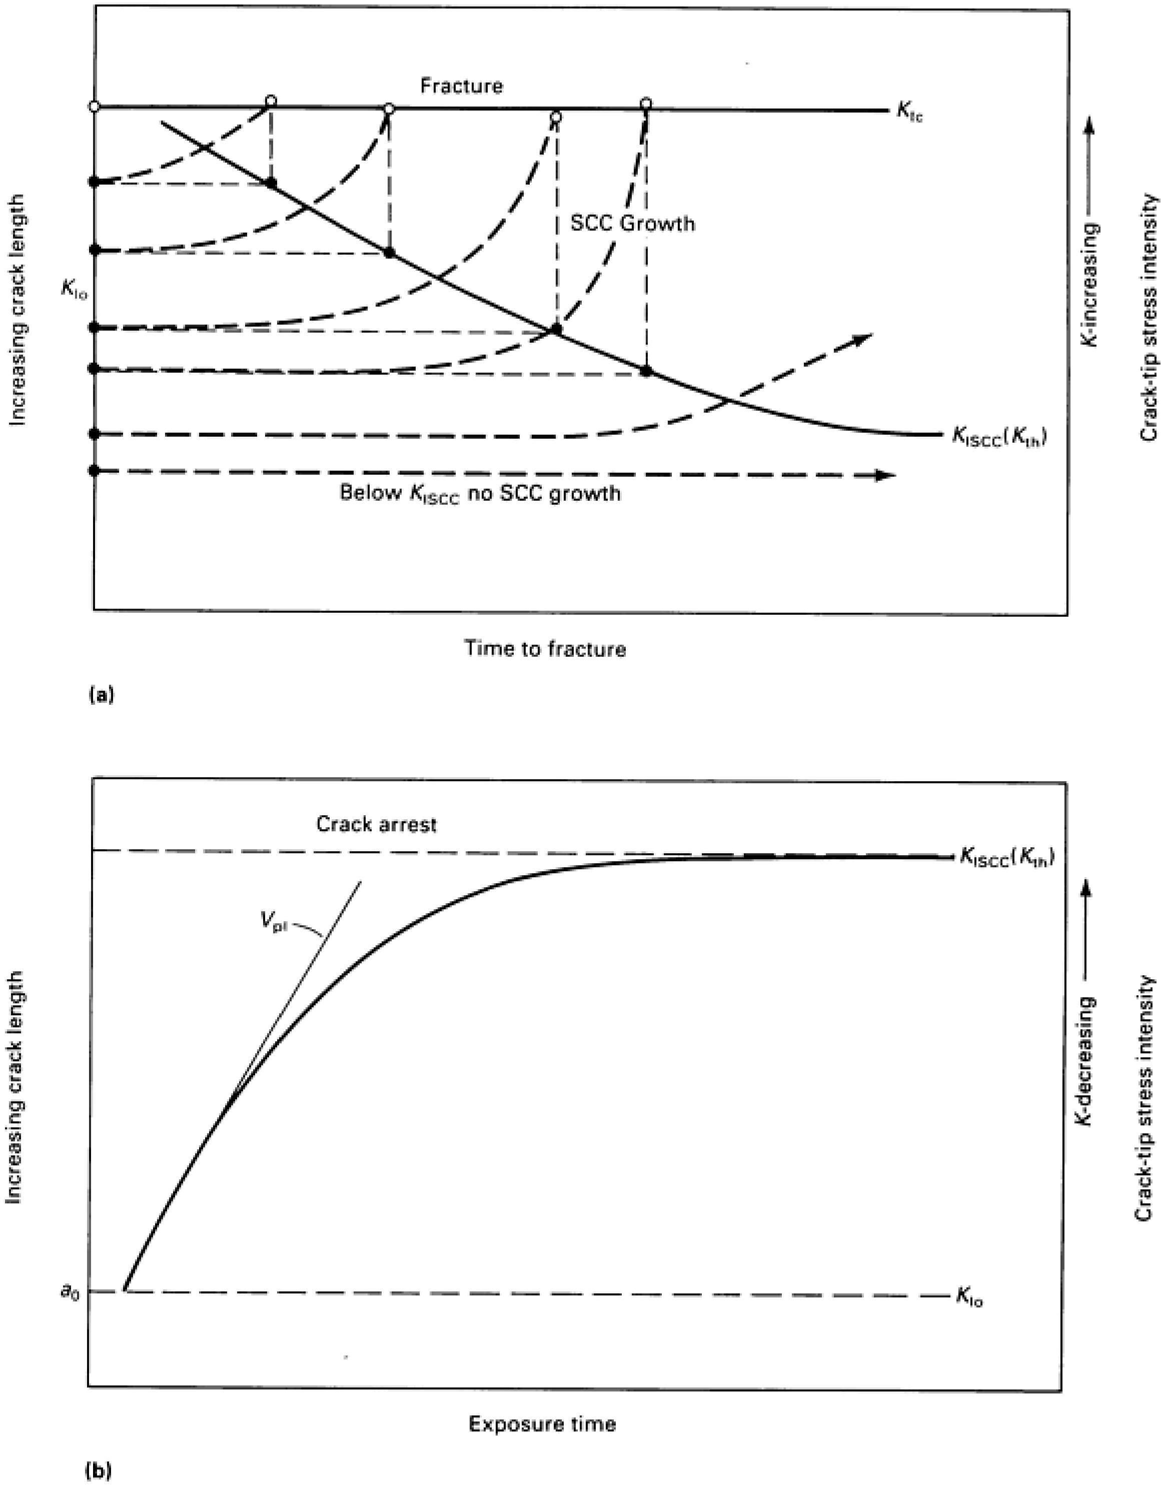

Fig. 29 Schematic comparison of determination of K_{ISCC} by crack initiation versus crack arrest. (a) Constant-load test. (b) Constant crack opening displacement test. a_0 = depth of precrack associated with the initial stress intensity K_{Io}; V_{pl} = plateau velocity.

***K*-Increasing Versus *K*-Decreasing Tests.** In constant-load specimens (*K*-increasing tests), stress parameters can be quantified with confidence. Because crack growth results in an increasing crack opening, there is less likelihood that corrosion products will block the crack or wedge it open. Crack-length measurements can be made readily with several continuous-monitoring methods.

A wide selection of constant-load specimen geometries are available to suit the test material, experimental facilities, and test objective. Therefore, crack growth can be studied under either bend or tension loading conditions. Specimens can be used to determine K_{ISCC} by the initiation of a stress-corrosion crack from a preexisting fatigue crack using a series of specimens or to measure crack growth rates.

The principal disadvantages of constant-load specimens are the expense and bulk associated with the need for an external loading system. Bend specimens can be tested in relatively simple cantilever beam equipment, but specimens subjected to tension loading require constant-load creep-rupture equipment or similar testing machines. In this case, expense can be minimized by testing chains of specimens connected by loading links that are designed to prevent unloading upon failure of individual specimens. Because of the size of these loading systems, it is difficult to test constant-load specimens under operating conditions, but they can be tested in environments obtained from operating systems.

Constant-displacement specimens (*K*-decreasing tests) are self-loaded; therefore, external stressing equipment is not required. Their compact dimensions also facilitate exposure to operating service environments. They can be used to determine K_{ISCC} by the initiation of stress-corrosion cracks from the fatigue precrack, in which case a series of specimens must be used to bracket the threshold value. This can also be achieved by the arrest of a propagating crack, because under constant-displacement testing conditions stress intensity decreases progressively as crack propagation occurs. In this case, a single specimen suffices in principle; in practice, the use of several replicate specimens is recommended to assess variability in test results.

Constant-displacement specimens are subject to several inherent disadvantages. Oxide formation or corrosion products can wedge the crack surfaces open, thus changing the applied displacement and load. Oxide formation or corrosion products can also block the crack mouth, thus preventing the entry of corrodent, and can impair the accuracy of crack length measurements by electrical resistance methods. Applied loads can be measured only indirectly by displacement changes or by other sophisticated instrumentation. Crack arrest must be defined by an arbitrary crack growth rate below which it is impractical to measure cracks accurately (commonly about 10^{-10} m/s, or 1.5×10^{-5} in./h).

Loading Arrangements and Crack Measurement. To monitor crack propagation rate as a function of decreasing stress intensity when testing constant-displacement loaded specimens, two of the three testing variables must be measured--crack depth (a_i) or load (P_i), and crack opening displacement at the load line (V_{LL}). Although crack initiation and growth can be detected from change in either load or crack length, load change is usually more sensitive to these conditions. Therefore, crack advance is easier to detect in specimens loaded in a testing machine, an elastic loading ring, or an instrumented bolt than in specimens loaded with a bolt or wedge. 30(a) and Figure 30(b) illustrates typical loading arrangements for which load changes can be automatically monitored (Ref 3, 33, 47).

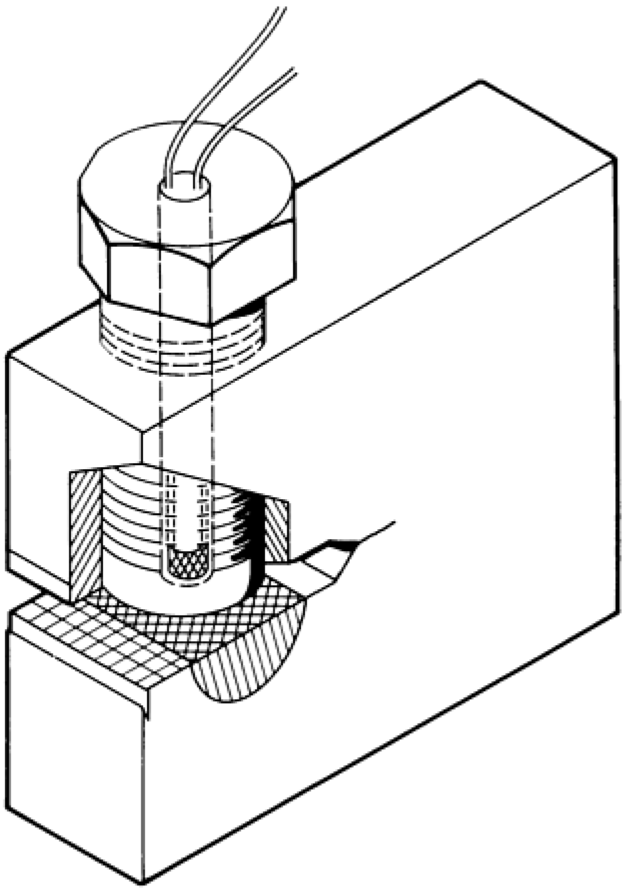

Fig. 30(a) Wedge-opening load specimen loaded with instrumented bolt. Source: Ref 47

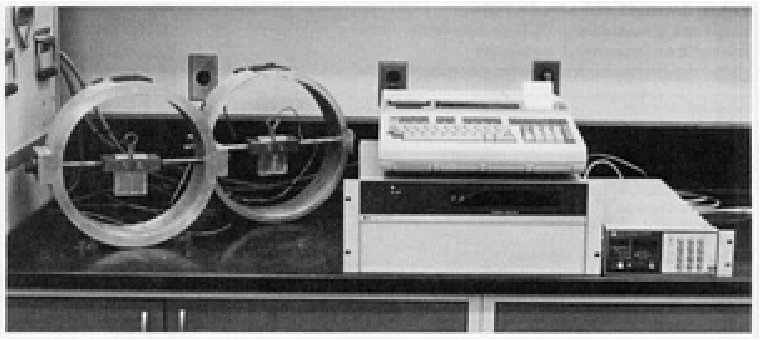

Fig. 30(b) Ring-loaded wedge-opening load specimen test setup. Box to the left of loading rings contains analog signal conditioning for load and displacement signals. The digital data acquisition system consists of a scanner connected to the analog load and displacement signals, a digital voltmeter, and a portable computer used to read and store data and to control the other instruments. Source: Ref 3

Figure 31 illustrates an ultrasonic method of measuring crack length at the interior (midwidth and quarter widths) of a bolt-loaded double-beam specimen. This method provides a more accurate measure of crack depth than visual measurements made on the specimen surfaces. Various other techniques have been used, such as measurement of beam deflection for cantilever beam specimens (Ref 29) and changes in electrical resistance. Such arrangements, however, require calibration. It is feasible and desirable to obtain crack length measurements with a precision of at least ±0.127 mm (0.005 in.).

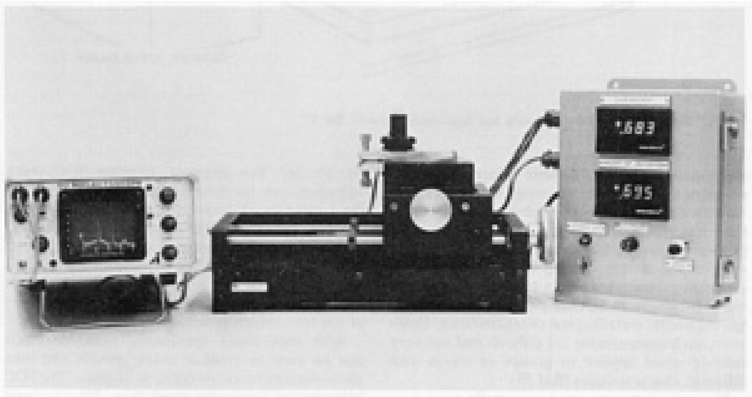

Fig. 31 Ultrasonic crack measurement system for double-beam specimens. Bolt-loaded specimen is mounted on translation stage at center. Ultrasonic transducer is located above specimen, and the oscilloscope at left indicates (left to right) the top of the specimen, the crack plane, and the bottom face reflection. Digital readouts of stage position and peak height for the crack front measurement used to make consistent positioning measurements are shown (right). This system has a crack growth resolution of approximately 0.127 mm (0.005 in.). Source: Ref 3

Exposure to Environment. When practical for laboratory accelerated testing, the test environment should be brought into contact with the specimen before it is stressed or immediately afterward; this enhances access of the corrodent to the crack tip to promote earlier initiation of SCC and to decrease variability in test results. Similarly, in certain cases, it may also be beneficial to introduce the corrodent even earlier, that is, during precracking. However, unless facilities are available to begin environmental exposure immediately after precracking, corrodent remaining at the crack tip may promote blunting due to corrosive attack. In addition, corrosion of the specimen surfaces in the small volume of the precrack or the advancing stress-corrosion crack will change the composition of the environment that is in contact with the crack tip and can significantly affect the test results. Therefore, hydrolysis reactions can drastically reduce the pH of the aqueous test environment (Ref 48) and can induce embrittlement of some steels by corrosion product hydrogen.

Selection of an appropriate test duration presents problems that vary with the testing system; this includes the alloy and metallurgical condition, the test environment, and the loading method. Errors in interpretation of the test results can be caused by test durations that are either too short or too long. The optimum length of exposure can be best approached through recognition of meaningful crack propagation rates. What is considered meaningful depends on the available precision of measurement of crack lengths and an acceptably low rate for the criterion of a stress intensity threshold (Fig. 3). A problem also exists with the correlation of SCC crack growth rates in the laboratory test and in an anticipated service environment. The question leads ultimately to the intended application and a determination of what is a tolerable amount of SCC growth for a given length of time.

Calculation of Crack Growth Rates. There is no generally accepted procedure for calculating crack growth rate, da/dt, as a function of stress intensity from crack growth curves. Various approaches exist; the simplest is a graphical $\Delta a/\Delta t$ technique that may incorporate smoothing of the a versus t curve (Ref 35, 36, 37). Another widely used approach is smoothing of the crack growth curve by computer techniques for curve fitting the entire a versus t curve by a multiple-term polynomial function (Ref 29).

Other techniques include a secant method and an incremental polynomial method, in which derivatives of the smoothed crack growth curve are calculated at various points to determine instantaneous crack growth rates. Instantaneous growth rates are then plotted against the instantaneous stress intensities. K_{Ii}, at corresponding time intervals to obtain graphs similar to that shown in Fig. 3. Additional information on the secant and incremental methods, which are often used in fatigue studies, can be found in the article "Fatigue Crack Growth Data Analysis" in *Mechanical Testing,* Volume 8 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

A limited study of the above four methods of treating crack growth data is presented for a high-strength aluminum alloy in Ref 3. All of the methods used to calculate crack growth rates produced the same general results, which were difficult to interpret because of large amounts of scatter resulting from the use of small crack growth increments. Moreover, the

significance of such graphs is dubious when the corrosivity of the environment and the length of exposure can invalidate the estimate of K by causing gross corrosion product wedging effects and/or crack branching.

Reduction of crack length data becomes useless without prior subjective interpretation of crack length versus time curves. Allowances should be made for extraneous effects caused by erratic or apparent initiation of stress-corrosion crack growth, scatter in the measurement data due to excessive crack front curvature, multiple crack planes, crack-tip branching, and gross wedging caused by corrosion products.

A simple method of comparing materials by using crack growth curves is based on average growth rates taken from an exposure time of zero to an arbitrary time that is sufficient to achieve significant crack extension in the most SCC-susceptible materials being compared (Ref 41). This method not only rapidly identifies materials with relatively low resistance to SCC, but also provides numerical test results for highly resistant materials that may not develop a K_I versus da/dt curve with a definite plateau (see the section "Testing of Aluminum Alloys" in this article).

Dynamic Loading: Slow Strain Rate Testing

The most recently developed method for accelerating the SCC process in laboratory testing involves relatively slow strain rate tension testing of a specimen during exposure to appropriate environmental conditions. The application of slow dynamic strain exceeding the elastic limit assists in the SCC initiation. This accelerating technique is consistent with the various proposed general mechanisms of SCC, most of which involve plastic microstrain and film rupture.

Slow strain rate tests can be used to test a wide variety of product forms, including parts joined by welding. Tests can be conducted in tension, in bending, or with plain, notched, or precracked specimens. The principal advantage of slow strain rate testing is the rapidity with which the SCC susceptibility of a particular alloy and environment can be assessed.

Slow strain rate testing is not terminated after an arbitrary period of time. Testing always ends in specimen fracture, and the mode of fracture is then compared with the criteria of SCC susceptibility for the test material. In addition to its timesaving benefits, less scatter occurs in the test results. Comprehensive discussions on the slow strain rate testing technique can be found in Ref 49, 50, 51, 52.

Critical Strain Rate. The most significant variable in slow strain rate testing is the magnitude of strain rate. If the strain rate is too high, ductile fracture will occur before the necessary corrosion reactions can take place. Therefore, relatively low strain rates must be used. However, at too low a strain rate, corrosion may be prevented because of repassivation or film repair so that the necessary reactions of bare metal cannot be sustained, and SCC may not occur. Although typical critical strain rates range from 10^{-5} to 10^{-7} s^{-1} depending on the alloy and environment system, the most severe strain rate must be determined in each case.

The repassivation reaction that is observed at very low strain rates and that prevents the formation of anodic SCC does not occur when cracking is the result of embrittlement by corrosion product hydrogen. This mechanistic difference can be used to distinguish between anodic SCC (active path corrosion) and cathodic SCC (hydrogen embrittlement) as illustrated in Fig. 32.

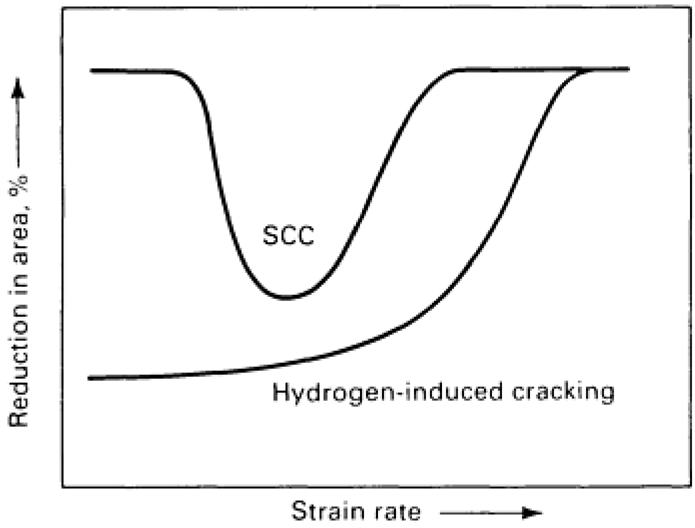

Fig. 32 Schematic showing the effect of strain rate on SCC and hydrogen-induced cracking. Source: Ref 53

The fastest strain rate that will promote SCC in a given system depends on crack velocity. Generally, the lower the stress-corrosion cracking velocity, the slower the strain rate required. Applied strain rates known to have promoted SCC in metal/environment systems are listed in Table 2.

Table 2 Critical strain rate regimes promoting SCC in various metal/environment systems

System	Applied strain rate, s^{-1}
Aluminum alloys in chloride solutions	10^{-4} and 10^{-7}
Copper alloys in ammoniacal and nitrite solutions	10^{-6}
Steels in carbonate, hydroxide, or nitrate solutions and liquefied ammonia	10^{-6}
Magnesium alloys in chromate/chloride solutions	10^{-5}
Stainless steels in chloride solutions	10^{-6}
Stainless steels in high-temperature solutions	10^{-7}
Titanium alloys in chloride solutions	10^{-5}

The most relevant strain rates for various aluminum alloys are illustrated in Fig. 33. These trends illustrate that slow strain rate tests should be performed in a strain rate regime that is appropriate for the given alloy and environment system.

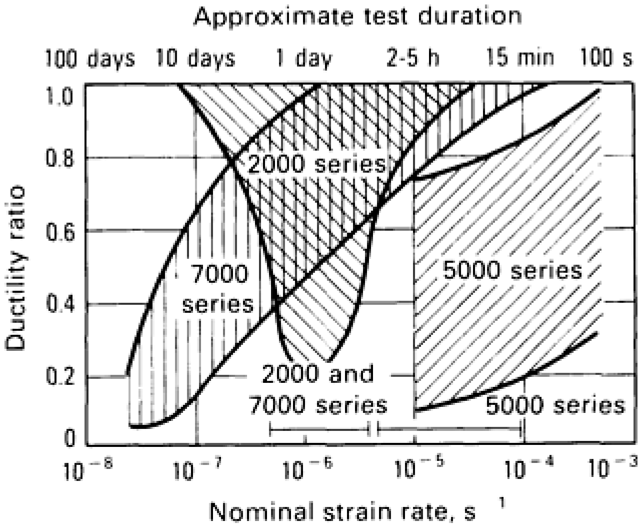

Fig. 33 Strain rate regimes for studying SCC of various aluminum alloys. Corrodent: 3% sodium chloride plus 0.3% hydrogen peroxide. Source: Ref 52

Test Specimen Selection. Standard tension specimens (ASTM E 8) (Ref 54) are generally recommended for use with the specified conditions of gage lengths, radii, and so on, unless specialized studies are being conducted. For initially smooth specimens, the strain rate at the onset of the test is clearly defined: however, once cracks have initiated and grown, straining is likely to concentrate in the vicinity of the crack tip, and the effective strain rate is unknown. Rigorous solutions for determining the strain rate at crack tips or notches are not available, but effective strain rates are likely to be higher than for the same deflection rate applied to plain specimens.

Notched or precracked specimens can be used to restrict cracking to a given location--for example, when testing the heat-affected zone associated with a weld. Notched or precracked specimens can also be used to restrict load requirements where bending, as opposed to tensile loading, may offer an added benefit. The section thickness or diameter of such specimens is usually relatively small, so the testing duration is short.

Testing Equipment. Constant strain rate apparatus requirements include sufficient stiffness to resist significant deformation under the loads necessary to fracture the test specimens; a system to provide reproducible, constant strain rates over the range of 10^{-4} to 10^{-8} s^{-1}; and a cell to contain the test solution. Auxiliary equipment is used to control environmental conditions and to record test data. The testing equipment can also be instrumented to record load-elongation curves, which is convenient when testing at various strain rates. A typical constant strain rate unit is illustrated schematically in Fig. 34. Various types of corrosion cells may be required to control the test conditions for specific studies.

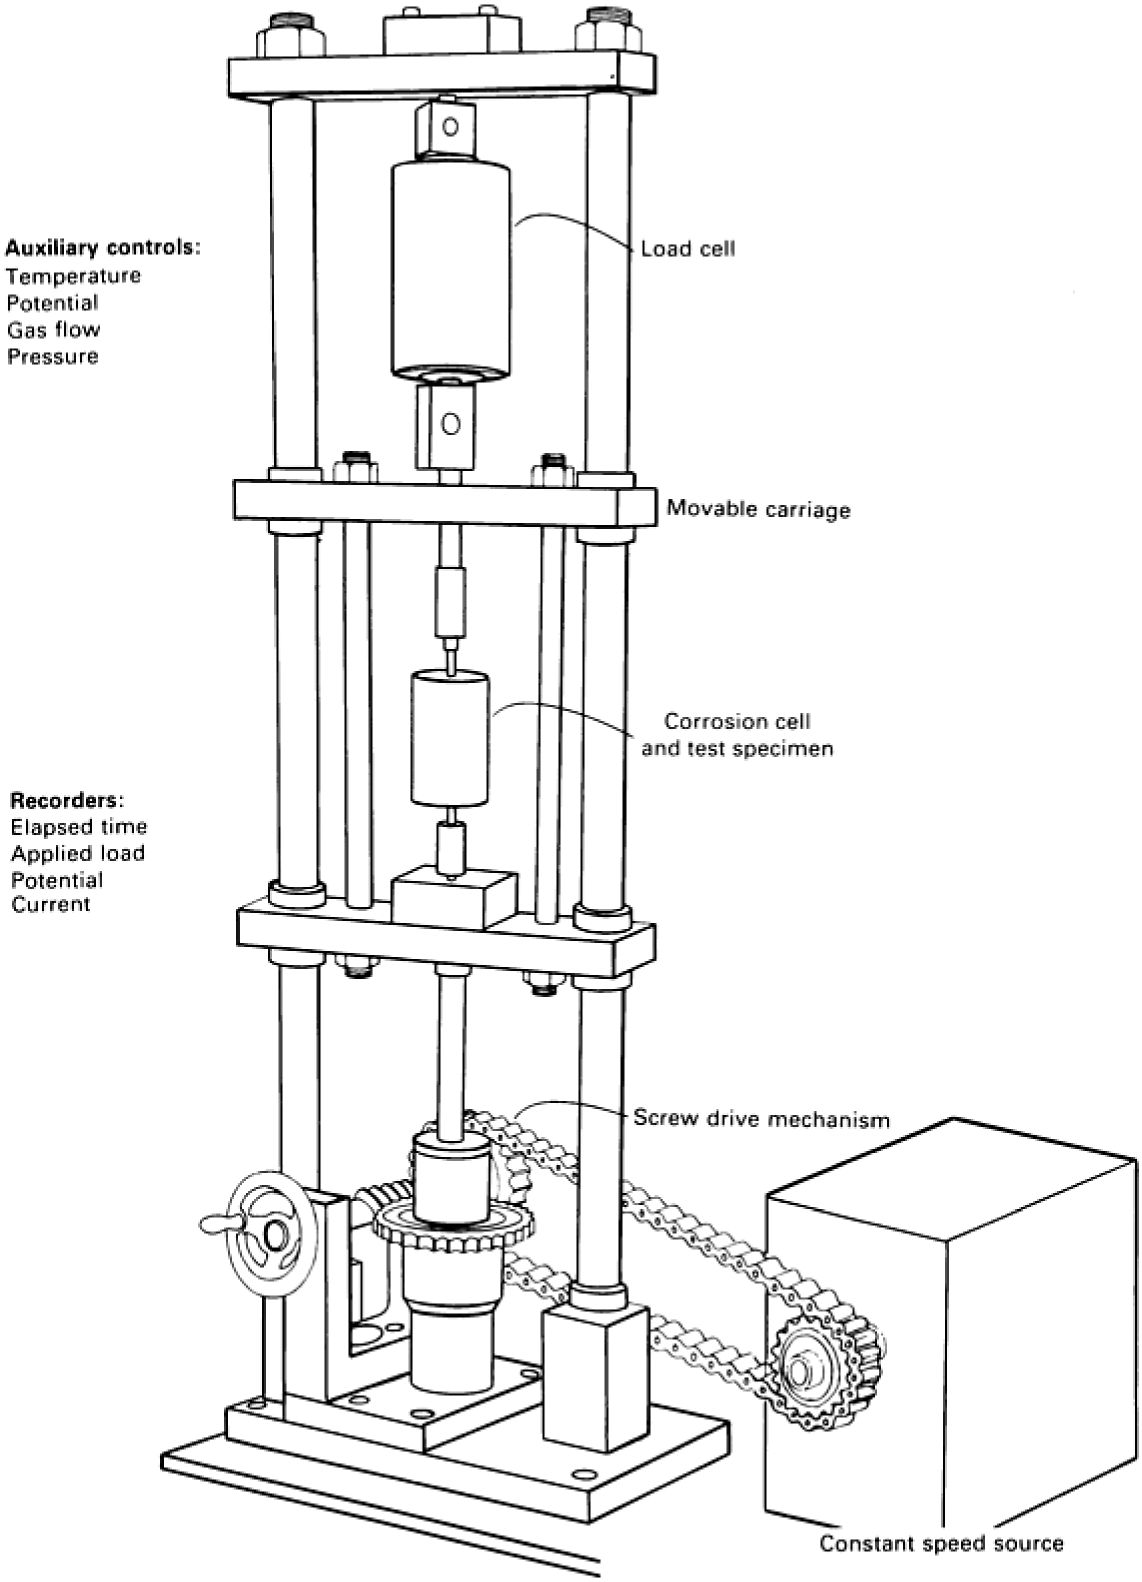

Fig. 34 Typical slow strain rate test apparatus. Source: Ref 51

In addition to uniaxial tensile units, cantilever constant strain rate apparatus has also been used in which an extension arm attached to a cantilever beam specimen is lowered at a constant rate. This technique has been successfully used to study SCC of low-carbon steel in carbonate-bicarbonate environments to determine crack velocity, critical strain rates, and

inhibitor effectiveness (Ref 55). Additional information on slow strain rate testing equipment and procedures is available in Ref 45 and 49.

Assessment of Results. Historically, the principal methods of SCC assessment derived from slow strain rate tension testing were based on time to failure, maximum gross section stress developed during the tension test, percent elongation, area bounded by the load-elongation curve, and reduction in area. Figure 35 depicts stress-elongation curves that illustrate how stress-corrosion cracks influence the elongation to fracture as well as the maximum load.

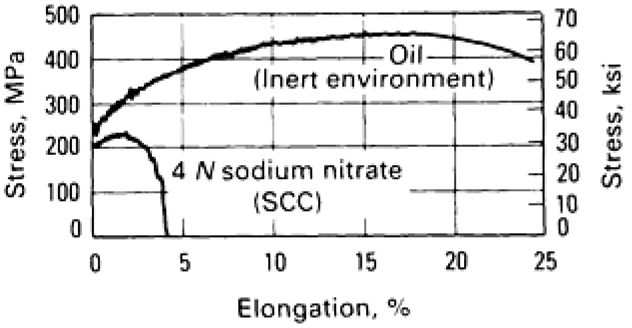

Fig. 35 Nominal stress versus elongation curves for carbon-manganese steel in slow-strain rate test in boiling 4 *N* sodium nitrate and in oil at the same temperature. Source: Ref 50

To eliminate non-SCC effects, parallel tests are conducted in an inert environment, and a ratio of the result obtained in the corrodent divided by the result obtained in the inert environment is commonly used as an index of SCC susceptibility. For example, in Fig. 33, higher SCC resistance is denoted by higher ductility ratios.

Figure 36 shows a stress-corroded specimen containing many secondary stress-corrosion cracks and reduced ductility at fracture. Some alloys experience rapid deterioration of mechanical properties on contact with certain corrosive environments; any additional effect of applied straining can best be assessed by comparison with the behavior of unstrained specimens. Therefore, it is essential that the cause of environmental degradation be verified as SCC.

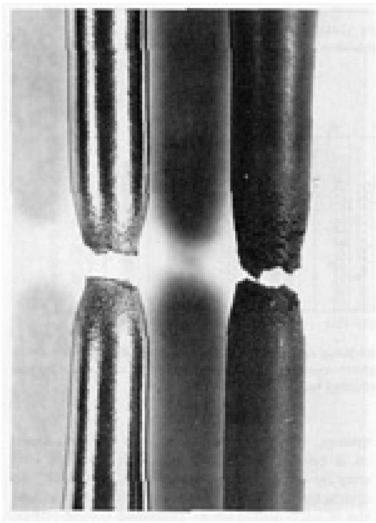

Fig. 36 Photomacrographs of two carbon steel specimens after slow strain rate tests conducted at a strain rate of 2.5 × 10^{-6} s^{-1} and 80 °C (180 °F). The ductility ratio in this example was 0.74 (original diameter: 2.54 mm, or 0.100 in.). (left) Ductile fracture in oil. (right) SCC in carbonate solution

Slow strain rate testing is very efficient in comparing environments in terms of their capability to produce SCC, for example, in steels having similar metallurgical characteristics. However, such comparisons are difficult and not very reliable when applied to groups of steels with different characteristics (Ref 53).

Slow strain rate testing as generally used does not provide data that can be used for design purposes. Recent work, however, has shown that average SCC velocities, threshold stresses, and threshold strain rates can be obtained with modified techniques combined with microscopy (Ref 50, 55, 56). For example, average SCC crack velocities can be determined from the depth of the largest crack measured on the fracture surfaces of specimens that have failed completely, or in longitudinal sections on the diameter of specimens that have not experienced total failure, divided by the time of testing. With this procedure, SCC is assumed to initiate at the start of the test, which is not always true.

With precracked specimens, other methods can be used to monitor crack growth and thus allow determination of crack velocities. The SCC behavior of a pipeline steel (Fig. 37) has been studied by using a precracked cantilever bend specimen in terms of threshold strain rate for crack growth and also in terms of crack growth rates analogous to the Stage II plateau velocity illustrated in Fig. 3. Material properties, such as strength and toughness, that influence SCC performance when measured by tension testing are eliminated as factors; therefore, valid comparisons can be made of alloys with widely different structures and mechanical properties. Additional information on this method of assessment and the effects of strain rate can be found in Ref 57, 58, 59.

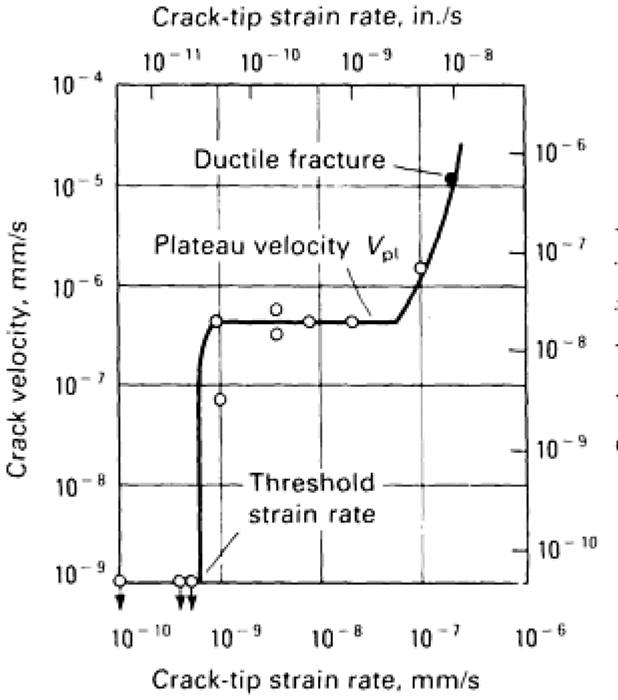

Fig. 37 Effects of beam deflection rate on stress-corrosion crack velocity in precracked cantilever bend specimens of a carbon-manganese steel. Tested in a carbonate-bicarbonate solution at 75 °C (165 °F) and at a potential of -650 mV versus SCE. Source: Ref 50

Selection of Test Environments

The primary environmental factors in SCC testing are the nature and concentration of anions and cations in aqueous solutions, electrochemical potential, solution pH, the partial pressure and nature of species in gaseous mixtures, and temperature. Separately or in combination, environmental variables can have a profound effect on the thermodynamics and kinetics of the electrochemical processes that control environmentally assisted fracture. Therefore, the choice of environmental conditions provides an important basis for developing accelerated SCC test methods.

The environmental requirements for SCC vary with different alloys. Although a mechanical precrack or a critical strain rate provides a worst case for SCC from a mechanical standpoint, there does not appear to be a generally applicable worst

case from an environmental standpoint. However, because the presence of moisture and salt water is universal, the SCC characteristics of alloys in these environments--as well as in any special environment a given engineering structure may experience--are always of interest.

Figure 38 illustrates that electrochemical factors can override mechanical factors in determining SCC initiation sites. Three cantilever beam specimens of PH13-8Mo stainless steel were tested in salt water. Specimen A was tested at a high *K* level. With the participation of the chloride ions, the protective oxide film ruptured at the bottom of the precrack and initiated SCC, which was halted before the beam fractured completely. Specimen B was loaded at a lower *K* level. After 1300 h, a stress-corrosion crack initiated, but not in the precrack. Crack initiation occurred under the wall of the cell that surrounded the central portion of the specimen and contained the salt water.

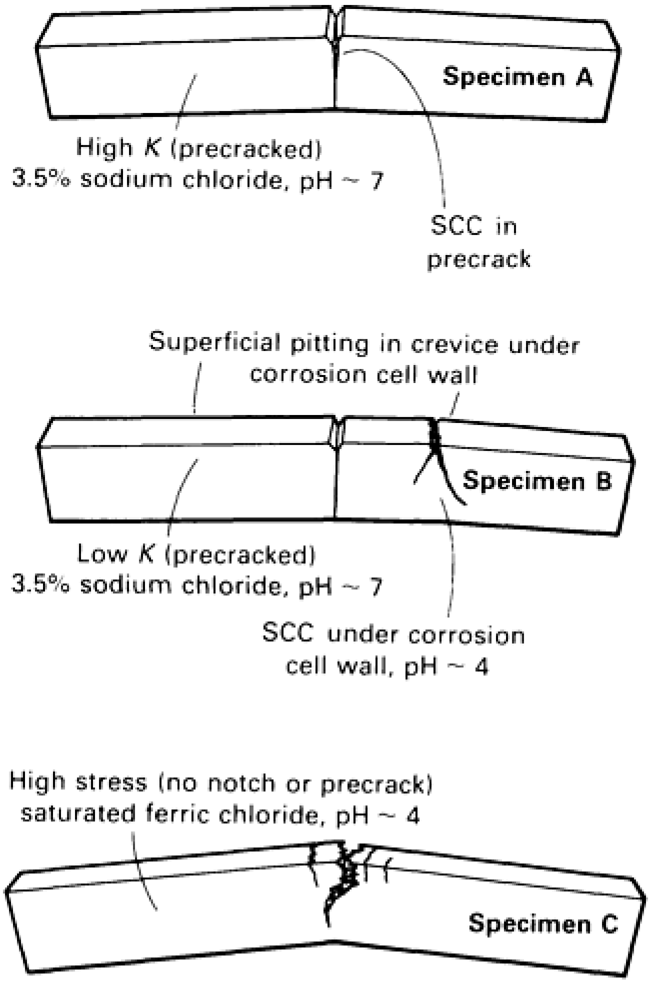

Fig. 38 Cantilever beam specimens of PH13-8Mo stainless steel after testing. Experiments demonstrate that electrochemical factors can override mechanical factors in determining initiation sites of SCC. See text for details. Source: Ref 60

Careful examination of this specimen and replicate specimens revealed small crevice corrosion pits under the wall that initiated SCC in an almost smooth surface. Even if these small pits had been as sharp as a fatigue crack, the *K* level would have been much lower than at the machined and fatigued notch. In the stagnant situation under the cell wall, the stainless steel reacted with the salt water to form hydrochloric acid and other corrosion products from the metal. Therefore, the low pH in a crevice, due to the hydrolysis of chromium corrosion product, overcame the mechanical disadvantage of the lack of a precrack. Specimen C was then tested to verify the effectiveness of electrochemical conditions in crack initiation. Saturated ferric chloride was selected to lower the pH to the range inside an active corrosion pit in the stainless steel; application of the solution to the unnotched beam resulted in the immediate initiation of many cracks in the smooth surface. Hydrochloric acid was found to be equally effective.

Stress-corrosion tests can be divided into two broad environmental classes: those conducted in actual service environments and those conducted under laboratory conditions.

Service Environments and Field Testing. The following examples illustrate the value, and in some cases the necessity, of exposure tests performed in actual service environments as an adjunct to laboratory evaluation. The standard 3.5% sodium chloride alternate immersion test data for aluminum alloys 2024 and 7075 proved useless in predicting the serviceability of these aluminum alloys for handling rocket propellant oxidizers such as nitrogen tetroxide and inhibited red fuming nitric acid (Ref 61). The alternate immersion test showed 2024-T351 and 7075-T651 to be susceptible to SCC at low short-transverse stresses, but 2024-T851 and 7075-T7351 were quite resistant even at high stresses. These data were supported by outdoor field tests in seacoast and industrial atmospheres.

However, in proof tests consisting of exposure to the actual service environment--inhibited red fuming nitric acid at 74 °C (165 °F)--SCC occurred in both tempers of 7075 alloy and did not occur in either temper of 2024 alloy (Fig. 39). There were no unexpected failures with the 2219-T87 and 6061-T651 materials, however.

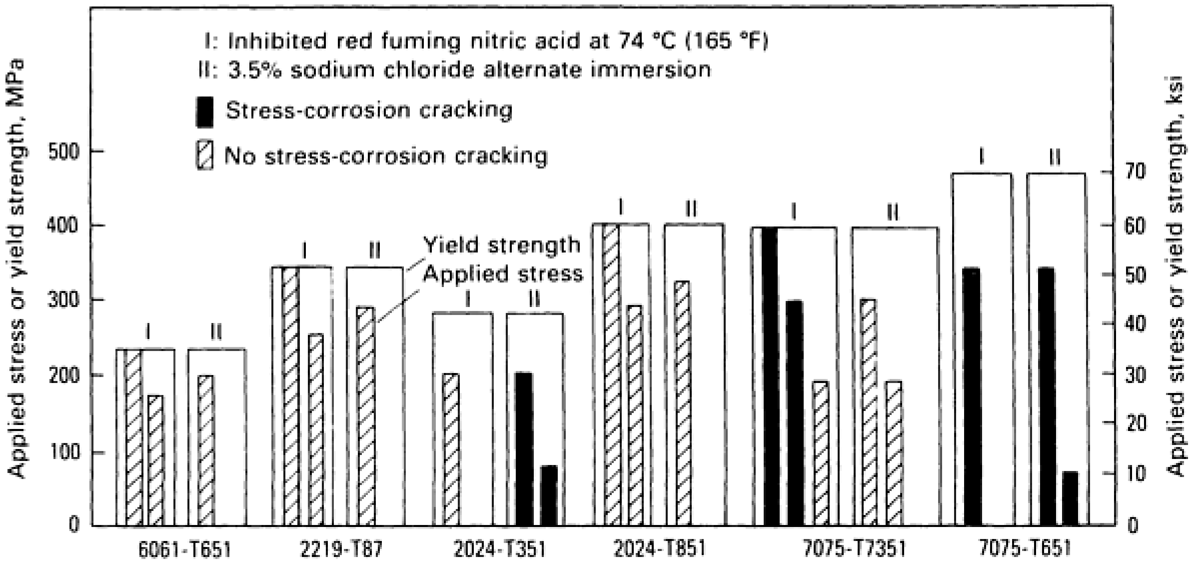

Fig. 39 SCC resistance of various aluminum alloys in inhibited red fuming nitric acid versus alternate immersion in 3.5% sodium chloride solution. Each bar graph represents an individual short-transverse C-ring test specimen machined from rolled plate and stressed at the indicated level. Source: Ref 61

Simulated-service tests should be conducted under conditions duplicating the service environment exactly, as illustrated by the following example with Ti-6Al-4V alloy pressure tanks for propellant-grade nitrogen tetroxide (<0.20 wt% moisture) (Ref 62). Preliminary laboratory SCC tests using specimens of Ti-6Al-4V demonstrated satisfactory compatibility with the nitrogen tetroxide and gave no indication of SCC.

In subsequent tests of actual pressurized tanks, however, SCC occurred rapidly, and the tanks failed. It was subsequently shown that the nitrogen tetroxide used in the tanks was of a higher-purity grade than that used in the laboratory tests. When test specimens were exposed to this grade of nitrogen tetroxide, they also failed. The small quantities of water and nitric oxide (impurities) present in the nitrogen tetroxide used in previous studies were sufficient to inhibit SCC of Ti-6Al-4V in nitrogen tetroxide.

Field testing consists of placing a metal specimen in an environment in which conditions represent those anticipated in service. Typical examples include immersion in seawater, exposure to the atmosphere at marine or industrial sites, chemical plant streams, and so on. Field tests can be performed with test coupons or with actual or simulated structural components.

Laboratory Environments. Accelerated testing is conducted extensively in controlled laboratory environments for developmental studies in which it is not considered necessary that the test medium duplicate a particular service

environment. Reliance should not be placed on such test results, however, unless they can be correlated with practical service experience or with the results of appropriate field tests.

Ideally, the results of a short exposure in a laboratory test will enable a reliable prediction of the SCC performance of an alloy over a long service period under particular environmental conditions. To fulfill this function, test conditions should be selected with regard to the anticipated service conditions. However, accelerated test media that yield reliable results for one alloy may not yield dependable results for another alloy, even though both alloys are of the same basic metal (Ref 9, 58). Therefore, caution must be exercised in the development and use of standardized test media. Recommended test media for various metals and alloys are discussed in later sections.

Mercury, other liquid-metal systems, and molten salts can also cause failure by cracking of metal under stress. In most cases of this type, oxidation-reduction reactions (corrosion) are not involved with the alloy, and the mechanisms of the cracking under such conditions are quite different from the mechanism of SCC.

Cracking caused by hydrogen embrittlement has been found to occur in titanium-base alloys and many high-strength ferrous alloys in various service environments. Hydrogen, under some conditions, enters the stressed metal without the presence of a corrosion reaction, and cracking ensues. Hydrogen can also enter stressed metal as a corrosion reaction product, and cracking may be stimulated or may ensue. Therefore, to characterize adequately the environmental cracking of such alloys under sustained tensile stress, testing should be performed both with and without conditions that could involve hydrogen damage. More information on testing for susceptibility to hydrogen embrittlement is available in the article "Evaluation of Hydrogen Embrittlement" in this Volume.

Length of Exposure. The question of appropriate test durations for the different material-environment combinations and the apparent need to establish them experimentally on a case-by-case basis has been a major stumbling block in the adoption of standard SCC test methods. The situation become acute when the results of an SCC test must be evaluated before all replicate specimens have cracked. In these cases, when a statistical probability evaluation must be performed, it should be recognized that time to failure is often normally distributed with respect to the logarithm of test time (see the section "Interpretation of Test Results" in this article). Exposure periods that are too short can result in a test that is trifling; when too long, they can introduce extraneous effects. An example is the excessive pitting of smooth test specimens that leads to failure by a different (and possibly unsuspected) mode of SCC, or by mechanical overload rather than by SCC (Ref 18). Problems in the case of precracked specimens can result from test periods being too short to develop a proper estimate of an apparent threshold stress intensity, especially in *K*-increasing tests; on the other hand, periods that are too long may result in corrosion product wedging or crack tip blunting, both of which can invalidate calculations of the effective stress intensity and SCC growth rates in *K*-decreasing tests (Ref 24, 36, 37). Therefore, it is necessary to scrutinize test results carefully so that extraneous effects can be excluded from the analysis of the test results.

Electrochemical Tests. Recognition of the importance of electrical potential as one of the controlling parameters in SCC has resulted n increasing use of tests with potentiostatic control or impressed electrical current. No standards exist for such electrochemical tests, although several methods are routinely used. These tests involve specific conditions that are applicable only to given alloy and environment systems under consideration. These types of tests offer greater rapidity and precision than free corrosion tests.

Sophisticated approaches for studying systems involving active path corrosion use potentiodynamic methods. Anodic polarization curves can provide reasonably accurate predictions of the critical potential ranges and kinetic factors controlling SCC in a given system. One procedure (Ref 63) involves first scanning a range of potentials in the anodic direction at a relatively high scan rate (~1000 mV/min) to determine regions with high current density, in which intense anodic activity is likely. This is followed by a relatively low scan rate (~20 mV/min), which indicates regions where relative inactivity is likely.

Scans should be started at a potential at which the surface is film free. The rapid scan minimizes film formation so that the observed currents relate to relatively film-free conditions. The slow scan allows time for filming to occur. Comparison of the two curves reveals any ranges of potential within which high anodic activity in the film-free region reduces to insignificant activity when the time requirements for film formation are met, thus indicating the critical potential range in which SCC is likely.

Figure 40 illustrates this type of experiment for a low-carbon steel in a carbonate-bicarbonate solution with the predicted domains of behavior. Establishing a precise range of critical potentials for SCC requires subjective determination of boundary conditions relating to the current densities.

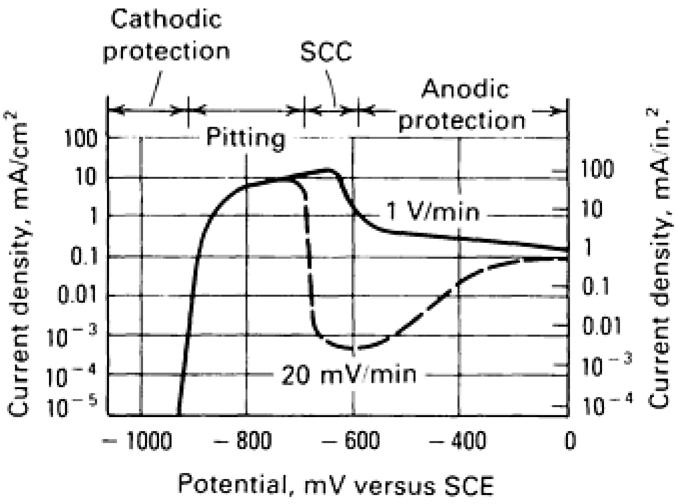

Fig. 40 Potentiodynamic polarization curves for carbon-manganese steel in 1 *N* sodium carbonate plus 1 *N* sodium bicarbonate at 90 °C (195 °F) showing the domains of behavior predicted from the curves. Source: Ref 63

A different approach with the use of anodic polarization curves has been used to characterize the SCC behavior of aluminum alloys (Ref 64). Corrosion of a susceptible microstructure in aqueous chloride solutions was exclusively intergranular only for a limited range of potentials between the first and second breakdown potentials, E_{BR}, determined from the anodic polarization curve, where E_{BR_1} approximates the critical pitting potential of the active corrosion path at the grain boundaries and E_{BR_2} approximates the critical pitting potential of the grain bodies. Figure 41 depicts a schematic anodic polarization curve for aluminum alloy 7075-T651 that illustrates the predicted domains of behavior.

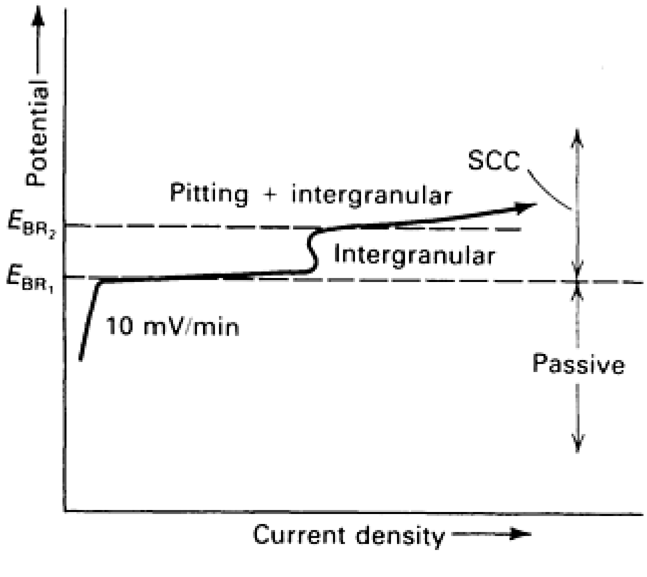

Fig. 41 Anodic polarization curves for aluminum alloy 7075-T651 in deaerated 3.5% sodium chloride solution showing the domains of behavior predicted from the curve. Source: Ref 65

The use of anodic polarization curves and related measurements is discussed in ASTM G 5 (Ref 8). Information obtained from the anodic polarization curve can be useful for screening environmental test media to reduce the number of actual SCC tests required. However, such electrochemical tests are concerned with testing a bulk environment in contact with an exposed surface, and it should not be assumed that such measurements represent the crack tip under conditions of crack

growth. Therefore, even when an environment is identified as innocuous, a potent local environment may exist, such as in a pit when the pitting potential is exceed or in a crevice or precrack.

Moreover, when laboratory SCC tests involve cracks or crevices, the potential at the crack tip may differ appreciably from that measured at the surface where the crack or crevice emerges. In laboratory tests, it must be considered whether or not environmental changes in composition or potential are involved and how they may relate to service conditions (Ref 58). Further discussion of electrochemical approaches to the evaluation of SCC is presented in the article "Laboratory Testing" in this Volume.

Testing of Aluminum Alloys

Stress-corrosion cracking of susceptible high-strength aluminum alloys can occur in moist air, seawater, and potable waters, and it varies with the alloy and temper and the magnitude of sustained tensile stress. Chloride solutions are generally favored for laboratory tests because sodium chloride is widely distributed in nature, and the test results are potentially relatable to stress-corrosion behavior in natural environments.

Testing With Smooth Specimens

Historically, stress corrosion testing of aluminum alloys has been done with smooth (notch-free) specimens, and most published SCC ratings of aluminum alloys are based on such tests.

Alternate Immersion in 3.5% Sodium Chloride. Exposure to 3.5% sodium chloride or to substitute ocean water (ASTM D 1141) by alternate immersion (ASTM G 44) (Ref 8) is a widely used procedure for testing smooth specimens of aluminum alloys. Aeration of the specimens, achieved by the alternate immersion, enhances the corrosion potential (Ref 66) and produces more rapid SCC of most aluminum alloys than continuous immersion. The ASTM G 44 standard practice consists of a 1-h cycle that includes a 10-min soak in the aqueous solution followed by a 50-min period out of solution in air at 27 °C (80 °F) and 45% relatively humidity, during which time the specimens are air dried. This 1-h cycle is repeated continuously for the total number of days recommended for the particular alloy being tested. Typically, aluminum alloys are exposed from 10 to 90 days, depending on the resistance of the alloy to corrosion by salt water. This test method is widely used for testing most types of aluminum alloys with all types of smooth specimens.

The alternate immersion test is primarily used for alloy development studies and for quality control of alloys with improved resistance to SCC (Ref 9, 67). This test method is specified in ASTM G 47 (Ref 8), which covers the method of sampling, type of specimen, specimen preparation, test environment, and method of exposure for determining the susceptibility to SCC of high-strength 2000-series alloys (1.8 to 7.0% Cu) and 7000-series alloys (0.4 to 2.8% Cu). Alternate immersion in 3.5% sodium chloride is also specified in ASTM G 64 (Ref 8).

The parallel SCC behavior of a variety of aluminum alloys in the ASTM G 44 test and in a severe seacoast atmosphere is shown in Table 3. Additional comparisons may be found in Ref 18 and 69. The relatively conservative estimate of the SCC behavior of an intermediate-resistance alloy in the ASTM G 44 test compared to that in various atmospheric environments is shown in Fig. 42, which also illustrates the wide range in behaviors in various atmospheric environments.

Table 3 Comparison of the SCC behavior of various aluminum alloys in the ASTM G 44 test and after 5 years in a seacoast atmosphere

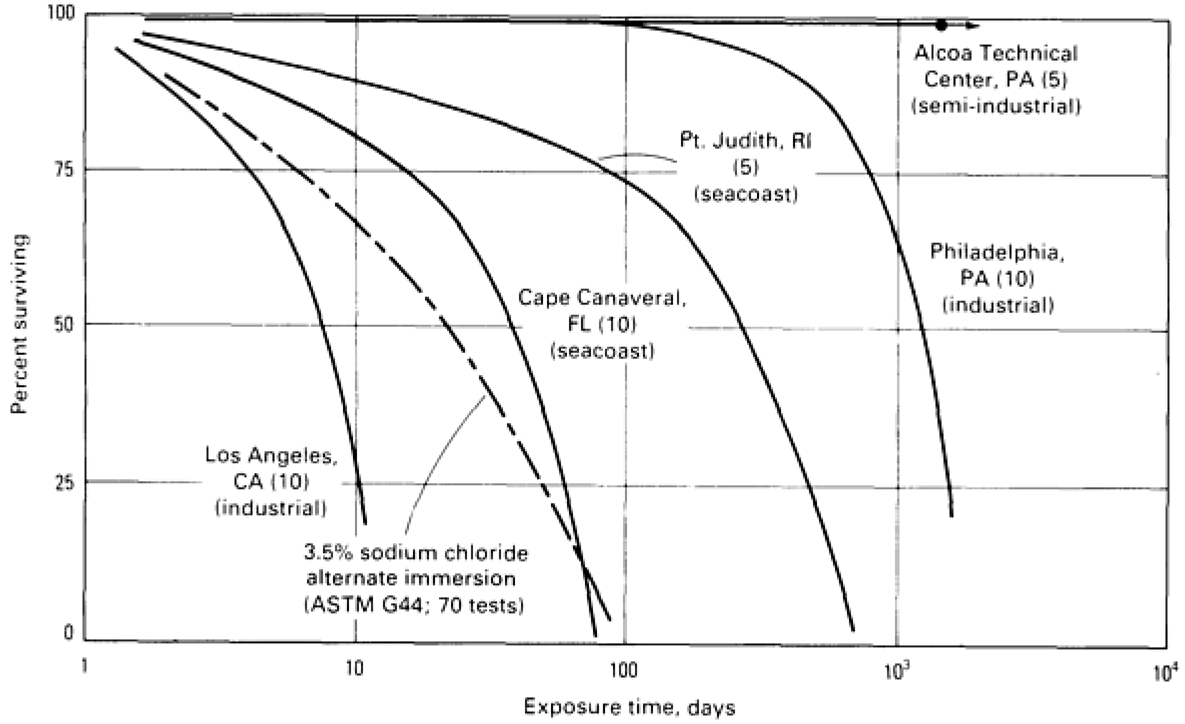

Fig. 42 Effect of variations in atmospheric environment on the probability and time to failure by SCC of a material with an intermediate susceptibility. Tests were made on short-transverse 3.2-mm (0.125-in.) diam tension specimens from 7075-T7651 type plate stressed 310 MPa (45 ksi). Parenthetical values indicate replication of tests. Source: Ref 3

Although ASTM G 44 is a good general-purpose test for aluminum alloys, it is not equally discriminating of all alloys at near-threshold stress levels. This tendency has been reported for 7000-series (aluminum-zinc-magnesium-copper) alloys

containing less than about 1% Cu (Ref 9, 16, 69). Also, the test is not representative of special chemical environments, such as inhibited red fuming nitric acid (Fig. 39).

Continuous Immersion in Boiling 6% Sodium Chloride. A 4-day exposure by continuous immersion in boiling 6% sodium chloride solution is widely used by U.S. aluminum producers for testing smooth specimens of 7000-series alloys containing no more than 0.25% Cu. Comparison of this test and a modified ASTM G 44 test to the industrial atmospheric exposure shown in Fig. 43 illustrates the advantage for the boiling salt test. An ASTM standard is in preparation at this writing.

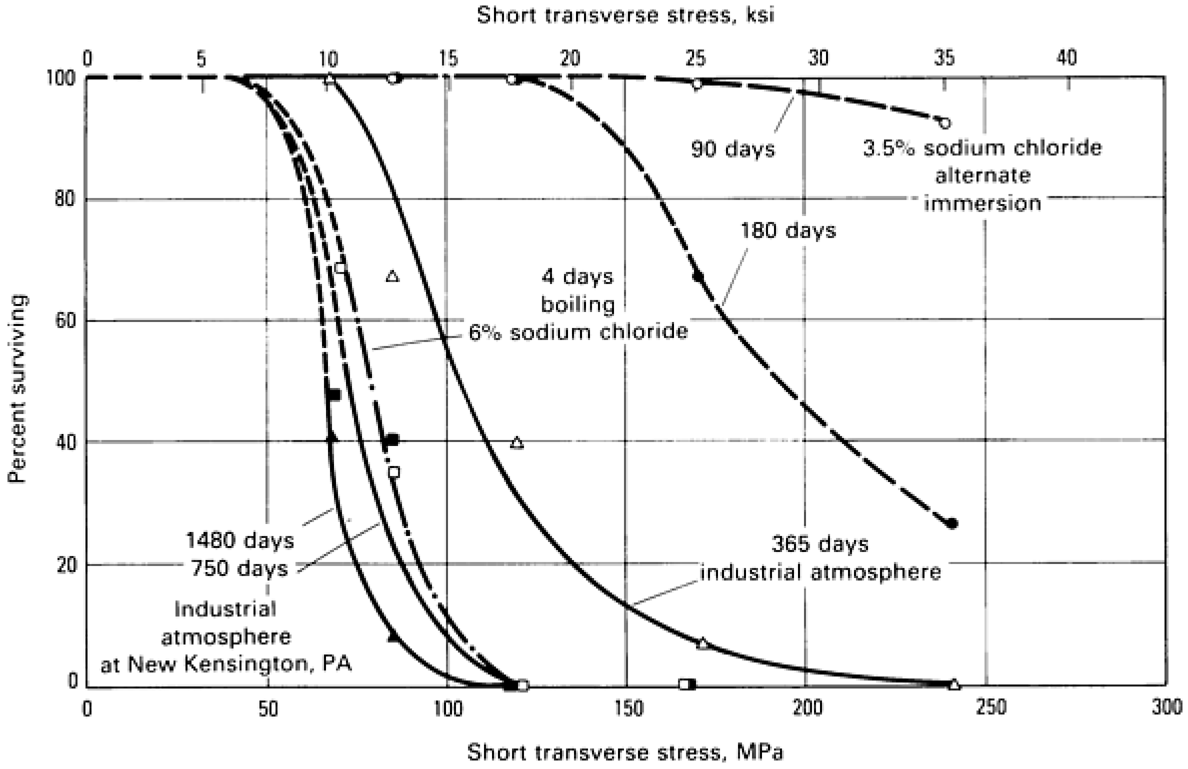

Fig. 43 Correlation of accelerated test media with service environment (industrial atmosphere). Combined data for five lots of rolled plate of aluminum alloy 7039-T64 (4.0Zn-2.8Mg-0.3Mn-0.2Cr). Tests in 3.5% sodium chloride were similar to ASTM G 44, except salt solution was made with commercial grade sodium chloride and New Kensington tap water. Source: Ref 9

This test is not effective for and therefore not recommended for, the 2000-series (aluminum-copper) alloys, the 5000-series (aluminum-magnesium) alloys, or the 7000-series (aluminum-zinc-magnesium-copper) alloys containing more than about 1% Cu. Also, it is not recommended for testing precracked specimens because of the interference of wedges of corrosion products developed on the crack surfaces.

The impressed-current test for 5000-series alloys was developed for rapid evaluation of smooth coupon specimens of the 5000-series (aluminum-magnesium) alloys. The test solution is 3.5% sodium chloride, and the acceleration is provided by impressing on the test specimen a dc electrical current of 6.2×10^{-2} mA/mm^2 (40 mA/in.^{2}) of specimen surface. Good correlation with natural environment exposures is reported in Ref 70.

Other Testing Media. Although nitrates and sulfates, when dissolved in distilled water, tend to retard SCC, their presence in chloride environments can produce a synergistic stimulation of intergranular corrosion and SCC (Ref 65, 71, 72). Stress-corrosion cracking can also be accelerated for certain alloys by increasing acidity (lower pH), increasing temperature, adding oxidants, or electrochemically driving the SCC process by impressing an appropriate potential or electrical current density. These procedures, either singly or in combination, have been used to create various special-purpose tests:

- Continuous immersion test for 7000-series (aluminum-zinc-magnesium) alloys (Ref 73): aqueous solution containing 3% sodium chloride, 0.5% hydrogen peroxide (30%), 100 mL/L 1 *N* sodium hydroxide, and 20 mL/L acetic acid (100%); pH 4.0
- Continuous immersion test for high-strength aircraft alloys (Ref 74): aqueous solution containing 2% sodium chloride plus 0.5% sodium chromate
- Impressed-current test for 7000-series (aluminum-zinc-magnesium) alloys (Ref 75): aqueous solution containing 2% sodium chloride plus 0.5% sodium chromate; pH 8.1, current density 4.65×10^{-4} mA/mm^2 (0.3 $mA/in.^2$); 30-day maximum exposure time
- Alternate immersion test using an aqueous solution containing 2.86% sodium chloride plus 0.52% magnesium chloride (total chloride equal to that in ocean water): proposed in Ref 76 as a less corrosive substitute for 3.5% sodium chloride solution for ASTM G 44
- Continuous immersion test for 2000-series (aluminum-copper) and 7000 series (aluminum-zinc-magnesium-copper) alloys (Ref 77): aqueous 1% sodium chloride plus 2% potassium dichromate at 60 °C (140 °F); 168-h maximum exposure time
- Continuous immersion test for 2000-series (aluminum-copper) and 7000-series (aluminum-zinc-magnesium-copper) alloys (Ref 36, 37): aqueous solution containing 0.6 *M* sodium chloride, 0.02 *M* sodium dichromate, 0.07 *M* sodium acetate, plus acetic acid to pH 4; used principally for testing precracked specimens

Testing With Precracked Specimens

Testing aluminum alloys with precracked specimens, especially the bolt-loaded double-beam type, has received widespread use in recent years, and the ranking of materials by this method is generally in good agreement with that established with smooth specimen tests. However, a number of problems in the interpretation of test results must be taken into account (Ref 34, 35, 36, 37, 78, 79, 80, 81). Subjective interpretations of the test results can be variable because there are as yet no standardized test procedures.

The bolt-loaded *K*-decreasing type of test is attractive because no complicated apparatus is required to perform the tests, and the results appear to be relatable to the control of SCC problems in engineering structures. Distinction among test materials or test environments is based on the amount and the rate of penetration by SCC, with the results being expressed in terms of crack depth, a threshold stress-intensity factor (K_{ISCC} or K_{th}), or plateau velocity (V_{pl}) (Fig. 3).

For example, the relative susceptibilities of various alloys can be determined from crack depth versus time curves after testing for exposure periods as short as 150 to 200 h (Ref 35). This is illustrated for an extreme range of susceptibilities in Fig. 44. Plateau velocities in this example are indicated by graphical estimates of the average slopes of the initial portions of the crack growth curves, beginning at the time when growth started and extending until the curves definitely started to bend over toward an arrest. An arrest would indicate K_{th}, but real arrests (zero crack growth) may not occur; therefore, it is customary to define K_{th} as the crack-tip stress intensity at which the crack growth rate has decreased to the limit of measuring capability. This is usually about 10^{-10} m/s (1 to 2×10^{-5} in./h), that is, where the growth is less than 0.2 mm (0.008 in.) within 30 days.

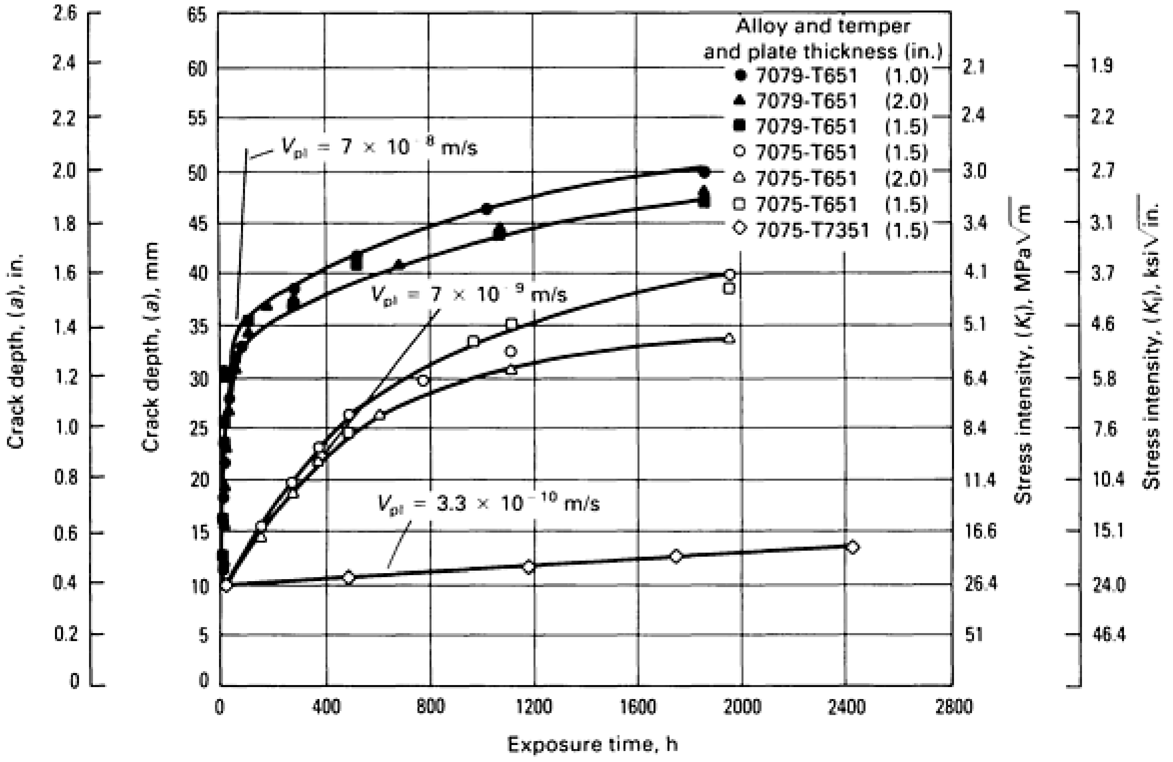

Fig. 44 Crack depth and stress intensity versus time curves for double-beam specimens of aluminum alloys 7075-T651, 7079-T651, and 7075-T7351 having nearly identical deflections and starting crack depths. Specimens with S-L orientation (see Fig. 28) measuring 25 × 25 × 127 mm (1 × 1 × 5 in.) bolt loaded to pop-in and wetted three times daily with 3.5% sodium chloride. Source: Ref 35

Plateau velocities can be readily determined for materials having a relatively low resistance to SCC, such as 7075-T651 and 7079-T651 alloy plates when stressed in the short-transverse direction. Such tests have been effectively used for the evaluation of corrosive environments and the study of SCC trends with the artificial aging of 7000-series (aluminum-zinc-magnesium-copper) alloys (Ref 78, 79). However, the use of plateau velocities for comparing materials with higher resistance to SCC becomes complicated when only small amounts of crack growth occur in normal exposure periods. In such cases, the initial penetration of SCC, even at near-critical stress intensities, may be delayed by an initiation (incubation) period and then may begin at small independent sites along an uneven mechanical crack front. The crack measurements are erratic, and the interpretation of the crack growth curves is subjective. Comparisons among relatively resistant materials are difficult.

Figure 45 shows a number of crack growth curves for several resistant materials. It is evident that the estimated plateau velocities are quite variable and do not correlate consistently with the total crack growth in a given exposure time. For these more SCC-resistant materials, average growth rates for the first 15 days of exposure appear to relate much better to the actual amount of crack growth and to smooth specimen ratings according to ASTM G 64 (Table 4).

Table 4 Correlation of SCC plateau crack velocities with smooth specimen SCC ratings

Alloy	Smooth specimen rating[(a)]	Plateau crack velocity			
		First growth		**Average (0 to 15 days)**	
		m/s	**in. × 10^{-5}/h**	**m/s**	**in. × 10^{-5}/h**
1	A	6×10^{-10}	10	2×10^{-10}	3
2	A	7×10^{-9}	100	1.8×10^{-9}	27[(b)]
3	B	2.1×10^{-9}	30	1.2×10^{-9}	19
4	B	4.2×10^{-9}	60	1.3×10^{-9}	20
5	B	7×10^{-9}	100	2.1×10^{-9}	30
6	C	6.3×10^{-9}	90	4.2×10^{-9}	60

Note: S-L (see Fig. 28) double-beam specimens bolt-loaded to pop-in and wetted three times daily with 3.5% sodium chloride.

(a) Short-transverse ratings per ASTM G 64 (Ref 8).

(b) Fractographic examination revealed mechanical fracture rather than the intergranular SCC verified in all other materials.

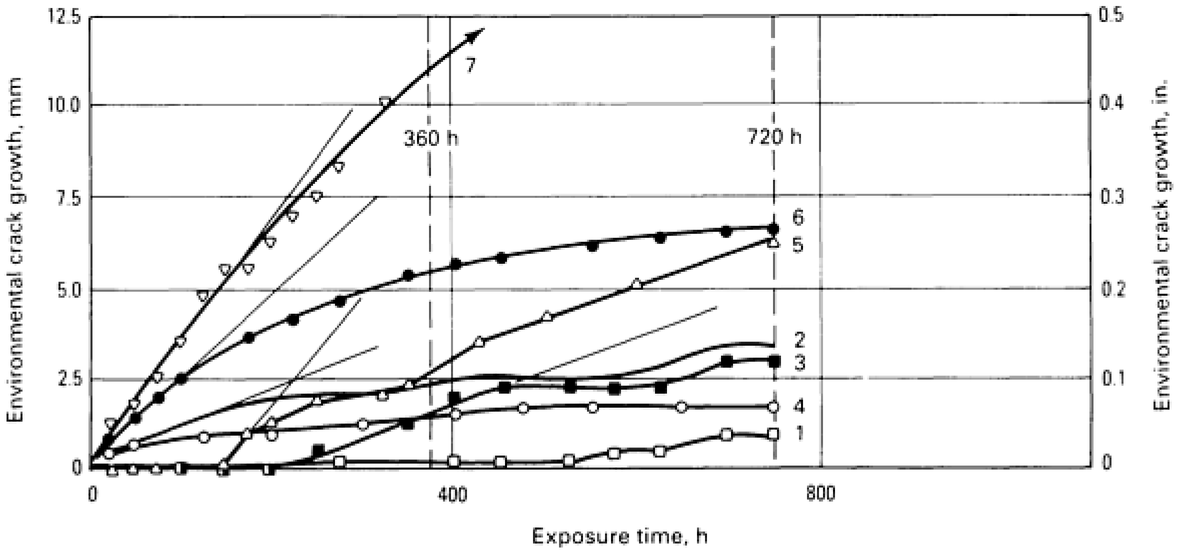

Fig. 45 Examples of SCC crack growth in various aluminum alloys with relatively high resistance to SCC. S-L (see Fig. 28) double-beam specimens bolt-loaded to pop-in and wetted with 3.5% sodium chloride three times daily; relative humidity 45%. The numbers 1 to 7 indicate different test materials listed in order of decreasing resistance to SCC (see Table 4), dashed lines indicate plateau velocities. The alloy 2 specimen failed by mechanical fracture rather than intergranular SCC. Source: Ref 36, 41

The performance of alloy 2 in Table 4 indicates another potential problem with tests performed at very high stress intensities; that is, with some very resistant materials, environmental crack growth will possibly be the result of mechanical fracture rather than by SCC. Therefore, it is necessary when testing SCC-resistant materials to verify that the crack growth is in fact SCC.

The determination of threshold stress intensities by the arrest method is frequently complicated by corrosion product wedging, which changes the stress state at the tip of the crack and invalidates the calculation of effective stress intensities from the crack lengths. With low-resistance alloys, such as 7075-T651, an arrest may never occur, because the crack is continually driven ahead by the advancing wedge of insoluble corrosion products (Ref 36, 79). An indication of this was shown by the initiation of SCC in precracked specimens exposed with no applied load for just a few months in a seacoast atmosphere (Ref 36). Experimental evidence of a threshold stress intensity will depend on the amount of corrosion occurring in a given alloy/environment system (Fig. 46).

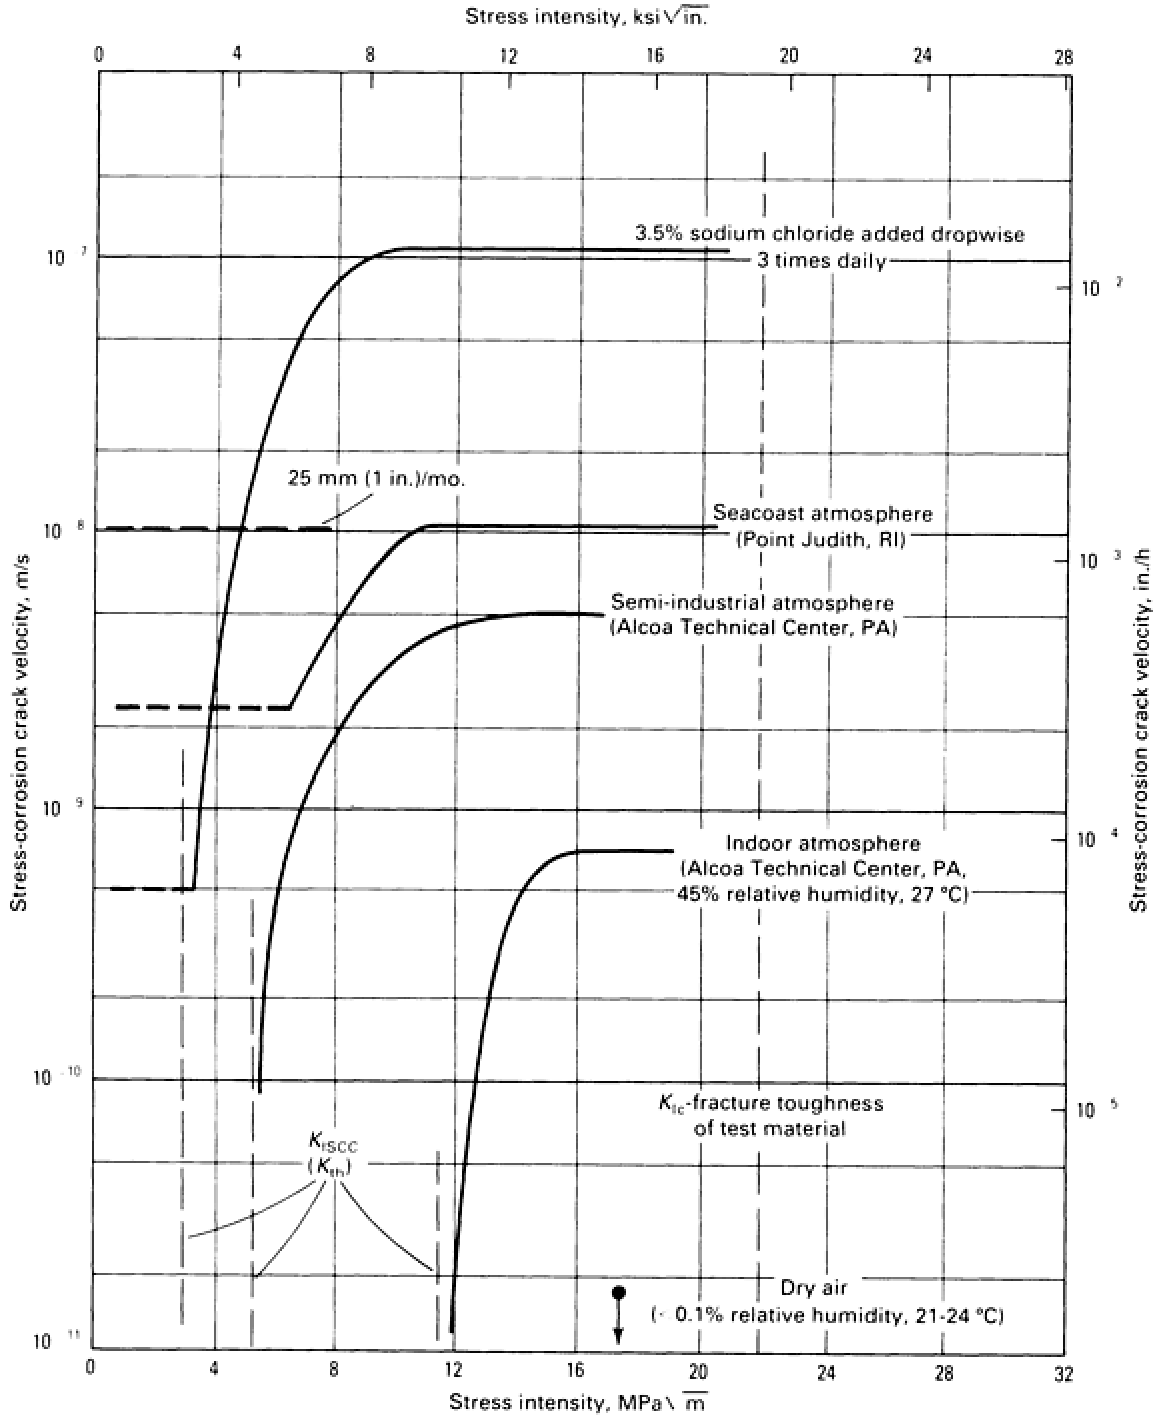

Fig. 46 Effect of corrosive environment on SCC velocity and threshold stress intensity for 7079-T651 plate (64 mm, or 2.5 in., thick) stressed in the short-transverse direction (S-L; see Fig. 28). Double-beam specimens bolt-loaded to pop-in. No SCC occurred during 3 years of exposure to dry air in a desiccator; however, the plateau velocity (horizontal part of each curve) and the apparent threshold stress intensity (K_{ISCC} or K_{th}) vary with the environment. Dashed portions of the curves represent the effect of corrosion product wedging. Source: Ref 41

With intermediate-resistance materials, the growth curves may develop prominent steps indicative of temporary arrests. Figure 47 shows some of the various curves that may be obtained, depending on the resistance to corrosion and SCC of the test material, the corrosivity of the test medium, the magnitude of the applied stress intensity, and the length of exposure. The significant portion of the curve is that which goes from the beginning of the test to the first appreciable

cessation of the crack growth. It is assumed that if it were not for the intervention of the corrosion product wedging the curve would proceed to an arrest.

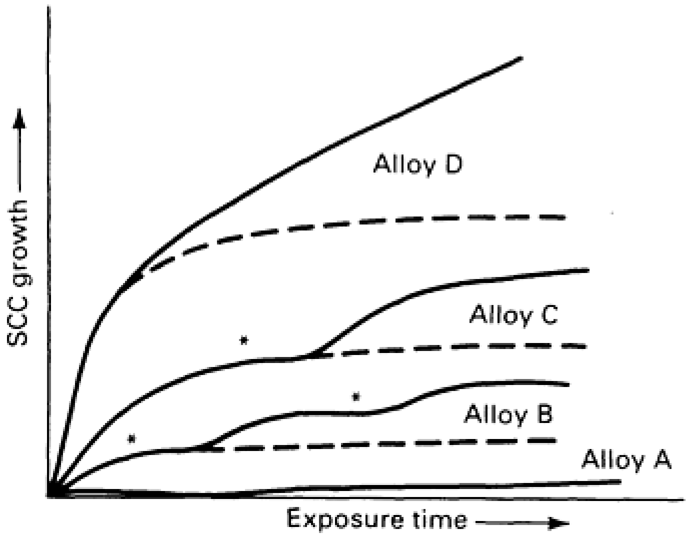

Fig. 47 Schematic of the variable effects of corrosion product wedging on SCC growth curves in a *K*-decreasing test. Solid lines: measured curve. Dashed lines: estimated true curve excluding the effect of corrosion product wedging. Asterisks indicate temporary crack arrests.

The threshold stress intensities determined by this method can be useful for ranking materials, but usually cannot be considered valid. Therefore, they cannot be used in design calculations based on fracture mechanics. Displays of complete *V*-*K* curves provide convenient comparisons of various materials, as shown in Fig. 48. Problems with the control of the testing procedure and of correlations with service conditions have impeded the standardization of this test method (Ref 24, 34).

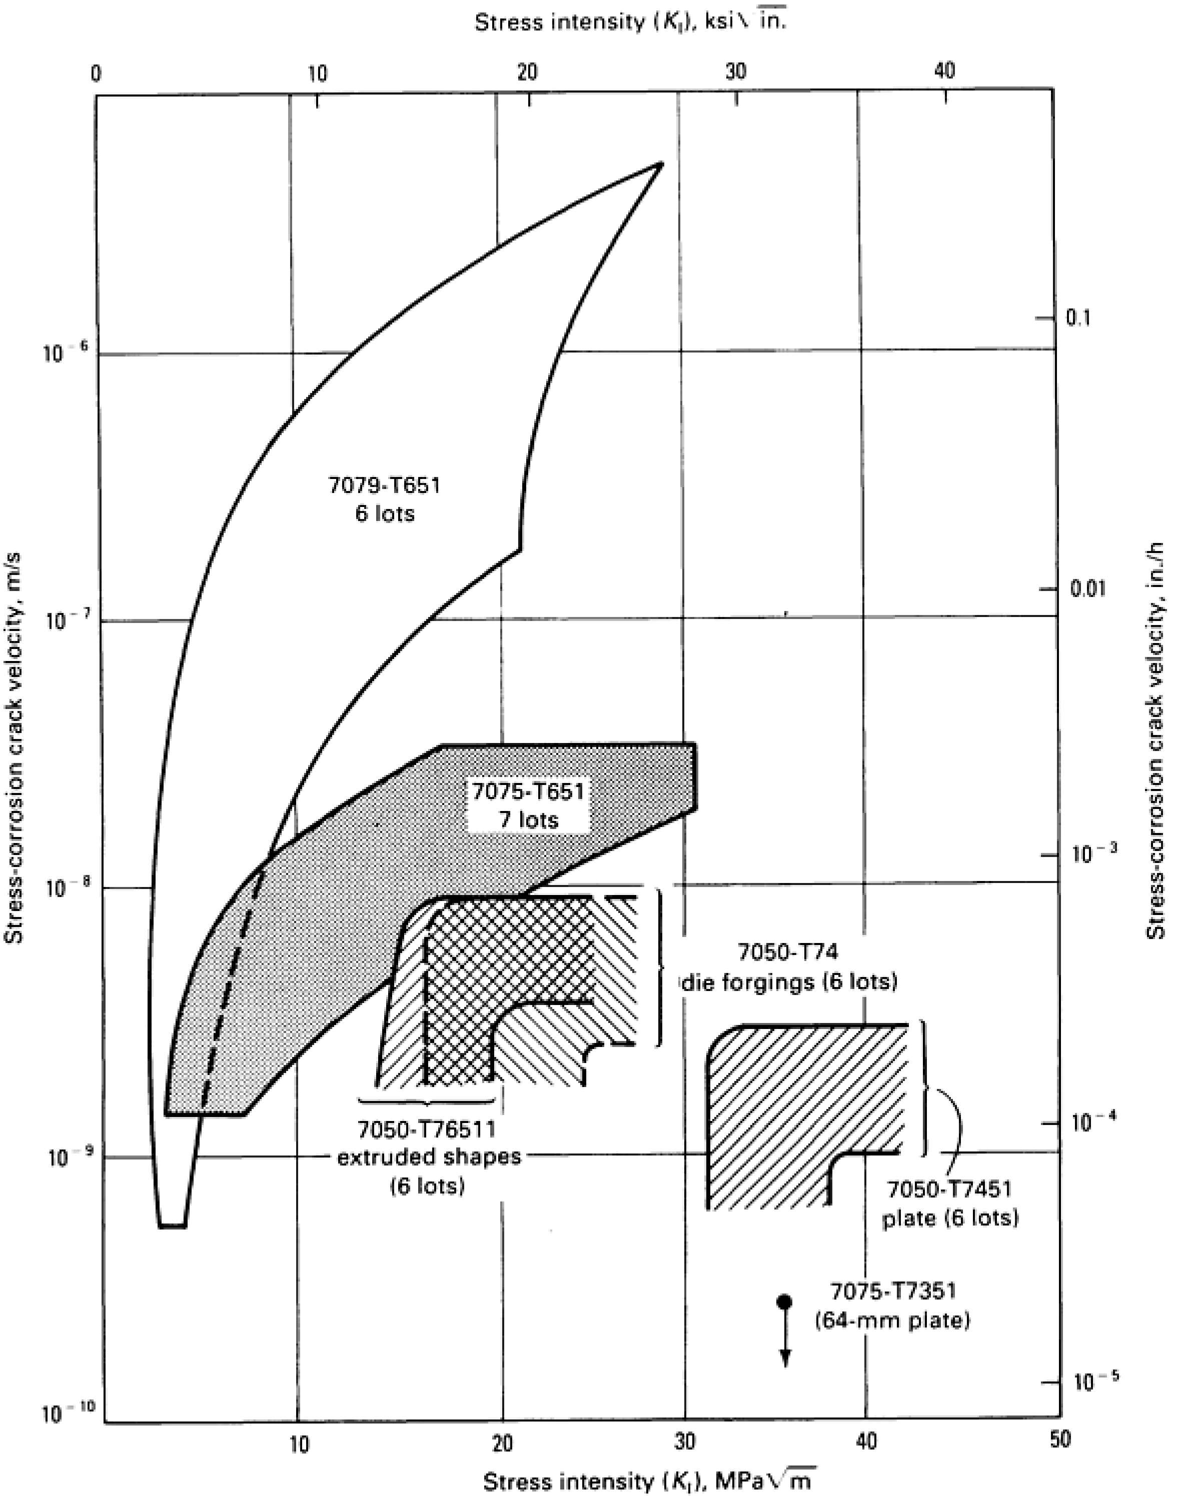

Fig. 48 SCC propagation rates for various aluminum alloy 7050 products. Double-beam specimens (S-L; see Fig. 28) bolt-loaded to pop-in and wetted three times daily with 3.5% NaCl. Plateau velocity averaged over 15 days. The right-hand end of the band for each product indicates the pop-in starting stress intensity (K_{Io}) for the tests of that material. Data for alloys 7075-T651 and 7079-T651 are from Ref 35. Source: Ref 82

Dead-weight loading, or a simulated dead-weight loading system used in conjunction with automatic data logging equipment (Fig. 30(b), has proved to be a rigorous method for evaluating threshold stress intensities by SCC initiation (Ref 33, 34). Because crack growth results in increasing stress intensity and an increasing crack opening, corrosion product wedging is minimal, and each test usually has a definite end point (fracture). In these tests, fatigue precracked compact or modified compact specimens (Fig. 25(b)) are loaded to various initial stress intensities K_{Io} and exposed until

fracture or until completion of a designated time period (Fig. 29). The designated cut-off period should be long enough for extended initiation times and yet not long enough to allow corrosion product wedging to exert a dominant influence.

The test results shown in Fig. 49 indicate that near-threshold values were reached within 1200 h, as judged by the flattening tendency of the curves. The slight downward slope of some of the curves after 1200 h may be the result of wedging by corrosion products, but this was not determined. The effect of such wedging would be to give lower estimates of the threshold stress intensity.

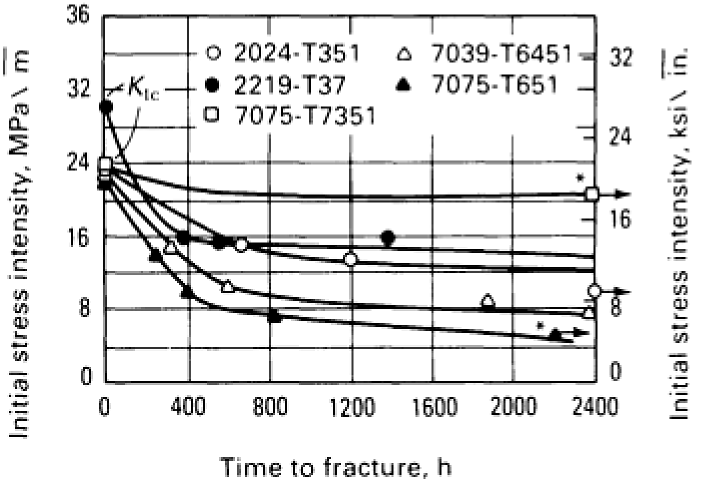

Fig. 49 Initial stress intensity versus time to fracture for S-L (see Fig. 28) compact specimens of various aluminum alloys exposed to an aqueous solution containing 0.06 *M* sodium chloride, 0.02 *M* sodium dichromate, 0.07 *M* sodium acetate, and acetic acid to pH 4. Asterisk indicates metallographic examination showed that SCC had started. Source: Ref 33

The testing of longitudinal (L-T, L-S in Fig. 28) and long-transverse (T-L, T-S in Fig. 28) specimens presents special problems with materials having typical directional grain structures. Stress-corrosion cracking growth is small and tends to be in the L-T plane, which is perpendicular to the plane of the precrack (Ref 36, 83). Such out-of-plane crack growth invalidates calculations of the plane-strain threshold stress intensity K_{ISCC}. On the other hand, the testing of materials having an equiaxed grain structure also presents problems with stress intensity calculations because of gross crack branching; this would be applicable to specimens of any orientation.

The most widely used corrodent for testing precracked specimens is 3.5% sodium chloride solution applied dropwise to the precrack two or (usually) three times daily (Ref 34, 35, 36, 37). This intermittent wetting technique accelerates SCC growth but it also causes troublesome corrosion of the mechanical precrack. Less corrosive corrodents that have been used include substitute ocean water (ASTM D 1141) and an inhibited salt solution containing 0.06 *M* sodium chloride, 0.02 *M* sodium dichromate, 0.07 *M* sodium acetate, and acetic acid to pH 4 (Ref 36, 37, 81). Some investigators have tested 7000-series alloys in distilled water (Ref 78) and in water vapor at 40 °C (104 °F) (Ref 84). Typical test durations that have been used range from 200 to 2500 h.

With low-resistance alloys, both of the first two corrodents listed in the preceding paragraph ranked alloys similarly and in agreement with exposure to a seacoast and an inland industrial atmosphere. Plateau velocities in the laboratory tests were about five to ten times faster than in the seacoast atmosphere and ten times faster than in the industrial atmosphere. In these *K*-decreasing laboratory tests, corrosion product wedging effects dominated after exposure periods of about 200 to 800 h. The length of exposure time before the intervention of corrosion product wedging varies with several factors, including the magnitude of K_{Io} and the inherent resistance to crevice corrosion of the test material in the corrosive environment (Ref 36, 41).

Slow Strain Rate Testing

Slow strain rate testing is not governed by any standards. Various aqueous solutions have been used in addition to 3.5% sodium chloride. Because the 3.5% sodium chloride solution did not appear aggressive enough for slow strain rate testing,

more corrosive test mediums have been used, including oxidant additions to the sodium chloride solution or more acidic solutions, such as aluminum chloride (Ref 52, 85).

In a round-robin testing program using several aluminum alloy types and several corrodents, a solution containing 3% sodium chloride plus 0.3% hydrogen peroxide was considered the most promising candidate for possible standardization (Fig. 33). Additional study is needed to determine the optimum composition of these constituents. Another promising candidate was a solution of 2% sodium chloride plus 0.5% sodium chromate having a pH of 3.

Testing of Copper Alloys (Smooth Specimens)

Testing in Mattsson's Solution. According to ASTM G 37 (Ref 8), a stressed test specimen must be completely and continuously immersed in an aqueous solution containing 0.05 g-atom/L of Cu^{2+} and 1 g-mol/L of ammonium ion (NH_4^+) with a pH of 7.2. The copper is added as hydrated copper sulfate, and the NH_4^+ is added as a mixture of ammonium hydroxide and ammonium sulfate. The ratio of the latter two compounds is adjusted to achieve the desired pH.

Mattsson's pH 7.2 solution is recommended only for brasses (copper-zinc base alloys). This test environment may give erroneous results for other copper alloys and is not recommended. This is particularly true for alloys containing aluminum or nickel.

This test environment is believed to provide an accelerated ranking of the relative or absolute degree of susceptibility to SCC for different brasses. The test environment correlates well with the corresponding service ranking in environments that cause SCC, which may be due to the combined presence of traces of moisture and ammonia vapor. The extent to which the accelerated ranking correlates with the ranking obtained after long-term exposure to environments containing corrodents other than ammonia is not known. Such environments may be severe marine atmospheres (chloride), severe industrial atmospheres (predominantly sulfur dioxide), or superheated ammonia-free steam.

It is currently not possible to specify a time to failure in Mattsson's pH 7.2 solution that corresponds to a distinction between acceptable and unacceptable SCC behavior in brass alloys. Such correlations must be determined on an individual basis.

Mattsson's pH 7.2 solution may also cause some stress-independent general and intergranular corrosion of brasses. Therefore, SCC failure may possibly be confused with mechanical failure induced by corrosion-reduced net cross section. This is most likely with small cross-sectional specimens, high applied stress levels, long exposure times, and SCC-resistant alloys. Careful metallographic examination is recommended for accurate determination of the cause of failure. Alternatively, unstressed control specimens can be exposed to corrosive environments in order to determine the extent to which stress-independent corrosion degrades mechanical properties.

Other Testing Media. The most widely used SCC agent for copper and copper alloys is ammonia (NH_3) (Ref 86). The NH_4^+ ion does not appear to cause cracking in a stable salt, such as ammonium sulfate. Cracking will occur in a salt that dissociates (such as ammonium carbonate) to form ammonia.

The $Cu(NH_3)_x^{2+}$ ion (*x* is usually 4 to 5) is thought to be necessary to induce SCC in copper metals (Ref 87). Amine groups also cause cracking, or are easily converted to ammonia. Amines and sulfamic acid also cause cracking. Dry ammonia does not cause SCC of brass, as demonstrated by the successful use of brass valves and gages on tanks of anhydrous ammonia.

Stress-corrosion cracking of copper metals in ammonia will not occur in the absence of oxygen or an oxidizing agent. Carbon dioxide is also a requisite (Ref 88). Therefore, air rather than pure oxygen is necessary, and as a practical matter, moisture is essential. When other factors are favorable, a very small amount of NH_3 is sufficient to cause cracking. The controlling factor may therefore be moisture, because cracking may appear to be caused by the presence of a condensed moisture film.

Other than ammonia, the most effective agents for causing cracking are the fumes from nitric acid or moist nitrogen dioxide. Sulfur dioxide will also crack brass; but both maximum and minimum concentration limits exist, and the reaction

is slow (Ref 86). Alloy development studies have been conducted with a moist ammoniacal test atmosphere containing 80% air, 16% NH_3, and 4% water vapor at 35 °C (95 °F). However, none of these corrodents has received the attention that ammonia has garnered (Ref 87).

Historically, immersion of a copper alloy product in a mercurous nitrate solution has been used to test for residual stresses (Ref 89, 90). Because these residual stresses are possible sources of failure by SCC in other environments, some have regarded this test as a stress-corrosion test. However, it is only an indirect method of identifying SCC tendencies and does not correlate to the presence of SCC as well as test methods based on specific attack by ammonia (Ref 86). It does indicate, however, that mercury and other low-melting liquid metals can cause embrittlement and failure due to cracking.

Testing of Carbon and Low-Alloy Steels

Generally, steels with lower strengths are susceptible to SCC only upon exposure to a small number of specific environments, such as the hot caustic solutions encountered in steam boilers, hot nitrate solutions, anhydrous ammonia, and hot carbonate-bicarbonate solutions (Ref 91, 92).

Boiler Water Embrittlement Detector Testing. Caustic cracking failures frequently originate in welded structures in the vicinity of faying surfaces, where small leaks cause soluble salts to accumulate in high local concentrations of caustic soda and silica. As a general rule, crevices or splash areas on hot metal surfaces where the concentration of dissolved soluble salts can occur are likely sites for SCC. This type of intergranular cracking failure has been produced with concentrations of sodium hydroxide as low as 5%, but a concentration of 15 to 30% is usually required at 200 to 250 °C (390 to 480 °F) to produce this phenomenon. The apparatus and procedures used to determine the embrittling or nonembrittling characteristics of the water in an operating boiler are detailed in ASTM D 807 (Ref 8).

Other Testing Media. Caustic cracking occurs in digester vessels used in the chemical-processing industries, and laboratory studies have been conducted using sodium hydroxide concentrations of about 30 to 35% (Ref 93). Tests in boiling nitrate solutions have frequently been used to study the effects of composition and metallurgical variables (Ref 92). In studies of low-carbon steel in boiling nitrate solutions having different cations, solutions containing the more acidic cations in greater concentrations were found to be the most potent. This tendency is illustrated by the apparent threshold stresses for failure of a 0.05% C steel in nitrate solutions with a range of concentrations, as shown in Table 5.

Table 5 Apparent threshold stress values for 0.05% C steel in nitrate solutions of varying concentrations

Nitrate solution	Apparent threshold stress values at a solution concentration of:							
	8 *N*		**4 *N***		**2.5 *N***		**1 *N***	
	MPa	**ksi**	**MPa**	**ksi**	**MPa**	**ksi**	**MPa**	**ksi**
Ammonium nitrate	14	2	21	3	48	7	83	12
Calcium nitrate	34	5	48	7	83	12	159	23
Lithium nitrate	34	5	55	8	131	19 at 2 *N*	159	23
Potassium nitrate	41	6	62	9	97	14	165	24
Sodium nitrate	55	8	131	19	152	22	179	26

Source: Ref 92

Cracking can be accelerated by the addition of small amounts of acid or oxidizing agents, such as potassium permanganate, manganese sulfate, sodium nitrite, and potassium dichromate, but hydroxides and other salts, particularly those forming insoluble iron products, such as sodium carbonate or sodium hydrogen phosphate, retard or prevent failure. Sodium nitrite is also a known inhibitor if the nitrite concentration is equal to that of the nitrate ion. A standard test environment has not been established, and conditions should be tailored to individual testing requirements.

The ranking of a given series of alloys may vary with exposure conditions (Ref 58). Consequently, selection of a particular alloy for use in an environment that varies from that used in laboratory ranking tests may result in unexpected service failure. This tendency is illustrated by the effects of alloying additions in ferritic steels on cracking in two different environments (Fig. 50). Figure 50(a) illustrates that each of the alloying additions is beneficial in the carbonate-bicarbonate solutions, with molybdenum having the greatest effect. However, the molybdenum addition has an adverse effect in the 35% sodium hydroxide solution, although the beneficial effects of nickel and chromium additions remain the same (Fig. 50b). Although nickel additions are beneficial in the above example, a similar addition of nickel to a carbon-manganese steel produced susceptibility to SCC in boiling magnesium chloride; this did not occur in the steel without the addition of nickel (Ref 95).

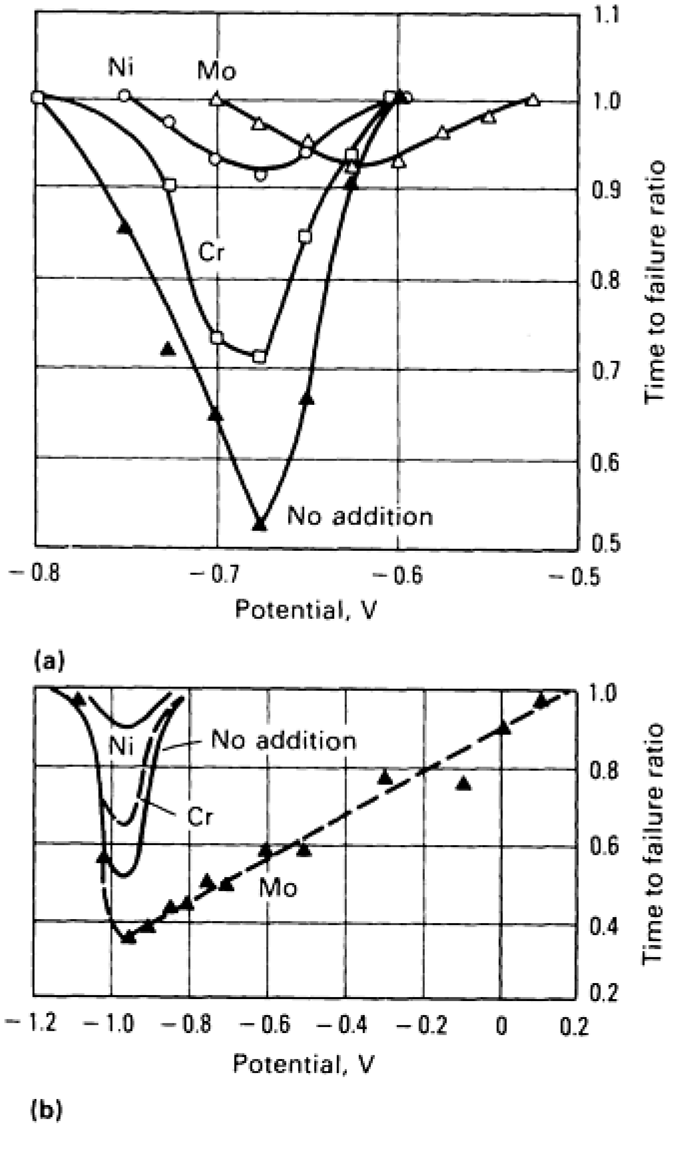

Fig. 50 Effect of various alloying elements on the SCC behavior of a low-alloy ferritic steel in two different corrosive environments. Behavior indicated by time to failure ratios in a slow strain rate test. (a) Immersed in 1 *N* sodium carbonate plus 1 *N* sodium bicarbonate at 75 °C (165 °F). (b) Immersed in boiling 35% sodium hydroxide. Source: Ref 94

The use of laboratory testing media that duplicate service conditions is equally important when accelerated tests are used for quality control through the acceptance or rejection of production lots of a particular alloys. Reference 96 discusses tests of prestressing steels intended for use as concrete reinforcing bars (rebars) in which an ammonium thiocyanate solution was used to discriminate between heats of steel.

Use of the carbonate-bicarbonate solutions for testing pipeline steels by the slow strain rate method revealed that the susceptibility to SCC was dependent on the electrochemical potential of the specimen surface in the test environment, as shown in Fig. 50(a). A critical range in which SCC occurred was established. The critical range varies with the test environment and alloy composition. Several tests at various carbonate-bicarbonate concentrations, temperatures, pH levels, and corrosion potentials indicated that test conditions using an impressed potential of -650 mV versus the saturated calomel electrode (SCE) and a temperature of 75 °C (165 °F) were optimal (Fig. 37).

Testing of High-Strength Steels (Ref 4, 97)

For steels with yield strengths greater than about 690 MPa (100 ksi)--such as low-alloy and alloy steels, hot-work die steels, maraging steels, and martensitic and precipitation-hardenable stainless steels--the environments that cause SCC are not specific. In many alloy systems, the phenomena of SCC and hydrogen embrittlement cracking are indistinguishable (Fig. 1). This is particularly the case in environments that contain sulfides or other promoters of hydrogen entry.

Environments of major concern are natural waters--for example, rainwater, seawater, and atmosphere moisture. Any of these environments may become contaminated, which significantly increases the likelihood of SCC. Contamination with hydrogen sulfide is particularly serious; consequently, the presence of hydrogen sulfide in high concentrations in salt water associated with certain deep oil wells (termed sour wells; see the article "Corrosion in Petroleum Production Operations" in this Volume) places an upper limit of approximately 620 MPa (90 ksi) on the yield strength that can be tolerated in stressed steel in such environments without cracking.

Sulfide Stress Cracking. Determination of sulfide stress cracking is covered in NACE TM-01-77 (Ref 98). Stressed specimens are immersed in acidified 5% sodium chloride solution saturated with hydrogen sulfide at ambient pressure and temperature. The solution is acidified with the addition of 0.5% acetic acid, yielding an initial pH of approximately 3. Applied stress at convenient increments of the yield strength is used to obtain cracking data that are plotted as shown in Fig. 51. A 30-day test period is considered sufficient to reveal failure of susceptible material in most cases.

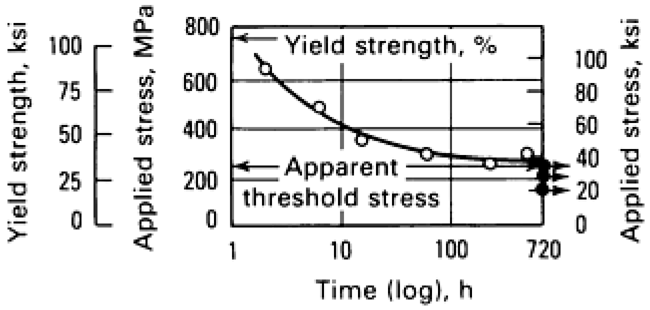

Fig. 51 Method of plotting results of sulfide stress cracking tests. Open symbols indicate failure; closed symbols indicate runouts. Source: Ref 98

The purpose of this test standard is to facilitate conformity in testing. Evaluation of data requires individual judgment on several points based on the specific requirements of the end use. Consequently, the test should not be used as a single criterion for evaluating an alloy for use in environments containing hydrogen sulfide or other hydrogen charging elements. Attention should be paid to other factors that may affect SCC, such as pH, temperature, hydrogen sulfide concentration, corrosion potential, and stress level, when determining the suitability of a metal for use.

The NACE test method recommends the use of smooth, small-diameter tension specimens stressed with constant-load or sustained-load devices (Ref 98). However, different types of beam and fracture mechanics specimens may be included in the testing standard in the future.

Another test method, known as the Shell Bent Beam Test, has been used for over 25 years in the petrochemical industry to rank various materials for use in sour environments (Ref 99). However, acceptance has not been sufficient to generate the interest for standardization.

Testing in sodium chloride solution constitutes a worst-case determination for high-strength steels; as such, it is generally considered unrealistically aggressive for the useful ranking of steels in service environments that do not contain hydrogen sulfide or other conditions favoring entry of hydrogen. Tests are usually performed in water containing about 3.5% sodium chloride, artificial seawater, natural seawater (rarely), or a marine atmosphere (Ref 4), unless specific environmental conditions are under study. ASTM G 44 (Ref 8) is used where applicable.

In salt water and freshwater, a true threshold K_{ISCC} exists for high-strength steels that is useful for characterizing resistance to SCC. Ideally, K_{ISCC} defines the combination of applied stress and defect size below which SCC will not occur under static loading conditions in a given alloy and environment system. However, the reported value of K_{ISCC} for a given system often reflects the initial K_I level and the exposure time associated with the testing. Table 6 illustrates the risk of overestimating K_{ISCC} by terminating the exposure test too soon when using the SCC initiation method (Ref 23, 24). A similar risk exists in tests conducted with the arrest method. Table 7 shows that K_{ISCC} values determined by the initiation and arrest methods may be the same when testing times are sufficiently long and when compatible criteria are used for establishing the threshold (Ref 24).

Table 6 Influence of cutoff time on apparent K_{ISCC} using the SCC initiation method

Exposure time, h	Apparent K_{ISCC}	
	MPa $\sqrt{m}$	**ksi $\sqrt{in.}$**
100	187	170
1000	127	110
10,000	28	25

Note: The initiation method was used on a constant-load cantilever bend specimen (*K*-increasing) of alloy steel with a yield strength of 1240 MPa (180 ksi). Test environment was synthetic seawater at room temperature.

Source: Ref 24

Table 7 Comparison of K_{ISCC} values determined by initiation and arrest methods

Steel alloy	K_{ISCC}, MPa $\sqrt{m}$ (ksi $\sqrt{in.}$)	
	Initiation	**Arrest**
10Ni, normal purity	24 (22)	26 (24)
10Ni, high purity	59 (54)	57 (52)
18Ni, normal purity	22-33 (20-30)	28 (25)
18Ni, high purity	<33 (<30)	<33 (<30)

Note: Based on a crack growth rate of 2.5 × 10^{-4} mm/h (10^{-5} in./h). Modified compact specimens: constant load for initiation and wedge-loaded with a bolt for arrest. Test environment: salt water at room temperature.

Source: Ref 24

Figure 52 illustrates a method used to compare various high-strength steels (Ref 4, 100). Data were obtained in salt water or seawater, and K_{ISCC} values are plotted versus yield strength. Envelopes are used to enclose all known valid data for the various steels. The crosshatched envelopes or individual data points represent the featured steels, which allows comparison with characteristics of the other steels. The straight lines in Fig. 52 illustrate how K_{ISCC} values relate to the maximum depth of long surface flaws that can be tolerated without stress-corrosion crack growth.

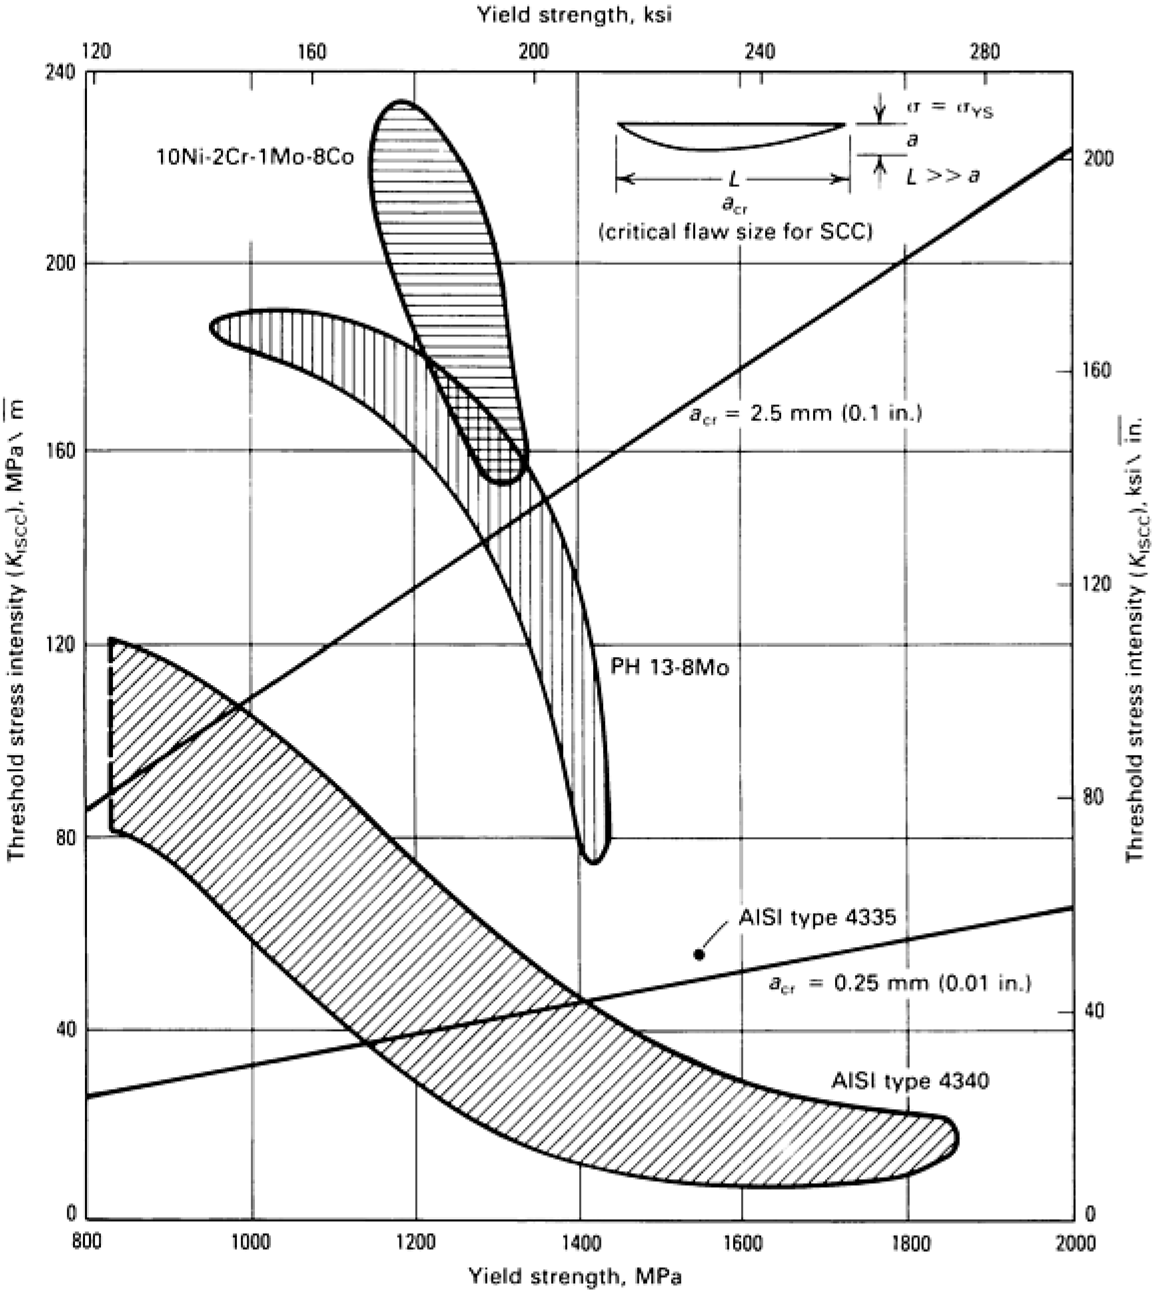

Fig. 52 Comparison of SCC behavior of several high-strength steels based on threshold stress intensity (K_{ISCC}) values in salt water. Source: Ref 100

Electrochemical Polarization. Although the mechanism of cracking in hydrogen sulfide environments is predominantly one of hydrogen embrittlement, the mechanism of environmentally induced failures in environments not containing sulfides or other promoters of hydrogen entry is not clearly agreed upon (Ref 97). Time to failure in a sodium chloride solution depends on the corrosion potential (Ref 4, 101), which determines whether failure results from active path corrosion or hydrogen embrittlement cracking. Electrochemical studies have shown that embrittlement of high-strength steels by corrosion product hydrogen occurs when, for a given environment, the electrochemical potential of the metal is equal to or more anodic than the reversible hydrogen potential, that is, for thermodynamic conditions that favor the deposition of hydrogen on the surface of the steel.

Figure 53 compares the various types of cracking behavior that can be expected from electrochemical polarization (Ref 102). All of the curves except curve G were obtained experimentally. Curve A represents the case in which only hydrogen embrittlement is obtained; curve B shows only active path corrosion. Both processes are shown in curves C and D.

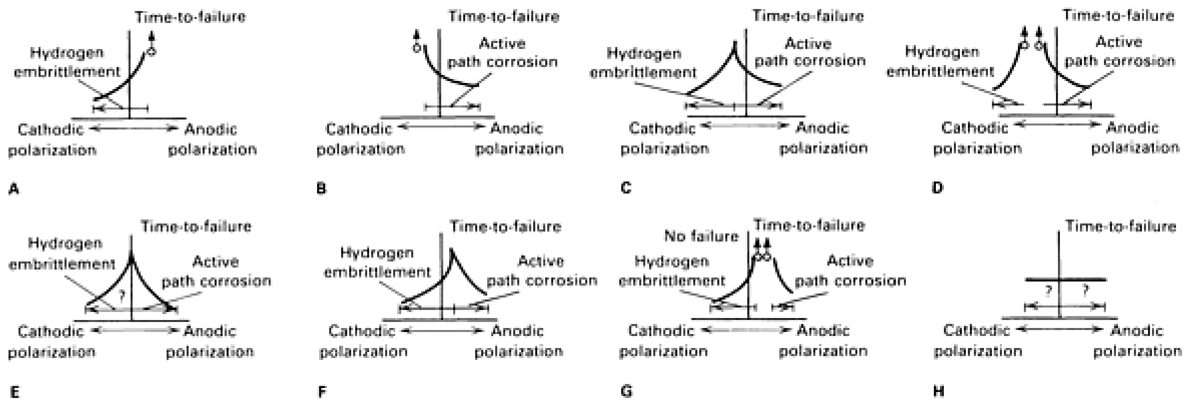

Fig. 53 Use of electrochemical polarization to distinguish between SCC and hydrogen embrittlement mechanisms in a high-strength steel immersed in sodium chloride solution. See text for explanation of curves A through H. Source: Ref 102

When both anodic and cathodic polarization shorten the cracking time, as in curve E, it is not possible to determine which mechanism prevails without applied current. Curves F and G can be expected in acid solutions when the corrosion potential is anodic to the reversible hydrogen potential.

In curve H, neither anodic nor cathodic polarization has any effect on cracking time. Therefore, it is possible that a hydrogen embrittlement mechanism is involved. However, the mechanism by which hydrogen enters the steels is not electrochemical. To perform realistic accelerated tests, the end use of the material and the environmental conditions involved should be considered so that the test procedure involves the appropriate cracking mechanism. It should be noted that hydrogen embrittlement cracking can also occur as a result of galvanic action between the test specimen and components of the stressing system. In all SCC testing, therefore, all electrical contact between the specimen and ancillary fixtures must be avoided, except when galvanic effects are desired.

Testing of Nonheat-Treatable Stainless Steels

The environments causing SCC that are encountered in the chemical industry are specific and are limited primarily to chloride and caustic solutions at elevated temperatures and sulfide environments at ambient temperatures. In seawater at or near room temperature, austenitic (iron-chromium-nickel) and ferritic (iron-chromium) steels do not experience SCC. Fully ferritic stainless steels are highly resistant to SCC in chloride and caustic environments that cause austenitic stainless steels to crack. However, laboratory studies have shown small additions of nickel or copper to ferritic steels may render them susceptible to SCC in severe environments (Ref 4).

Testing in Boiling Magnesium Chloride Solution. ASTM G 36 (Ref 8) is applicable to wrought, cast, and welded austenitic stainless steels and related nickel-base alloys. This method determines the effects of composition, heat treatment, surface finish, microstructure, and stress on the susceptibility of these materials to chloride SCC. Although this

test can be performed with various concentrations of magnesium chloride, ASTM G 36 specifies a test solution maintained at a constant boiling temperature of 155.0 ± 1.0 °C (311.0 ± 1.8 °F), that is, approximately 45% magnesium chloride. Also described is a test apparatus capable of maintaining solution concentration and temperature within the recommended limits for extended periods of time. Typical exposure times are up to 1000 h. However, historically, most of the SCC data on austenitic stainless steels were obtained by using a boiling 42% $MgCl_2$ solution (boiling point: 154 °C, or 309 °F). For this reason, much current testing is still done at the lower concentration.

Most chloride cracking testing has been carried out in accelerated test media such as boiling magnesium chloride (Ref 4, 103, 104). All austenitic stainless steels are susceptible to chloride cracking as shown in Fig. 54. It is noteworthy, however, that the higher-nickel types 310 and 314 were appreciably more resistant than the others (Fig. 55). Although this solution causes rapid cracking, it does not necessarily simulate the cracking observed in field applications.

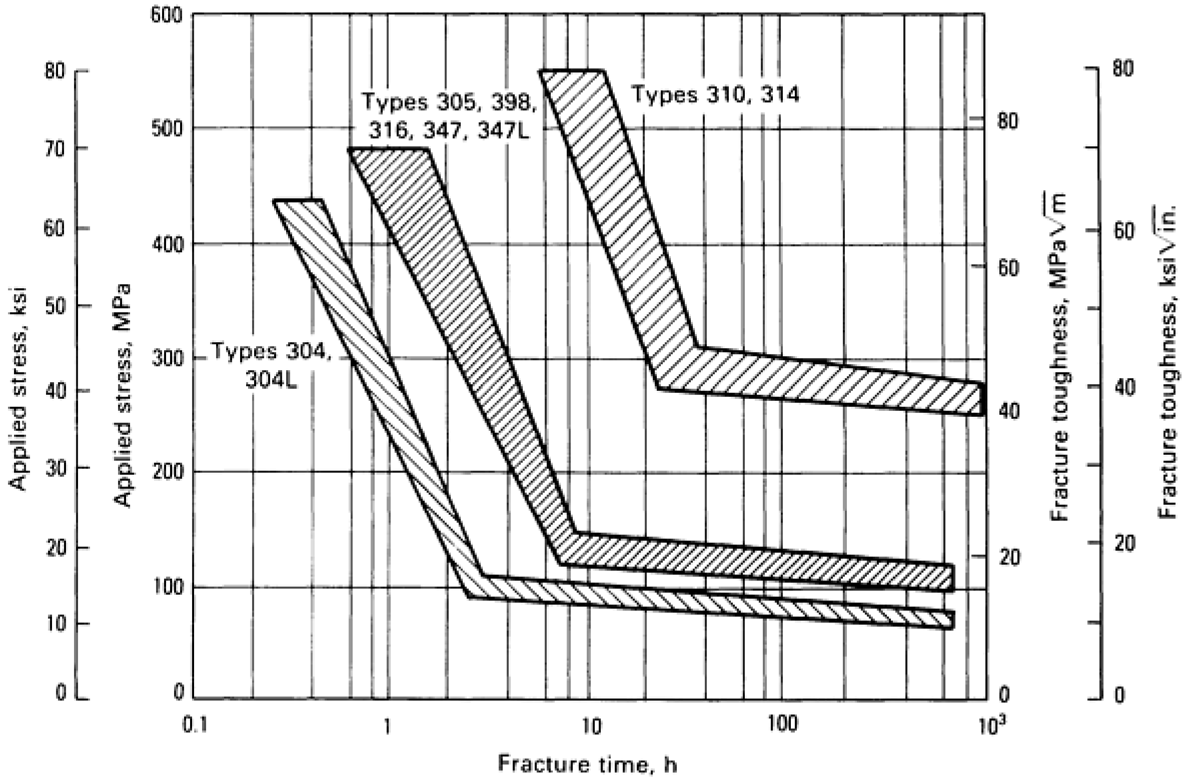

Fig. 54 Relative SCC behavior of austenitic stainless steels in boiling magnesium chloride. Source: Ref 105

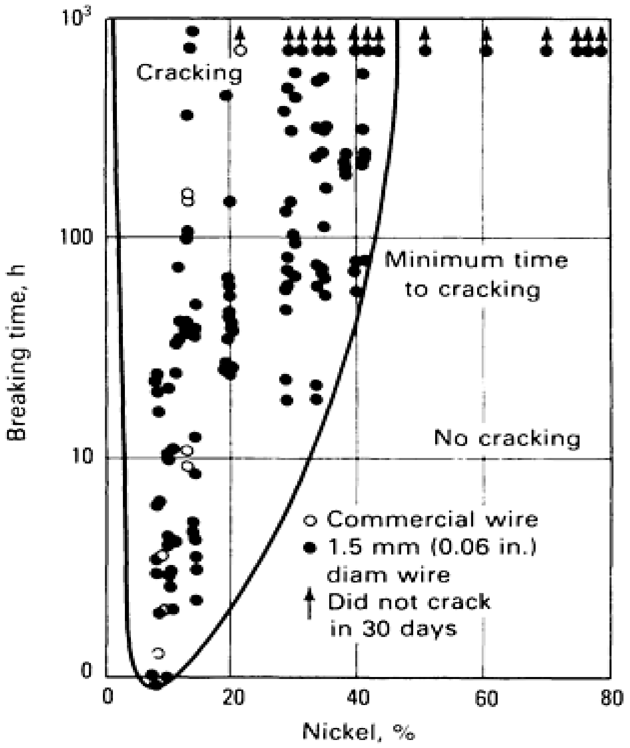

Fig. 55 Effect of nickel additions to a 17 to 24% Cr steel on resistance to SCC in boiling 42% magnesium chloride. 1.5-mm (0.06-in.) diam wire specimens dead-weight loaded to 228 or 310 MPa (33 or 45 ksi). Source: Ref 106

Other ions in addition to chloride can cause cracking. Of all halogen ions, chlorides cause the most cases of SCC in austenitic stainless steels. Known cases of fluoride and bromide SCC are few, and iodide is not known to produce SCC. In addition, cations, such as Li^+, Ca^{2+}, Zn^{2+}, NH_4^+, Ni^{2+}, and Na^+, affect test results to varying degrees (Ref 107). Although chloride SCC occurs primarily at temperatures above about 90 °C (190 °F), acidified chloride solutions can produce SCC at low temperatures (Ref 107, 108, 109). Therefore, in diagnosing service failures, it is necessary to establish which ions (and other environmental and stress conditions as well) have caused the failure. In this manner, an appropriate test procedure can be designed for the evaluation of alternative materials.

Reference 110 discusses laboratory reproduction of an environment that caused SCC at the top of a distillation tower in a crude oil refinery. The service environment consisted of a very dilute hydrochloric acid solution (36 ppm chloride) with a pH of 3 saturated with hydrogen sulfide gas at 80 °C (175 °F). In this test environment, austenitic stainless steels, such as type 304 or 316 failed, but the ferritic types 430 and type 434 did not.

Testing in Polythionic Acids. Petrochemical refinery equipment is subject to polythionic acid cracking, which may occur after shutdown. Polythionic acid forms by the decomposition of sulfides on metal walls in the presence of oxygen and water. ASTM G 35 (Ref 8) describes procedures for preparing and conducting exposures to polythionic acids ($H_2S_nO_6$, where n is usually 2 to 5) at room temperature to determine the relative susceptibility of sensitized stainless steels or related materials (high nickel-chromium-iron alloys) to intergranular SCC.

This test method can be used to evaluate stainless steels or other materials in the as-received condition or after high-temperature service (480 to 815 °C, or 900 to 1500 °F) for prolonged periods of time. Wrought products, castings, and weldments of stainless steels or other related materials used in environments containing sulfur or sulfides can also be evaluated. Other materials that are capable of being sensitized can also be tested.

A variety of smooth SCC test specimens, surface finishes, and methods of applying stress can be used. Stressed specimens are immersed in the polythionic acid solution, which can be prepared by passing a slow current of hydrogen sulfide gas for 1 h through a fritted glass tube into a flask containing chilled (0 °C, or 32 °F) 6% sulfurous acid, after

which the liquid is kept in a stoppered flask for 48 h at room temperature. Solutions can also be prepared by passing a slow current of sulfur dioxide gas through a fritted glass bubbler submerged in a container of distilled water at room temperature. This is continued until the solution becomes saturated. The hydrogen sulfide gas is then slowly bubbled into the sulfurous acid solution.

Prior to use, the polythionic acid solution should be filtered to remove elemental sulfur and then tested for acid content. This can be done by analytical tests or by using a control test specimen of sensitized type 302 stainless steel. The control should fail by cracking in less than 1 h.

The wick test can be used to evaluate the chloride cracking characteristics of thermal insulation for applications in the chemical process industry. ASTM C 692 (Ref 8) covers the methodology and apparatus used to conduct this procedure. When a dilute aqueous solution is transmitted to a metal surface by capillary action through an absorbent fibrous material, the process is called wicking. Cracking occurs at much lower temperatures when alternate wetting and drying is used than when the specimens are kept wet continuously.

Other Testing Media. Hot concentrated caustic solutions are another type of environment encountered in chemical industries that causes SCC of stainless steels. However, the conditions leading to caustic cracking are more restrictive than those leading to chloride cracking, and caustic environments have not received the attention that chlorides have. There is little difference in the susceptibilities among types 304, 304L, 316, 316L, 347, and USS 18-18-2 austenitic steels. All of these alloys crack rapidly in solutions of 10 to 50% sodium hydroxide at 150 to 370 °C (300 to 700 °F) (Ref 4, 104, 111).

Certain strong acid solutions containing chlorides, such as 5 *N* sulfuric acid plus 0.5 *N* sodium chloride, 3 *N* perchloric acid plus 0.5 *N* sodium chloride, and 0.5 *N* to 1.0 *N* hydrochloric acid, are capable of causing SCC in austenitic stainless steels at room temperature (Ref 4). Cracking in these environments is similar to the type of cracking that occurs in hot chloride environments.

Electrochemical Polarization. Stress-corrosion cracking in austenitic and ferritic stainless steels can be delayed or prevented by the application of cathodic current: however, if ferritic steels are overprotected by relatively large cathodic current, they are apt to blister or crack due to the hydrogen discharged by the cathodic protection action. Anodic polarization significantly accelerates the initiation of SCC, but appears to have a smaller accelerating effect on crack propagation (Ref 112).

Testing of Magnesium Alloys

There is no standard accelerated test environment recommended for assessing the susceptibility of magnesium-base alloys to SCC. Exposure of stressed specimens to the atmosphere has generally been used to determine the SCC susceptibility of specific products.

The chloride-containing solutions typically used in accelerated tests for aluminum alloys are unsatisfactory for SCC tests of magnesium alloys because of excessive general corrosion. In one investigation, a chromate-inhibited chloride solution (35 g/L sodium chloride plus 20 g/L potassium chromate; pH 8) was found to be suitable for testing magnesium alloys (Ref 113). Good correlation was observed between the SCC behavior of magnesium-aluminum-zinc alloys exposed by total immersion in this solution and the behavior of the same alloys exposed to an industrial atmosphere. Cracking of highly stressed susceptible alloys occurs within a few hours, but exposures can be continued up to 1000 h without incurring excessive pitting. Laboratory tests also have been conducted using potassium hydrogen fluoride and a dilute solution of sodium chloride plus sodium bicarbonate as the test medium (Ref 114).

Testing of Nickel Alloys

Nickel-base alloys are highly resistant to the chloride SCC that affects stainless steels. Iron-chromium-nickel alloys with nickel contents greater than 50% are immune to cracking in boiling 42% magnesium chloride (Fig. 55). However, SCC of nickel and high-nickel alloys has been experienced in high-temperature caustic soda and caustic potash solutions and in molten caustic.

Cracking of some nickel-base alloys has also occurred under special conditions in fluosilicic acid, hydrofluoric acid, mercuric salt solutions, and high-temperature water and steam that are contaminated with trace amounts of oxygen, lead,

fluorides, or chlorides (Ref 103, 106, 115). Sensitized alloys are susceptible to SCC in sulfur compounds such as sodium sulfite, sodium thiosulfate, and polythionic acids.

The standard test environments that are most frequently used for high-nickel alloys are the same as those employed for stainless steels. In a study of sulfur-induced SCC of sensitized Inconel alloy 600 steam generator tubing in water contaminated by air and sodium thiosulfate at temperatures from 22 to 95 °C (72 to 203 °F), a solution of 0.1 *M* sodium tetrathionate with a pH of 3.5 to 4.0 at 22 °C (72 °F) appeared to be an excellent test medium for sensitization in nickel alloys and stainless steels. Slow strain rate testing was also found to be more effective than tests with statically loaded U-bend specimens (Ref 116).

Slow strain rate testing was also effective for evaluating several nickel- and cobalt-base alloys in hot chloride and hot caustic solutions. The average length of secondary stress-corrosion cracks, as determined by metallographic examination, appeared to be a more appropriate parameter for quantifying the severity of SCC behavior than loss in ductility or loss in fracture strength parameters; this is illustrated in Table 8 for Hastelloy alloy C-276. However, when using slow strain rate testing methods, care must be taken not to confuse stress-assisted localized corrosion with SCC (Ref 117).

Table 8 Results of slow strain rate tests on Hastelloy alloy C-276

Alloy condition	Strain rate, s^{-1}	Environment	Reduction in area, %	Ultimate tensile strength		Time to failure, h	Average length of secondary stress-corrosion cracks
				MPa	**ksi**		
Mill annealed	3.4×10^{-6}	Air	71	745	108	60	0
	3.4×10^{-6}	50% sodium hydroxide, 147 °C (297 °F)	61	593	86	52	13×10^{-5} m (5 mils)
50% cold swaged	3.4×10^{-6}	Air	49	1524	221	17	0
	3.4×10^{-6}	50% sodium hydroxide, 147 °C (297 °F)	51	1503	218	18	$<1 \times 10^{-5}$ m (<0.1 mil); no obvious SCC
	9×10^{-7}	Air	53	1558	226	29	0
	9×10^{-7}	50% sodium hydroxide, 147 °C (297 °F)	47	1524	221	30	2.5 × 10 m (1 mil)
	5.3×10^{-7}	Air	51	1593	231	51	0
	5.3×10^{-7}	50% sodium hydroxide, 147 °C (297 °F)	47	1565	227	60	4.8×10^{-5} m (1.9 mils)

Testing of Titanium Alloys

Although titanium alloys are not susceptible to SCC in either boiling 42% magnesium chloride or boiling 10% sodium hydroxide solutions, which are commonly used to study SCC in stainless steels, the susceptibility of titanium and its alloys to SCC has been demonstrated in several environments. This information is given in Table 9.

Table 9 Environments and temperatures conducive to SCC of titanium alloys

Environment	Temperature, °C (°F)
Hot dry chloride salts	260-480 °C (500-900 °F)
Seawater, distilled water, and aqueous solutions	Ambient
Nitric acid, red fuming	Ambient
Nitrogen tetroxide	Ambient to 75 °C (165 °F)
Methanol, ethanol	Ambient
Chlorine	Elevated
Hydrogen chloride	Elevated
Hydrochloric, acid, 10%	Ambient to 40 °C (105 °F)
Trichloroethylene	Elevated
Trichlorofluoroethane	Elevated
Chlorinated diphenyl	Elevated

Testing in a Hot Salt Environment. The hot salt test consists of exposing a stressed salt-coated test specimen to an elevated temperature for various predetermined lengths of time. The exposure periods are determined by the alloy, stress level, temperature, and selected damage criterion (that is, embrittlement, cracking, or rupture, or a combination of these phenomena). Exposures are typically carried out in laboratory ovens or furnaces equipped with loading equipment for stressing specimens. Environmental conditions, the degree of control required, and the means for obtaining control are described in ASTM G 41 (Ref 8).

This test method can be used to test all metals if service conditions warrant. The test limits maximum operating temperatures and stress levels, or it categorizes different alloys according to their susceptibility if hot salt damage has been found to accelerate failure by creep, fatigue, or rupture. Although limited evidence relates this phenomenon to actual service failures, cracking under stress in a hot salt environment is a potential design-controlling factor.

The hot salt test should not be construed as being related to the SCC of materials in other environments. It should be used only in an environment that may be encountered in service.

Hot salt testing can be used for alloy screening to determine the relative susceptibility of metals to embrittlement and cracking and to determine the time-temperature-stress threshold levels for the onset of embrittlement and cracking. However, certain types of specimens are more suitable for each of these types of characterizations. Precracked specimens are unsuitable for testing of titanium alloys, because cracking reinitiates at salt/metal/air interfaces and results in many small cracks that extend independently. Therefore, smooth specimens are recommended.

Testing in Water and Aqueous Solutions. Water, seawater, and almost any neutral aqueous solution (except atmospheric water vapor) can cause SCC in many titanium alloys in the presence of preexisting cracklike flaws, although susceptibility in these environments cannot be detected by smooth specimens. Therefore, fracture mechanics type characterizations are necessary. For titanium alloys, the extremely rapid growth of stress-corrosion cracks in salt water and the dependency on specimen geometry preclude the possibility of using crack growth rate data for design purposes.

Therefore, ranking of materials must be based on K_{ISCC} values, and a true threshold stress intensity for SCC apparently does exist (Ref 118). Titanium alloys do not exhibit stage I type crack growth kinetics (Fig. 3) in neutral aqueous solutions. Tests have been performed for sufficient periods of time to allow detection of crack growth rates of 10^{-9} m/s (1.4×10^{-4} in./h), but SCC has not been observed. The slowest crack velocity that has been detected is 10^{-8} m/s (1.4×10^{-3} in./h). Therefore, in neutral aqueous solutions, a threshold K_{ISCC} exists at which SCC will not propagate (Ref 4, 118). The above rates, however, are not as slow as those observed in high-susceptibility aluminum alloys (Fig. 46). Tests are commonly performed in water containing about 3.5% sodium chloride, artificial seawater, or natural seawater unless specific environments are being tested.

Electrochemical Polarization. The halide ions (chloride, bromide, and iodide) are SCC agents unique for titanium alloys in aqueous solutions at room temperature. The crack initiation load and velocity are controlled by the applied potential, as illustrated for the crack initiation load in Fig. 56. At potentials more negative than about -700 to -1400 mV, depending on the solution, specimens were cathodically protected. Sodium fluoride solution and solutions of the other anions that do not produce SCC (hydroxide, sulfide, sulfate, nitrite, nitrate, perchlorate, cyanide, and thiocyanate) yielded results at all potentials in the same scatterband as the air values.

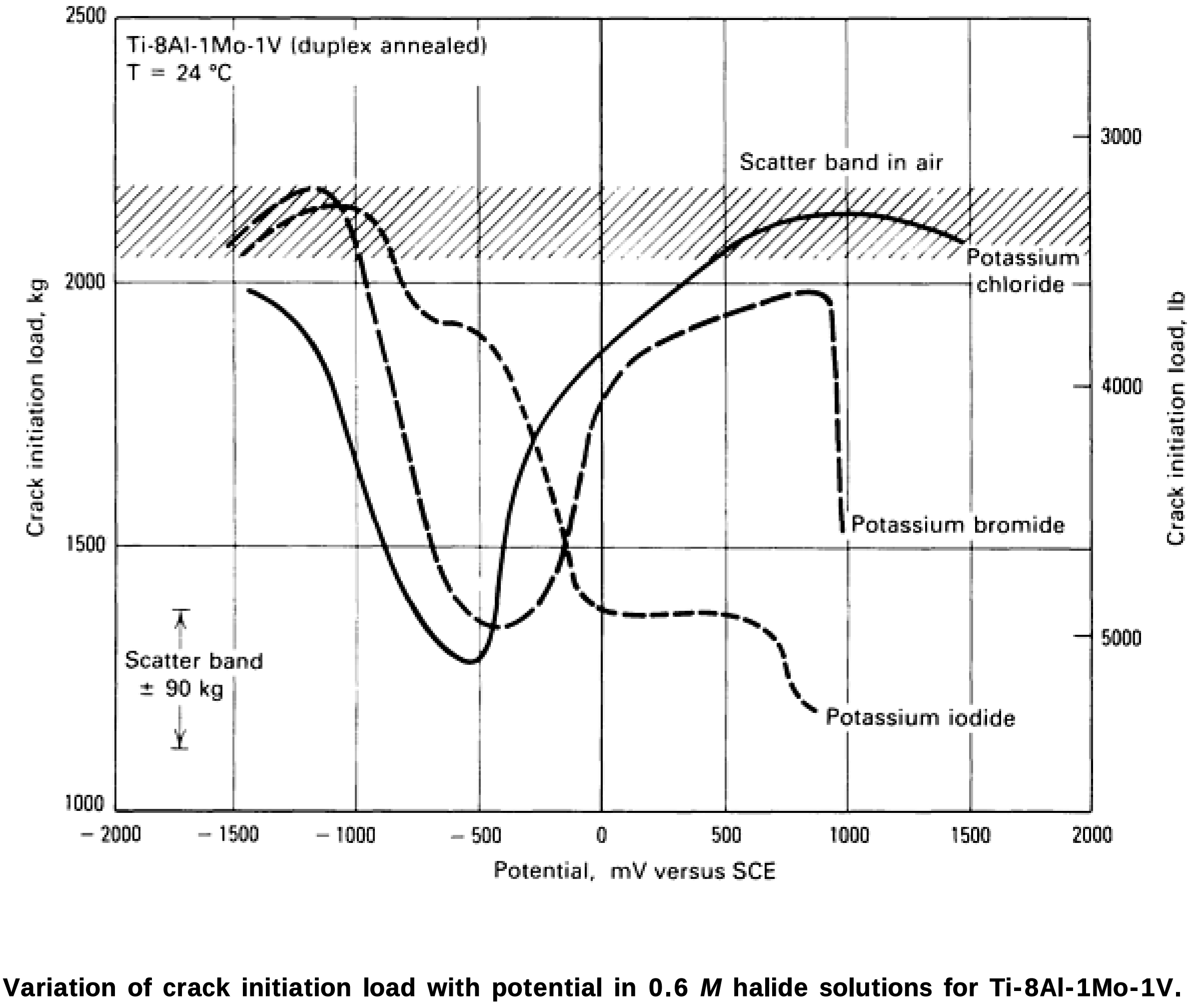

Fig. 56 Variation of crack initiation load with potential in 0.6 *M* halide solutions for Ti-8Al-1Mo-1V. Specimen: single-edge cracked sheet that was tension loaded by constant displacement. Source: Ref 118, 119

At potentials more positive than the above values, susceptibility in varying degrees occurred in the chloride, bromide, and iodide solutions. The width of the critical potential range and the potential for maximum susceptibility varies with the anion. A region of anodic protection occurred in the chloride and bromide solutions, but not in the iodide solution.

Crack propagation can be halted by switching the potential to either the anodic or cathodic protection zone. The corrosion potential of titanium alloys in 3.5% sodium chloride and seawater--about -800 mV versus SCE--is similar (slightly more negative) to the potential at which SCC susceptibility reaches a maximum (Ref 118).

Testing in Organic Fluids. A wide variety of organic fluids can cause SCC in some titanium alloys under specific test conditions (Table 9). Most of these fluids attack the passive surface film that is characteristic of titanium alloy products. Consequently, precracked specimens do not have to be used to accelerate the SCC initiation. A standard environment does not exist; test conditions must be selected with appropriate consideration given to the type of environmental service required.

Sustained-Load Cracking in Inert Environments. High-strength titanium alloys for use in highly stressed components for military aircraft and other similar applications may be susceptible to sustained-load cracking in inert environments (including dry air). Sustained-load cracking is similar to SCC except that it is much slower and occurs in the total absence of a reactive environment. Sustained-load cracking is caused by, or is greatly aggravated by, hydrogen dissolved in the titanium during processing. Vacuum annealing can reduce the hydrogen level to less than 10 ppm, at which concentration the tendency toward sustained-load cracking is greatly reduced (Ref 4, 120).

Figure 57 illustrates an example of sustained-load cracking in mill-annealed plate of Ti-8Al-1Mo-1V containing 48 ppm hydrogen. As shown in Fig. 57, the threshold stress intensity factor for sustained-load cracking in dry air is designated K_{IH} because it is attributed to hydrogen in the metal. When the hydrogen concentration was reduced to 2 ppm by vacuum annealing, the K_{IH} value was increased to equal the inherent plane-strain fracture toughness, K_{Ic}. However, the K_{ISCC} value was not affected (Ref 121). Therefore, in addition to the practical importance of sustained-load cracking, its potential contribution to cracking should be taken into account when evaluating environmental effects, particularly in mechanistic studies.

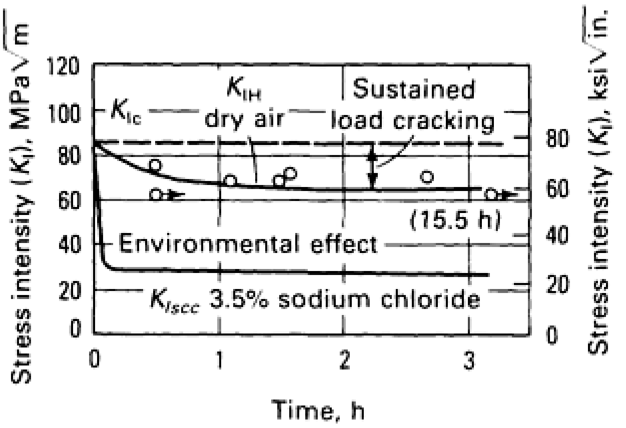

Fig. 57 Effect of sustained-load cracking compared to SCC in Ti-8Al-1Mo-1V mill-annealed sheet. Hydrogen concentration, 48 ppm; yield strength, 850 MPa (123 ksi); cantilever bend specimen (T-S); *B* = 6.35 mm (0.25 in.). See Fig. 28 for an explanation of specimen orientation and fracture plane identification. Source: Ref 121

Special Considerations for Testing of Weldments

ASTM G 58 (Ref 8) covers test specimens in which stresses are developed by the welding process only (that is, residual stress, Fig. 23), an externally applied load in addition to the stresses due to welding (Fig. 7e), and an externally applied load only, with residual welding stresses removed by annealing.

The National Materials Advisory Board Committee on Environmentally Assisted Cracking Test Methods for High-Strength Weldments recently published the following guidelines on SCC testing of weldments (Ref 24). Fracture mechanics of cracked bodies was found to be a valid and useful approach for designing against environmentally assisted cracking, although several limitations and difficulties must be taken into consideration. For static loading, K_{ISCC} and da/dt

versus K_I are useful parameters. They are specified to a material, temperature, and metal/environment system and are functions of local chemical composition, microstructure, and so on.

Superimposed minor load fluctuations and infrequent changes in load can alter environmental cracking response. This effect, which cannot be predicted from K_{ISCC} and da/dt values, may be significant and detrimental. Reexamination of static loading as a design premise may be required. Existing test methodology or environmentally assisted cracking tendency is applicable to the evaluation of weldments. As in other structural components, residual stress must be treated in a quantitative and realistic manner.

The National Materials Advisory Board report supports current design emphasis based on the presumption of preexisting cracklike flaws in the structure and covers testing with precracked (fracture mechanics) specimens only. It contains a critical assessment of the problems associated with environmentally assisted cracking in high-strength alloys and of state-of-the-art design and test methodology.

Surface Preparation of Smooth Specimens

The pronounced effect of surface conditions on the time required to initiate SCC in test specimens is well known (Ref 5). Unless the as-fabricated surface is being studied, the final surface preparation generally preferred is a mechanical process followed by degreasing. However, chemical etches or electrochemical polishes can be used to remove heat-treating films or thin layers of surface metal that may have become distorted during machining.

Care should be exercised to select an etchant that will not selectively attack constituents or phases in the metal and that will not deposit undesirable residues on the surface. Etching or pickling should not be used with alloys that are susceptible to hydrogen embrittlement.

Precautions should be taken when machining specimens to avoid overheating, plastic deformation, or the development of residual stress in the metal surface. Machining should be performed in stages so that the final cut leaves the principal surface with a clean finish of 0.7 μm (30 μin.) rms or smoother. The required machining sequences, types of tools, and feed rate depend on the alloy and metallurgical condition of the testpiece. Lapping, mechanical polishing, and similar operations that produce flow of the metal should be avoided.

Interpretation of Test Results

This is the most fallible part of SCC testing and evaluation; it includes the analysis that leads to the conclusions and recommendations. Stress-corrosion test data are at best imprecise and test dependent, and they must be qualified with the testing conditions. It is important to verify the mode of environmental cracking (Fig. 1) and then to review the data to exclude all extraneous results, as discussed previously with the individual test methods. Following are some comments on the nature of the test dependency of the most commonly used criteria of SCC behavior.

Criteria of SCC Behavior

Specimen Life (Time to Failure). Stress-corrosion testing frequently involves determining the lives of specimens under specific test conditions. This includes the initiation (or incubation) of a stress-corrosion crack and its propagation to the point of fracture (Fig. 2). Such a determination is easily accomplished when only a single crack forms and the specimen fractures within the chosen test period. However, it often happens that SCC occurs but the specimen does not fracture. This is especially likely when testing relatively low-strength materials by constant strain loading (Fig. 5b) and when testing at applied stress or stress intensity levels only slightly above the threshold (Fig. 29a). Cracks may initiate at multiple sites in constant-strain loaded smooth specimens with relatively low applied stress, and a difficult problem arises in deciding when to consider a specimen failed if it does not fracture visibly.

It is often found that the majority of specimens in a set of replicates in a test fail rapidly; this leaves a few specimens that fail at much longer times or do not fail at all before the test is discontinued. Such behavior presents difficulties, both theoretical and practical, in deciding when to terminate a test, choosing a satisfactory representative value, and comparing such values.

The arithmetic mean specimen life is widely used for smooth specimens because it can be manipulated algebraically and can be used in many standard statistical tests of significance. It should be remembered, however, that extremely large or extremely small values may cause the mean to be atypical of the true distribution. Moreover, in using the arithmetic

mean, it is assumed that the population is normally or very nearly normally distributed. The median, on the other hand, has the advantages that it is influenced less by extreme values, requires no assumption about the population distribution, and can be obtained much faster than arithmetic mean values because only about half the number of replicates exposed need to be tested to failure. The median is used in a German specification (Ref 19) that also provides for the use of the geometric mean if the replication is small.

References 1 and 122 contain examples for highly susceptible steel and aluminum alloys, respectively; these examples demonstrate the normal distributions for the logarithms of the specimen lives. With such distributions, a geometric mean would be the best representative value of the specimen life. It has also been shown that a Weibull distribution can be appropriate for the non-normally distributed test data for a relatively resistant aluminum alloy (Ref 123). Thus, it should not be assumed that any one distribution is applicable for all testing situations.

Comparisons of alloys with differing strength and fracture toughness based on time to failure can be completely misleading. For example, SCC growth curves are illustrated schematically in Fig. 58 for alloys with different fracture toughnesses. Curves A, B, and C represent materials with decreasing toughness, with curve C showing fast fracture initiated by corrosion pits or fissures with no SCC.

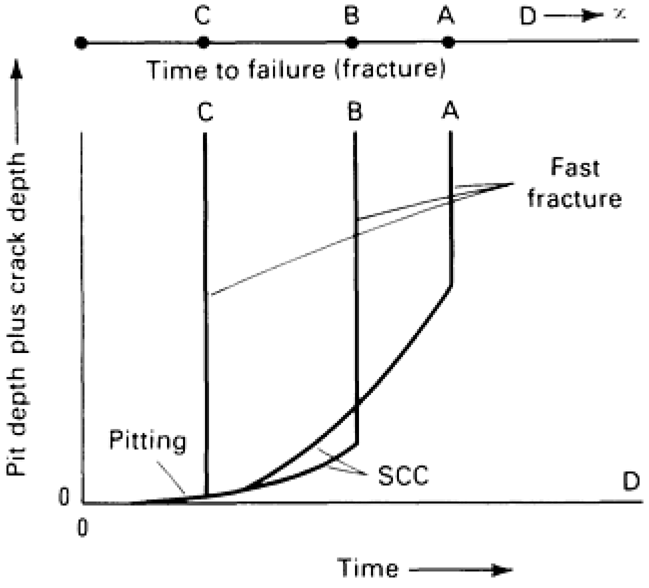

Fig. 58 Various processes in SCC as influenced by the fracture toughness of the metal. Kinetics for pitting (or, in material D, nonpitting), SCC (materials A and B only), and fast fracture. Line at top illustrates how time to failure data can be misleading. Source: Ref 124

The behavior of a material that does not develop localized pitting or intergranular attack is represented by a line coincident with the abscissa, designated D in Fig. 58. The time-to-failure ranking above the graph indicates D as best and A, B, and C as poorest. Actually, the SCC responses of C and D were not measured, and the true SCC ranking of A and B (indicated by depth of SCC at the time of fracture) exhibits a trend opposite to that inferred from the time to failure data above.

Further difficulties may arise, because the total time to fracture is also influenced by non-SCC factors. such as specimen type and size, method of loading, initial stress level, and initiation behavior of the alloy. Consequently, the SCC ranking of materials may vary among investigators using different testing techniques. Nevertheless, comparisons of specimen lives derived from smooth specimens can be useful in certain mechanistic studies and in tests for comparing environmental variations if the mechanical aspects of the investigation are held constant.

Threshold Stress (Stress-Time Curve). More information about the resistance to SCC of a material can be obtained when testing smooth specimens by using a range of applied stresses. Such data are usually presented graphically with the applied gross section stress plotted against specimen life (Fig. 54). The primary interest is generally in the long-life portion of the curve to obtain an estimate of the threshold stress.

A common method of estimating threshold stress involves the experimental determination of the lowest stress at which cracking occurs in at least one specimen and the highest stress at which cracking does not occur in several specimens (for example, three or more, depending on variability). An average of the lowest failure and highest no-failure stresses is usually taken as the threshold stress. Such determinations of critical stresses are carried out at specified test times that are known through experience or preliminary tests to be sufficient to produce SCC in the alloy-environment system of interest. Statistical methods are available for determining threshold stresses more precisely (for example, the Probit method or staircase method) and are commonly used for the determination of fatigue limits. However, the additional testing involved can be quite extensive.

Apparent threshold stresses determined in laboratory tests of coupon specimens are useful for ranking the SCC susceptibility of various materials, but, because such data are dependent on test conditions, they are not realistic for the purpose of engineering design (Ref 4). Also, when using such data as an aid in selecting the material for a specific structure, caution should be exercised in trying to relate the laboratory test conditions to the anticipated service conditions. Not only the environmental condition but also the geometry and size of the test specimens and the method of stressing should be compared (Fig. 6, 17). Further, threshold stresses obtained with statically loaded smooth specimens are likely to be nonconservative; it has been shown in tests on carbon-manganese steel that the threshold stress obtained by static loads is reduced by applied constant slow strain rates and that it can be reduced even further with cyclic loading (Ref 49). With appropriate frequency, load change, and temperature, average creep rates can be sustained over extended periods, but with static loading, the creep rate may fall below the level needed to promote SCC. In general, experimentally determined threshold stresses for materials with only limited susceptibility to SCC are more sensitive to variations in testing conditions than in the case of highly susceptible materials.

Percent Survival (Curve). This method of analyzing stress corrosion test results is especially useful when some of the specimens in a group survive the duration of the test. Examples of various comparisons by this technique are shown in Fig. 17, 42, and 43. Although the curves can be drawn on regular coordinate graph paper, the percent survival values will often lie along a straight line when plotted on normal probability paper, as illustrated in Fig. 59. The linearity of this plot indicates that the statistical distribution of the test results is logarithmic-normal. The vertical positions of the lines indicate the cracking ability of the environment, which can be represented by median cracking times. The slopes of the lines correspond to the variance, which can be used to calculate confidence limits.

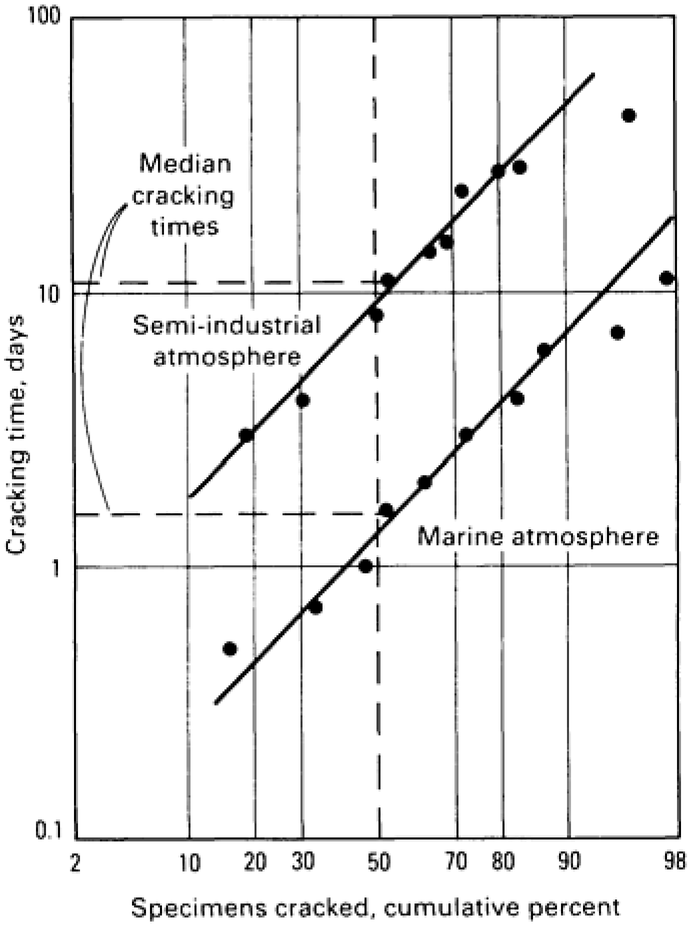

Fig. 59 Distribution of SCC test results for a stainless steel. Source: Ref 1, 125

Threshold Stress Intensity (K_{ISCC}, K_{th}). Linear elastic fracture mechanics is well established as a basis for materials characterization, including environmental cracking (Ref 24, 126, 127). In practice, it is most practical to define K_{ISCC} as the K_I level associated with some generally acceptable and definably low rate of crack growth that is commensurate with the design service life. When K_{ISCC} values are reported, the criterion for their assessment and the exposure time in the environment must accompany the threshold values. A rational approach to the development of useful data for design is to establish an operational definition of K_{ISCC} that is appropriate for the structure under consideration.

Such characterization requires that linear elastic fracture mechanics and plane-strain conditions be satisfied. However, for certain low-strength steels and aluminum alloys, existing data show that SCC can occur under conditions that deviate substantially from plane-strain, and that SCC is by no means limited to or is most severe under plane-strain loading conditions (Ref 24, 36, 128, 129). In these cases, the application of linear elastic fracture mechanics is no longer valid, and the parameter K_{ISCC} is no longer meaningful. Similarly, when testing materials with a high resistance to SCC, loading to high percentages of K_{Ic} may cause a relaxation of stress due to creep. In this case also, the apparent K_{ISCC} values are meaningless. Constant-load tests, therefore, are preferred for lower strength materials (Ref 130).

The symbol K_{th} has been used to identify threshold stress intensity factors developed under test conditions that do not satisfy all the requirements for plane-strain stress. Design calculations using such values should not be employed unless it is clear that the laboratory tests exhibit the same stress state as that for the intended application. Nevertheless, properly determined K_{th} values can be useful for ranking materials.

In principle, experimentally determined K_{ISCC} values should be the same whether they are determined by the initiation or the arrest test method (Fig. 29). In both tests, there are dimensional requirements for ensuring that the test results are independent of geometrical effects (see the section "Preparation of Precracked Specimens" in this article). However, precautions must be exercised during testing to avoid the potential problems involved with the environmental exposure

(incubation, corrosion product) wedging, crack branching, crack tip blunting, and so on). Comparisons of K_{ISCC} values determined for selected steels by both methods, along with examples of overestimated values resulting from insufficient length of exposure, are shown in Tables 6 and 7. It is advisable, when practicable, to use a test that matches the type of loading encountered in the anticipated service.

From the parameter K_{ISCC}, a value of a_{cr} can be calculated using the relation $a_{cr} = 0.2\ (K_{ISCC}/\text{TYS})^2$ (see the section "Static Loading of Precracked (Fracture Mechanics) Specimens" in this article). This is the shallowest crack (surface length is long compared to its depth) that will propagate as a stress-corrosion crack at a yield strength level of gross stress under the given environmental conditions. This can be a very useful parameter for comparing materials, especially when the measured a_{cr} values can be related to the capability of the flaw inspection system used for a given engineering structure (Fig. 52). Straight lines representing assumed values of a_{cr} in Fig. 52 illustrate how K_{ISCC} values for the various steel alloys relate to the maximum depth of long surface flaws that can be tolerated without growth of SCC.

Such a plot can be used as follows. If the inspection system to be used can detect all long surface flaws deeper than 0.25 mm (0.01 in.), then the materials engineer would select an alloy with a K_{ISCC} above the 0.25-mm (0.01-in.) line. Conversely, if the K_{ISCC} and tensile yield strength of a material are known, the equation can be used to estimate the maximum tolerable flaw size. Substitution of an anticipated design stress in terms of percentage of tensile yield strength in the formula for a_{cr} will generate a new series of a_{cr} lines of lower slope.

Alternatively, the following method, which is specific for a given loading method, can be used, inasmuch as the flaw depth and applied stress are uniquely related for a specific loading situation, a family of curves for constant K_{th} values can be developed within these parameters. Figure 60 shows such curves for long, shallow flaws; the curves were generated according to the following equations (Ref 132, 133, 134);

$$K_I = M_B\, \sigma \sqrt{\frac{\pi a}{Q}} \quad \textbf{(Eq 16)}$$

$$M_B = \frac{Y}{6} \sqrt{\frac{t}{\pi a}} \quad \textbf{(Eq 17)}$$

$$Y = \sqrt{139\left(\frac{a}{t}\right) - 221\left(\frac{a}{t}\right)^2 + 783\left(\frac{a}{t}\right)^3} \quad \textbf{(Eq 18)}$$

where K_I is stress intensity, σ is applied stress, a is flaw depth, Q is a shape parameter, and t is thickness. When K_{th} is substituted into Eq 16 and a flaw shape is assumed (Q = 0.8), this parameter is related to the flaw size and the applied stress. In this representation, SCC growth will not occur below the curve for the appropriate K_{th}. For example, for a steel with K_{th} of 60.5 MPa$\sqrt{\text{m}}$ (55 ksi$\sqrt{\text{in.}}$), a very deep flaw (6 mm. or 0.25 in.) would be required to cause crack propagation in hydrogen gas of a steel component stressed to 360 MPa (52 ksi) in bending. Such representations are useful for relating test data and K_{th} in design and in the development of crack inspection requirements, as well as for ranking alloys.

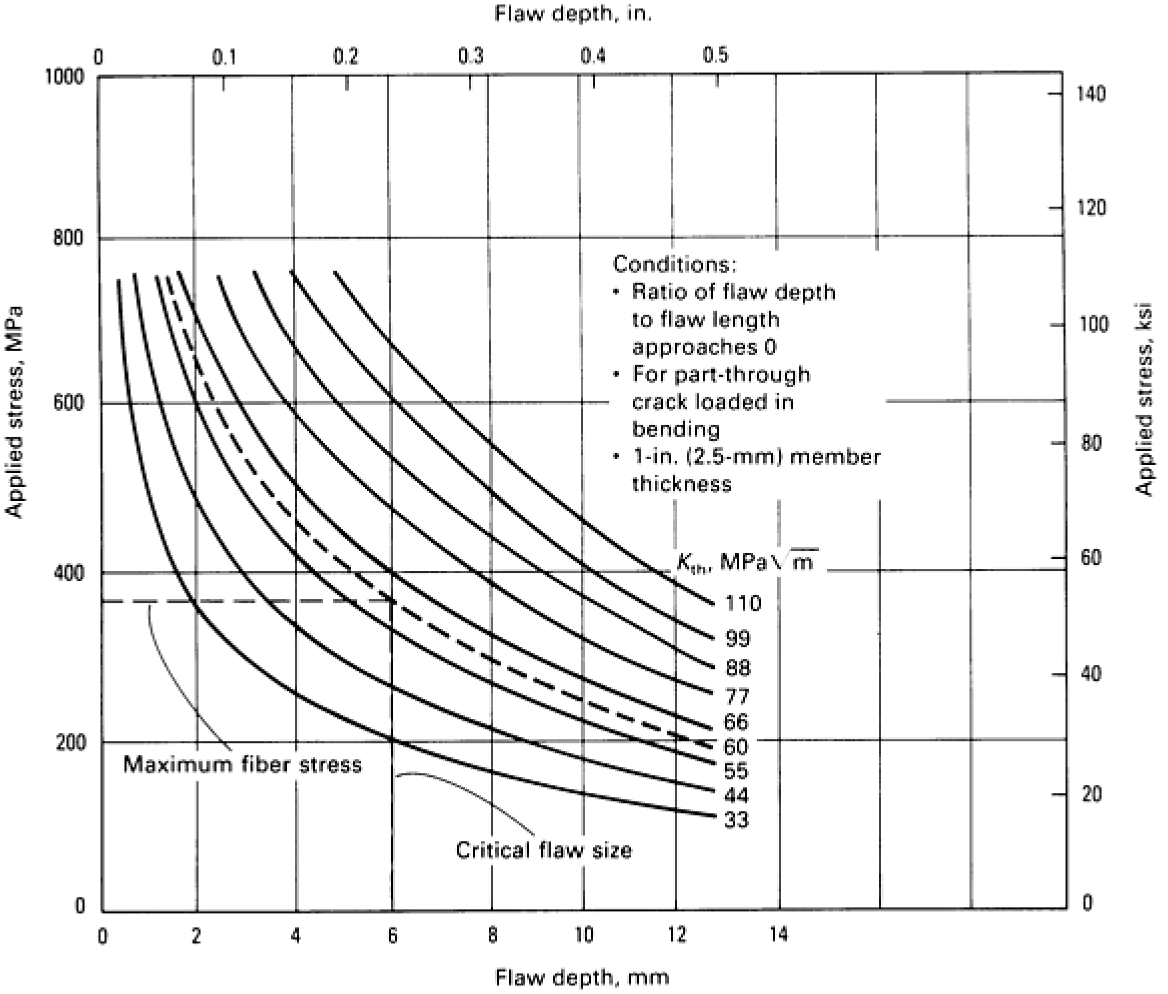

Fig. 60 Relationship of applied stress and flaw depth to crack propagation in hydrogen gas. Dashed lines show an example of the use of such a chart for a steel with K_{th} of 60.5 MPa$\sqrt{m}$ (55 ksi$\sqrt{in.}$) at an operating stress of 359 MPa (52 ksi). Source: Ref 131

The requirements for K_{ISCC} tests, as well as for other fracture mechanics tests, include very explicit criteria regarding the minimum crack length for ensuring that the test results can be analyzed properly using existing linear fracture mechanics concepts. Therefore, a typical K_{ISCC} test uses a relatively large starting crack of the order of 25 mm (1 in.) long in a 25-mm (1-in.) thick specimen. In many types of service, however, initial defects of this size are rare. For example, damage-tolerant design criteria for military aircraft specify a flaw size of the order of 1.27 mm (0.05 in.) as the initial worst-case damage assumption upon introduction of a new part into service (Ref 126). Experimental work on high-strength steels exposed to hydrogen sulfide gas indicates that for a given combination of materials and applied stress there may indeed be a defect size below which the direct applicability of linear elastic fracture mechanics is questionable (Ref 135). Because of their susceptibility to SCC, however, high-strength steels should not be contemplated for service in the presence of hydrogen sulfide.

For example, Fig. 61 represents a concept of combining SCC thresholds based on smooth specimen and linear elastic fracture mechanics tests of aluminum alloy plate to give a conservative estimate of materials for design. As shown in Fig. 61, the threshold stress intensity analysis breaks down in the small flaw region (ABE) when the smooth specimen threshold stress is exceeded. Therefore, the definition of a safe zone requires results from both types of tests; the exclusive use of either one of the test methods can yield nonconservative conclusions. It is anticipated that application and further development of elastic-plastic fracture mechanics theory will lead to improved estimates of critical stress/flaw size combinations for the onset of SCC and tensile fracture, as proposed in Fig. 62.

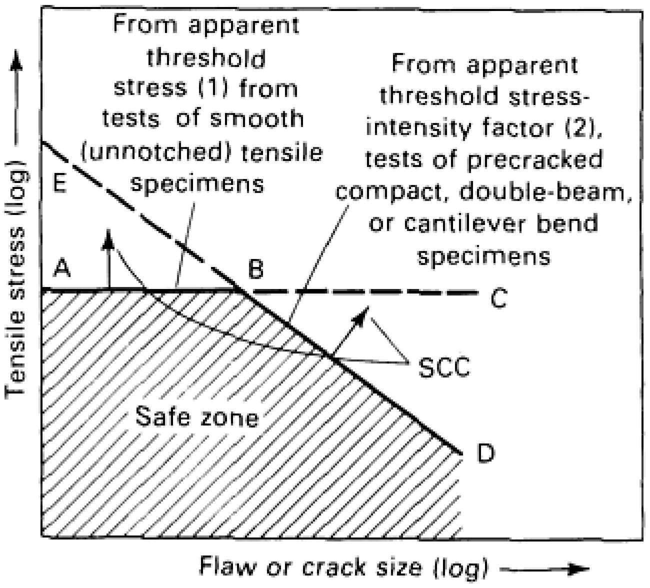

Fig. 61 Concept for combining SCC thresholds obtained on smooth and linear elastic fracture mechanics specimens to yield a conservative assessment of materials. (1) Minimum stress at which small tensile specimens fail by SCC when stressed in environment of interest. (2) Minimum stress intensity at which significant stress-corrosion crack growth occurs in environment of interest. Source: Ref 136

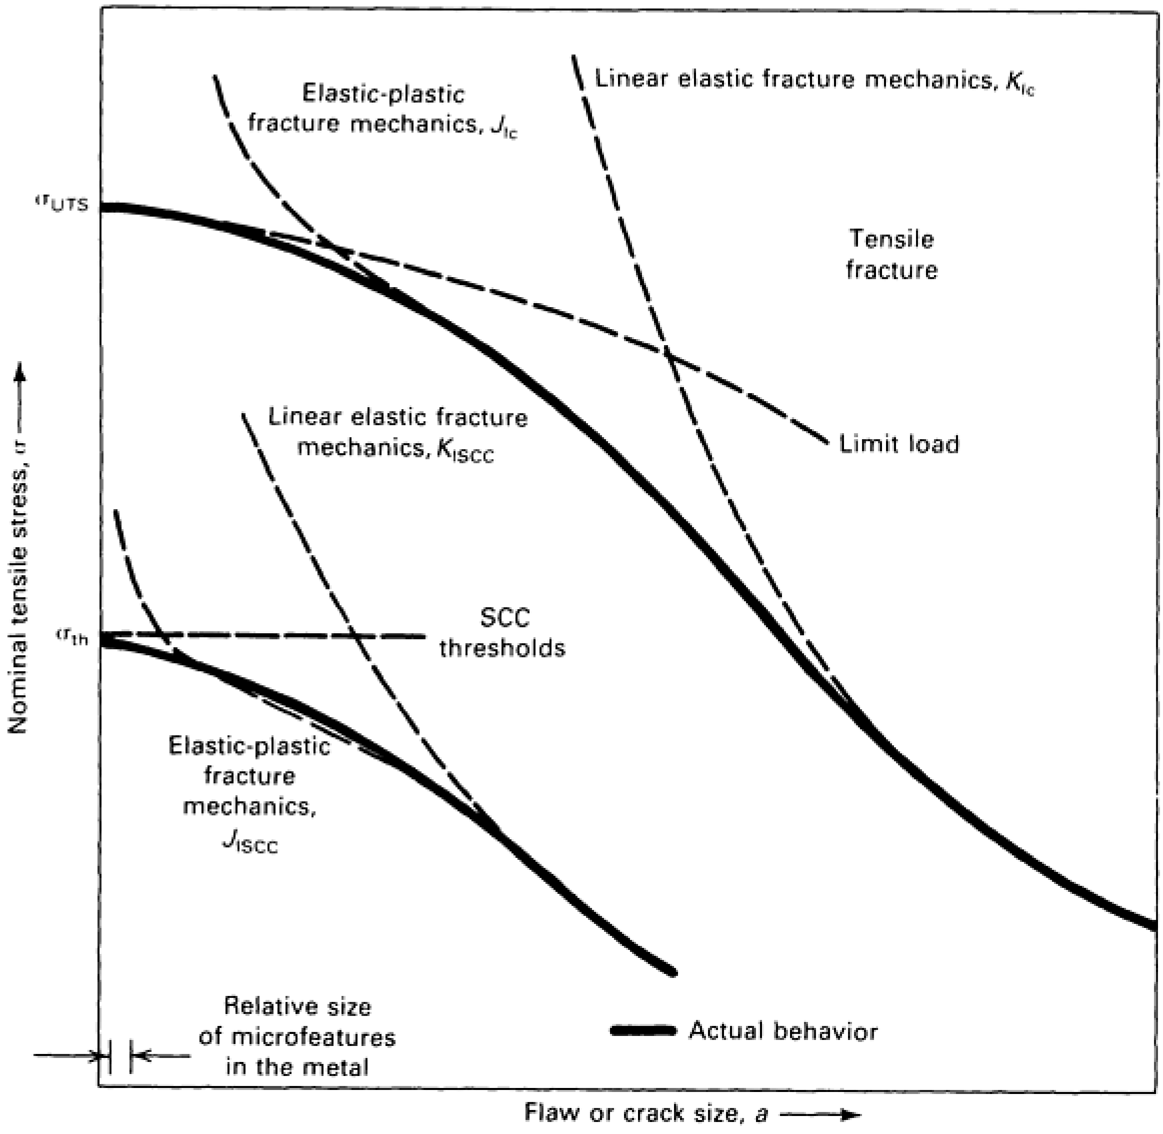

Fig. 62 Proposed linear elastic and elastic-plastic models for describing critical combinations of stress and flaw size at SCC thresholds and at the onset of rapid tensile fracture. Source: Ref 3

SCC Velocity (*V*-K_I Curves). The issues of crack initiation and crack growth must be addressed for proper consideration of SCC response (Fig. 2). The use of mechanically precracked specimens provides a convenient approach for kinetic measurements where the crack growth rate can be determined as a function of the crack-tip stress intensity factor (Fig. 3). Current emphasis, however, is on the identification of a steady-state response (plateau velocity) for the ranking of materials (Fig. 46). A disadvantage of this approach is that in some testing situations a plateau velocity is not observed (Fig. 63). However, for design purposes, the phenomena of incubation and the non-steady state response (Stage 1, Fig. 3) must also be taken into account. However, these latter requirements are not well understood.

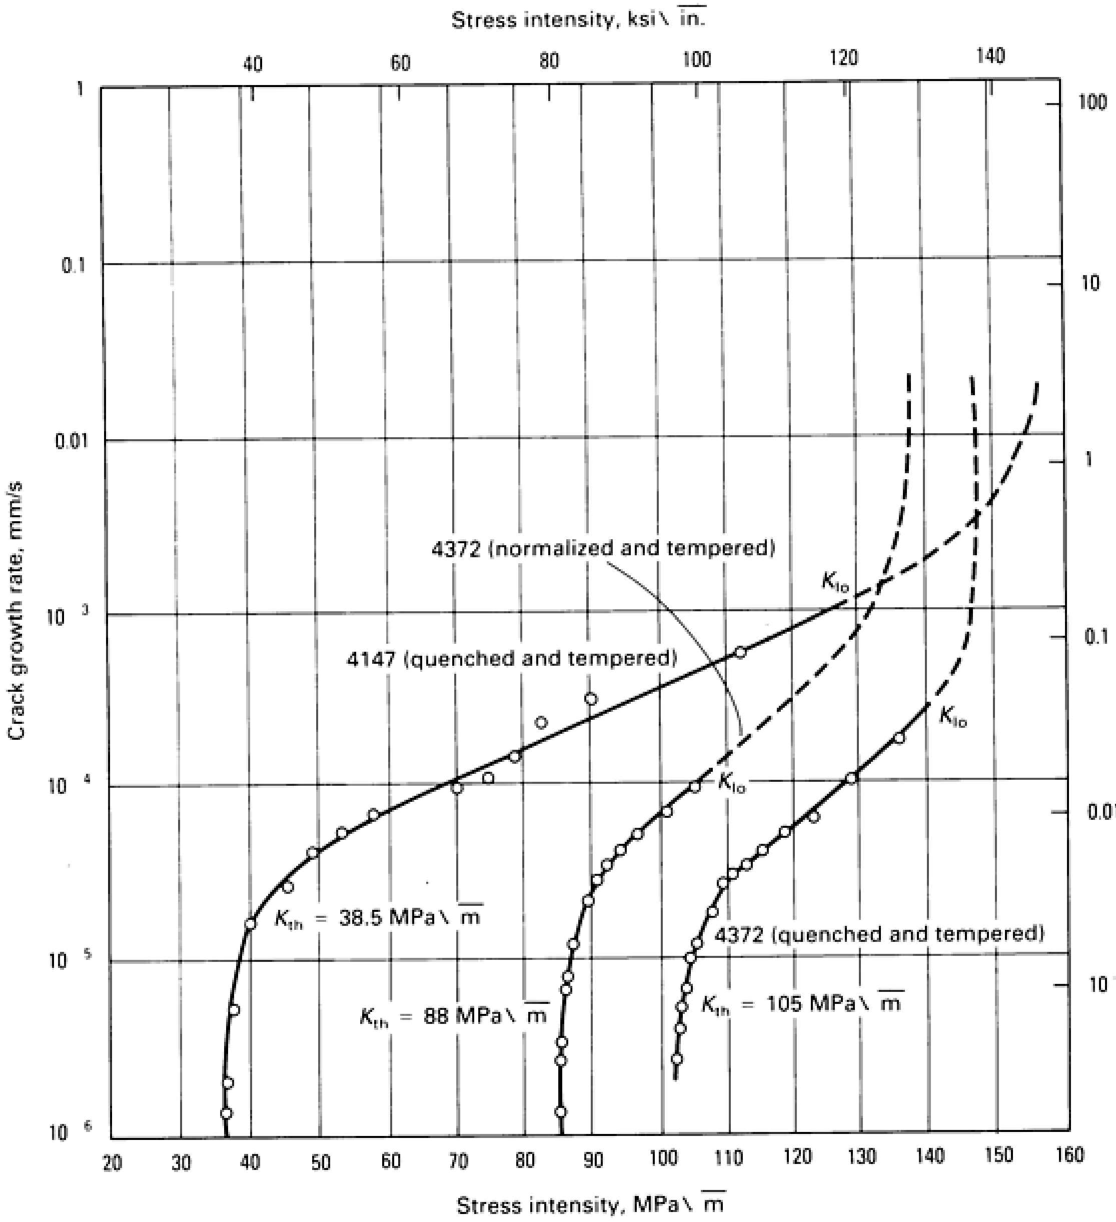

Fig. 63 Crack growth kinetics of three steels in hydrogen at 21 MPa (3000 psi). Source: Ref 131

An approximate approach to this problem of involving both the time of incubation (initiation) and the maximum crack growth rate of SCC at high stress intensities (plateau velocity) was proposed earlier in this article for use with testing of aluminum alloys with constant crack opening displacement tests (Fig. 45 and Table 4). This involves a simple average rate taken from time zero to a judiciously chosen test duration. Useful ranking of materials can be displayed on V-K_I diagrams such as that shown in Fig. 48.

Another approach to the average velocity concept is available through an elastic-plastic fracture mechanics interpretation of breaking load test data obtained from stress corrosion tests of smooth tension specimens (Ref 17). The stress-corrosion crack growth rates estimated from the slopes of the curves in Fig. 16 from 0 to 4 or 6 days are shown in Table 10 to agree reasonably well with the plateau (*K*-independent) growth rates determined from conventional fracture mechanics tests using bolt-loaded double-beam specimens. It is also noteworthy that a distinction between the intermediate resistance T7X1 temper and the nearly immune T7X2 temper was made more readily using either the smooth specimen test or the average crack growth over 42 days with the double-beam specimen. Fractographic examination confirmed that this was a correct distinction.

Table 10 Stress-corrosion crack growth rates in aluminum alloy 7075 obtained by different test methods

Test method	Stress-corrosion crack growth rate					
	7075-T651		7075-T7X1		7075-T7X2	
	m/s	in. × 10^{-5}/h	m/s	in. × 10^{-5}/h	m/s	in. × 10^{-5}/h
Breaking load test using smooth tensile bar stressed 207 MPa (30 ksi); 4 or 6 days	>3.8 × 10^{-9}	>54[(a)]	7 × 10^{-10}	10[(b)]	1.3 × 10^{-10}	2[(b)]
Bolt-loaded double-beam, pop-in stress; plateau velocity obtained from V-K_I curves	3.1 × 10^{-9}	44	7.5 × 10^{-10}	11	[(c)]	
Bolt-loaded double-beam, pop-in stress; average growth 0-15 days	3.4 × 10^{-9}	48	4 × 10^{-10}	6	4 × 10^{-10}	6
Bolt-loaded double beam, pop-in stress; average growth 0-42 days	2.8 × 10^{-9}	40	4 × 10^{-10}	6	2 × 10^{-10}	3

Source: Ref 3

(a) Over 4 days.

(b) Over 6 days.

(c) No plausible estimate could be made, because of the slight crack growth.

The implication here, which needs further investigation, is that from a single test method it is possible to compare materials (1) on the basis of their probabilities of initiating and propagating SCC flaws to an arbitrary depth or (2) by their respective crack growth rates, both being meaningful engineering descriptors of SCC damage. An additional advantage to this approach is that the effects of specimen size and alloy strength and toughness can be normalized (Fig. 16).

Ductility Ratio (DR versus Strain Rate Curves). Various ratio criteria, such as reduction of area, elongation, fracture stress, fracture energy, and time to failure, have been found to be useful in environmental studies with the slow strain rate test method. However, such criteria have limited use in comparing various materials because of their dependence on the strength and toughness of the alloy and the specificity of the critical strain rate and the environmental species (Fig. 33 and Table 2). Recent work has shown that average SCC growth rates, threshold stresses, and threshold strain rates can be obtained with modified techniques combined with microscopy. (Ref 50, 55, 56).

Other Criteria. Several other more specialized criteria can be found in the literature, such as:

- The Jones Stress Corrosion Index (Ref 70, 137)
- Critical Strain (Ref 99)
- Mean Critical Stress (Ref 138)

Precision of SCC Data

Variability in the measured values for SCC behavior arises from three primary sources: uncertainties associated with the measurement methods, variation in the test materials, and variation in the test environment. Suitable investigations must minimize the contributions from the first source and allow for quantitative assessment of the latter.

In the production of sophisticated high-strength and high-toughness alloys, close metallurgical control of the fabricating and thermal treatments is necessary to ensure that the required mechanical properties satisfy specifications. It is equally important from the standpoint of SCC that the metallurgical condition of the alloy be properly controlled. Just as there is a range of applicable mechanical properties for a given alloy and metallurgical condition (temper), a range in the SCC behavior can be expected from one heat (or lot) to another. Also, there can be an appreciable variation in the behavior of different-size mill products of the same material. An example of the variations in the SCC behavior of different lots and various mill products is shown in Fig. 48 for aluminum alloy 7050. When selecting a material for a particular structural component SCC tests should be made on the specific products and sizes that will be required. Costly mistakes have been made in the past in the evaluation of prototype structures by testing parts fabricated from different products for economic expediency.

It is an unfortunate circumstance that the precision of SCC test results is generally lower for materials with an intermediate resistance to SCC than for materials with a very low or a very high resistance. This presents a special challenge in the comparison of competitive materials with improved resistance to SCC. Unfortunately, there is a scarcity of test data for determining what portion of the scatter-bands shown in Fig. 48 is due to material variations and how much is due to the precision of the test measurements.

Variability can occur even in carefully controlled investigations. Reference 139 reports results of measurements of K_{ISCC} for a 4340 steel made in numerous laboratories by different test methods.

In another investigation, the precision in the measurement of plateau velocities was determined for a number of replicate bolt-loaded double-beam specimens of short-transverse orientation from a sample of 25-mm (1-in.) thick 7075-T651 aluminum alloy plate (Ref 140). Tension pop-in specimens were exposed by continuous immersion in aqueous solutions of 1 *M* sodium chloride and 1 *M* sodium perchlorate. For six tests in the chloride solution, the mean plateau velocity was 1.4×10^{-8} m/s (1×10^{-3} in./h) with a standard deviation of 0.2×10^{-8} m/s (0.1×10^{-3} in./h), and the range was 1 to 2×10^{-8} m/s (7×10^{-4} to 1.4×10^{-3} in./h) (±35%). For nine tests in the perchlorate solution, the mean plateau velocity was 8×10^{-9} m/s (6×10^{-4} in./h) with a standard deviation of 0.2×10^{-9} m/s (1.4×10^{-4} in./h), and the range was 5×10^{-9} to 1×10^{-8} m/s (4 to 8×10^{-4} in./h) (±31%).

Normalizing SCC Data

It is often necessary to normalize test results with respect to one of the mechanical properties of critical interest for a given engineering structure in order to place the SCC response in proper perspective. This is commonly done by expressing the exposure stress (or stress intensity) and the apparent threshold values in terms of percent yield strength (or percent critical stress intensity) rather than in absolute units. This process can sometimes result in a different ranking order of alloys, and controversy can arise over which ranking is more pertinent. The use of normalized data is usually most appropriate when the utmost resistance to SCC is required; that is, the material should be resistant even when stressed to nearly 100% of the normalizing property. For alloy development screening tests, consideration should be given to evaluating materials in both ways.

Predicting Service Life

Life predictions are difficult and should be made with caution because there are no workable mathematical models. The field is plagued with confusion created to a large extent by:

- The complex, multifaceted nature of the phenomenon, which involves metallurgy, mechanics, chemistry, and time
- The large number of variables known to affect SCC behavior
- Relatively poor correlation between laboratory test results and service experience
- Extensive data scatter
- Difficulty in assessing precisely the service conditions that the part must withstand

Designing to avoid SCC has traditionally taken the approach of preventing the initiation of SCC (safe-life concept). There is considerable service experience to justify this; one factor is that the materials that have given the most service problems are capable of developing relatively high SCC propagation rates (of the order of 25 mm, or 1 in., per month as shown in Fig. 46). Growth rates of this order, combined with relatively low thresholds of stress or stress intensity, make the fail-safe concept rather impractical. However, with the availability of advanced materials with higher thresholds for initiation of SCC and lower propagation rates, the damage-tolerant concept of design may become more practical for SCC and corrosion fatigue.

Selection of Test Method

The SCC test method selected should not be so severe that it rejects a material that is adequate for a particular application; on the other hand, the test should not be so mild that it passes materials that will fail in service. For tests of new and unfamiliar materials or environments, it is expedient to perform more than one type of test. Although standardized tests, which can be specified for screening tests in alloy or process development or quality control, are an essential link between research and engineering, there is a need for much freer choice of test conditions for research studies of SCC mechanisms.

The appropriate SCC test method is the one that is best adapted to test the material product form to be evaluated and the one that will yield the type of test results that best address the test objective(s). The newer methods that use fracture mechanics type specimens and loading by means of a constant slow strain rate are more severe, when applicable, than the older techniques that use smooth (defect-free) specimens. However, the results of all tests require interpretation. The application of linear elastic fracture mechanics has opened the way to the correlation of the mechanical aspects of SCC test methods. It is anticipated that further development of the science of elastic-plastic fracture mechanics will enhance the application of test data to service needs.

Evaluation of Hydrogen Embrittlement

Louis Raymond, L. Raymond & Associates

Introduction

HYDROGEN EMBRITTLEMENT of metals is an old, frequently encountered, and often misunderstood phenomenon. It is most commonly thought to occur by subcritical crack growth, often producing time-delayed fractures in production parts with no externally applied stress. Many problems still exists, starting with a basic definition of hydrogen embrittlement, in addition to identifying its source, controlling its effects, and preventing its occurrence.

This wide range of problems makes the evaluation of hydrogen embrittlement a multifaceted technical activity. Additional information on the mechanism of hydrogen embrittlement and susceptibility of a variety of ferrous and nonferrous alloys to hydrogen damage can be found in the section "Hydrogen Damage" in the article "Environmentally Induced Cracking" in this Volume.

Research investigations on the phenomenon range from studies of crack nucleation and growth, including such parameters as incubation time, crack growth rates, and threshold stress intensities, to studies on the relative susceptibility of materials to hydrogen embrittlement.

Toward a Definition (Ref 1)

Much confusion exists in the published literature over the definition of hydrogen embrittlement. Metal processing, chemical, and petrochemical industries have experienced various types of hydrogen problems for many years. The aerospace industry has experienced new and unexpected hydrogen embrittlement problems, principally in dealing with high-strength steels. There are many sources of hydrogen, several types of embrittlement, and various theories for explaining the observed effects.

Hydrogen embrittlement is often classified into three types:

- Internal reversible hydrogen embrittlement
- Hydrogen environment embrittlement
- Hydrogen reaction embrittlement

If specimens have been precharged with hydrogen from any source or in any manner and embrittlement is observed during mechanical testing, then embrittlement is caused by either internal reversible embrittlement or by hydrogen reaction embrittlement. If hydrides or other new phases containing hydrogen form during testing in gaseous hydrogen, then embrittlement is attributed to hydrogen reaction embrittlement. For all embrittlement determined during mechanical testing in gaseous hydrogen other than internal reversible and hydrogen reaction embrittlement, hydrogen environment embrittlement is assumed to be responsible.

Internal reversible hydrogen embrittlement has also been termed slow strain rate embrittlement and delayed failure. This is the classical type of hydrogen embrittlement that has been studied quite extensively. Widespread attention has been focused on the problem resulting from electroplating, particularly of cadmium in high-strength steel components. Other sources of hydrogen are processing treatments, such as melting and pickling. More recently, the embrittling effects of many stress-corrosion processes have been attributed to corrosion-produced hydrogen. Hydrogen that is absorbed from any source is diffusible within the metal lattice. To be fully reversible, embrittlement must occur without the hydrogen undergoing any type of chemical reaction after it has been absorbed within the lattice.

Internal reversible hydrogen embrittlement can occur after a very small average concentration of hydrogen has been absorbed from the environment. However, local concentrations of hydrogen are substantially greater than average bulk values. For steels, embrittlement is usually most severe at room temperature during either delayed failure or slow strain rate tension testing. This time-dependent nature (incubation period) of embrittlement suggests that diffusion of hydrogen within the lattice controls this type of embrittlement. Cracks initiate internally, usually below the root of a notch at the region of maximum triaxiality. Embrittlement in steel is reversible (ductility can be stored) by relieving the applied stress and aging at room temperature, provided microscopic cracks have not yet initiated. Internal reversible hydrogen embrittlement has also been observed in a wide variety of other materials, including nickel-base alloys and austenitic stainless steels, provided they are severely charged with hydrogen.

Hydrogen environment embrittlement was recognized as a serious problem in the mid-1960s when the National Aeronautics and Space Administration (NASA) and its contractors experienced failure of ground-based hydrogen storage tanks. These tanks were rated for hydrogen at pressures of 35 to 70 MPa (5 to 10 ksi). Consequently, the failures were attributed to high-pressure hydrogen embrittlement. Because of these failures and the anticipated use of hydrogen in advanced rocket and gas turbine engines and auxiliary power units, NASA has initiated both in-house and contractual research. The contractual effort generally has been to define the relative susceptibility of structural alloys to hydrogen environment embrittlement. A substantial amount of research has concerned the mechanism of the embrittlement process. There is marked disagreement as to whether hydrogen environment embrittlement is a form of internal reversible hydrogen embrittlement or is truly a distinct type of embrittlement.

Hydrogen Reaction Embrittlement. Although the sources of hydrogen may be any of those mentioned previously, this type of embrittlement is quite distinct from hydrogen environment embrittlement. Once hydrogen is absorbed, it may react near the surface of diffuse substantial distances before it reacts. Hydrogen can react with itself, with the matrix, or with a foreign element in the matrix. The chemical reactions that comprise this type of embrittlement or attach are well known and are encountered frequently. The new phases formed by these reactions are usually quite stable and embrittlement is not reversible during room temperature aging treatments.

Atomic hydrogen (H) can react with the matrix or with an alloying element to form a hydride (MH_x). Hydride phase formation can be either spontaneous or strain induced. Atomic hydrogen can react with itself to form molecular hydrogen (H_2). This problem is frequently encountered after steel processing and welding; it has been termed flaking or "fisheyes." Atomic hydrogen can also react with a foreign element in the matrix to form a gas. A principal example is the reaction with carbon in low-alloy steels to form methane (CH_4) bubbles. Another example is the reaction of atomic hydrogen with oxygen in copper to form steam (H_2O) resulting in blistering and a porous metal component.

Although hydrogen reaction embrittlement is not a major topic in this article, its definition is included for the sake of completeness and in the hope of establishing a single definition for each of the various hydrogen embrittlement phenomena to avoid problems with semantics.

Further confusion results from the relation of stress-corrosion cracking (SCC) to hydrogen embrittlement, because the crack growth mechanism is often found to be the same. On the surface, the active corrosion process produces the hydrogen that is the cause of the failure. In SCC, the pits or crevices (polarized anodically) are initiation sites, and therefore, although the growth mechanisms are the same, the method of prevention based on initiation can be different. Detailed information on the mechanisms of SCC and the methods of testing and/or evaluating susceptibility to SCC can

be found in the articles "Environmentally Induced Cracking" (see the section "Stress-Corrosion Cracking") and "Evaluation of Stress-Corrosion Cracking" in this Volume.

Sources of Hydrogen

In contrast to most forms of corrosion, hydrogen embrittlement generally occurs in service when the part is being protected from corrosion or when corrosion on the part is absent, that is, when a high-strength steel is cathodically protected. The corrosion is usually taking place elsewhere (at the anode), but atomic hydrogen is being generated at the surface of the steel (cathode) by the dissociation of water. Failures that occur after a period of time are related to the diffusion of atomic hydrogen into the steel. The fracture path is usually intergranular in steels; however, not all intergranular failures in steels are due to hydrogen embrittlement. In addition, not all hydrogen embrittlement failures in other metals and alloys are intergranular. The effects of hydrogen on the fracture appearance of metals are reviewed and illustrated in the article "Modes of Fracture" in *Fractography,* Volume 12 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Time-delayed embrittlement failures are caused by the residual atomic hydrogen in the steel from the making or melting process and the atomic hydrogen introduced into the steel during processing and subsequent manufacture (for example, plating, machining with hydrocarbon-base oils, pickling, and welding). The atomic, diffusible, or nascent hydrogen (H) is the cause of the problem, not the total hydrogen that includes molecular hydrogen (H_2). Also necessary is applied stress or residual stress from welding or heat treating. Hydrogen embrittlement is generally found in high-strength steels, but hydrogen stress cracking (HSC) has been reported for other materials, such as refractory metals, superalloys, and even austenitic steels, when tested under high-pressure hydrogen gas.

Source of Stress

Cracking studies of high-strength steels in aqueous chloride solutions at a potential exceeding the open-circuit potential of about -0.6 V versus a saturated calomel electrode (SCE) are, in reality, hydrogen embrittlement tests, because the steel is at a cathodic potential; that is, hydrogen is produced at the surface of the steel while under stress. The worst case, or the most severe condition that produces cracking is generated when atomic hydrogen is produced while the part (or test coupon) is under stress. This is the reason hardware is processed (plated) with no stress (except unavoidable manufacturing-induced residual stress) and then stress relieved or baked before the external stress is applied. If residual stress exists during plating, the part could break or at least could have microcracks that subsequently lead to an early service failure.

Hydrogen relief or baking treatments can be effective in removing the atomic hydrogen from the steel; however, this does not ensure that hydrogen is removed from the part. The hydrogen can reside as molecular hydrogen at the interface between the steel part and a plating or coating. Sulfur, in the form of manganese sulfide inclusions commonly found in steel, can act as a poison to dissociate the molecular hydrogen to atomic hydrogen. At the point of high stress, atomic hydrogen will then diffuse back into the steel part and eventually lead to a time-delayed hydrogen embrittlement failure.

Because there are three sources of hydrogen--the manufacture of steel (melting), processing and manufacturing, and in-service (environment)--and because there are three sources of stress--applied, residual from heat treatment, and residual from welding or plastic deformation--nine possible combinations exist. Therefore, it is not always easy to identify the specific cause of a hydrogen embrittlement service failure. A comprehensive evaluation for the prevention of hydrogen embrittlement service failures should include all nine possibilities. An evaluation of the possible controls that avoid in-service hydrogen embrittlement failures must focus on either eliminating the sources of hydrogen or operating at a sufficiently low stress (below the threshold) to prevent cracking.

Current hydrogen embrittlement prevention and control procedures are primarily directed at the plating process and maintenance chemicals. These procedures are covered in ASTM F 519 (Ref 2). Over 30 other military and federal specifications include hydrogen embrittlement relief treatments. Hardware, such as springs or structural fasteners, is tested directly by sustained or step-load stress tests to evaluate the effectiveness of the hydrogen embrittlement relief treatments.

Testing

Tests for hydrogen embrittlement are performed to determine the effect of hydrogen damage in combination with residual or applied stresses. In the past decade, conventional testing methods have been modified to incorporate fracture mechanics, and the various types of hydrogen damage have been further classified in terms of crack nucleation, crack growth rates, and threshold stress intensity measurements.

This section will discuss the current methods of hydrogen embrittlement testing and will focus on accelerated small-specimen testing methods for failure analysis and production control of hydrogen embrittlement. Additional information on hydrogen damage in metals and on test methods for hydrogen embrittlement can be found in Refs 1, 2, 3, 4, 5, 6, 7, 8, 9 and in the article "Environmentally Induced Cracking" in this volume.

Standardized Tests. Currently, the only standards for hydrogen embrittlement testing are ASTM F 519 (Ref 2) and F 326 (Ref 3). These standards are based on (1) not putting hydrogen into the steel by keeping the hydrogen in the plating bath at acceptably low levels (ASTM F 326) and (2) using mechanical tests to ensure that the amount of residual hydrogen after baking is under acceptably low levels (ASTM F 519).

ASTM F 326. This standard method covers an electronic hydrogen detection instrument procedure for the measurement of plating permeability to hydrogen, a variable that is related to hydrogen absorbed by steel during plating and to the hydrogen permeability of the plate during post plate baking. A specific application of this method involves controlling cadmium-plating processes in which the plate porosity relative to hydrogen is critical, such as with cadmium plating of high-strength steel.

This method uses a metal-shelled vacuum probe as an ion gage. A section of the probe shell is cadmium plated at the lowest current density encountered during the electroplating process. During subsequent baking, the probe ion current that is proportional to hydrogen pressure is recorded as a function of time. The slope of this curve has an empirical relationship to failure data, such as those discussed in ASTM F 519.

ASTM F 519. This method covers the evaluation of the hydrogen-generating potential of fluids (aircraft maintenance chemicals) and the hydrogen embrittlement control of electroplating processes. Test specimens are installed into the plating bath during the plating of hardware to monitor indirectly the amount of hydrogen in the plating bath. The acceptable level of hydrogen is determined by a go/no-go situation established by the failure of a sustained loaded, stressed specimen that has been baked at 191 °C ± 14 °C (375 °F ± 25 °F) for a minimum of 23 h. The procedures and requirements are specified for the following five types of AISI 4340 steel test specimens:

- Type 1a: notched round bars, stressed in tension, under constant load
- Type 1b: notched round bars loaded in tension with stressed O-rings
- Type 1c: notched round bars loaded in bending with loading bars
- Type 1d: notched C-rings loaded in bending with loading bolt
- Type 2a: unnotched ring specimens loaded in bending with displacement bars

For platings, no stress is applied until the parts have been baked; baking is specified to occur within 1 h after plating. For maintenance chemicals and cleaners, stress is applied before the test specimens are exposed to the environment. The latter condition is obviously much more severe and discriminates against much lower levels of hydrogen, but is more representative of their end use.

The cantilever beam test is a constant-load test in which a V-notched specimen is inserted along a portion of the beam and enclosed by an environmental chamber (Fig. 1). A crack at the root of the V-notch is initiated and extended by fatigue before testing. Notch-root thickness is prescribed by the American Society for Testing and Materials (ASTM), although the requirement is often excessive for high-toughness steels. The specimen is subjected to a constant load over a predetermined time period. As the crack grows, the stress intensity increases. Time to failure is plotted versus applied stress intensity. The lower limit of the resultant curve is a threshold stress intensity for hydrogen embrittlement. K_{IHE}, as shown in Fig. 2.

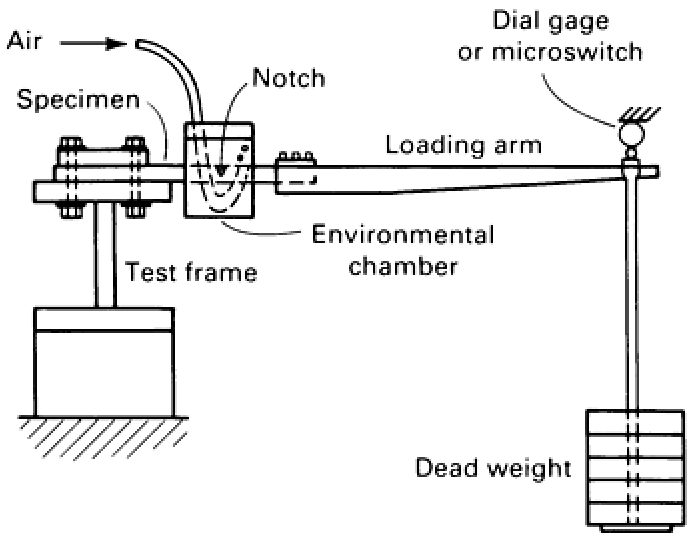

Fig. 1 Fatigue-cracked cantilever beam test specimen and fixtures. Source: Ref 10

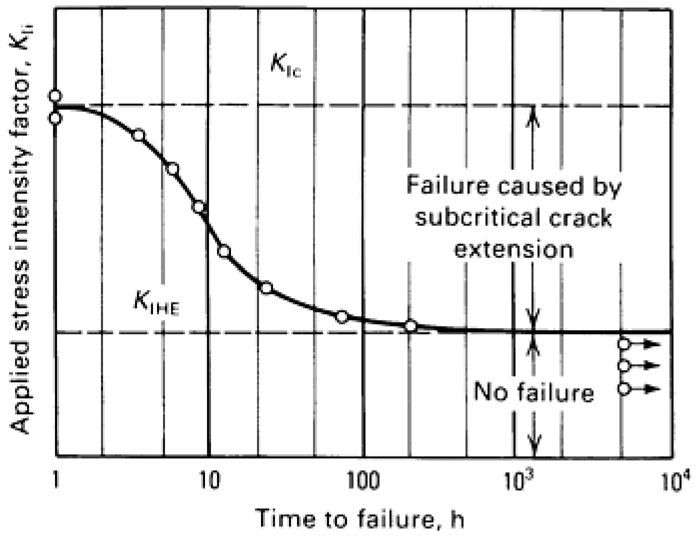

Fig. 2 Procedure to obtain K_{IHE} with precracked cantilever beam test specimen. Source: Ref 10

The K_{IHE} results of a cantilever beam test depend on how much time elapses before the test is terminated. Recommended test periods for establishing the true stress intensity threshold range from 200 h, which is typical for hydrogen embrittlement testing, to as long as 5000 h (Ref 11). Another limitation of this testing method is that it can be expensive in terms of materials and machining. As many as 12 specimens, placed under different loads in separate test machines, are needed for each test in order to obtain valid K_{IHE} values.

The wedge-opening load test applies a constant wedge- or crack-opening displacement; as the crack extends, stress intensity decreases until crack arrest occurs (Fig. 3). The initial load is assumed to be slightly above K_{IHE}. The specimen is maintained under these conditions for about 5000 h to establish the threshold. The crack grows to a point after which further growth is not measured (K_{IHE}). However, it is difficult to determine precisely when the no-growth criterion is met. Crack tip opening displacement should also be monitored. Corrosion reactions, accompanied by expansion in volume, may occur at the crack tip. This changes the opening displacement and increases the load, thus altering the desired testing conditions.

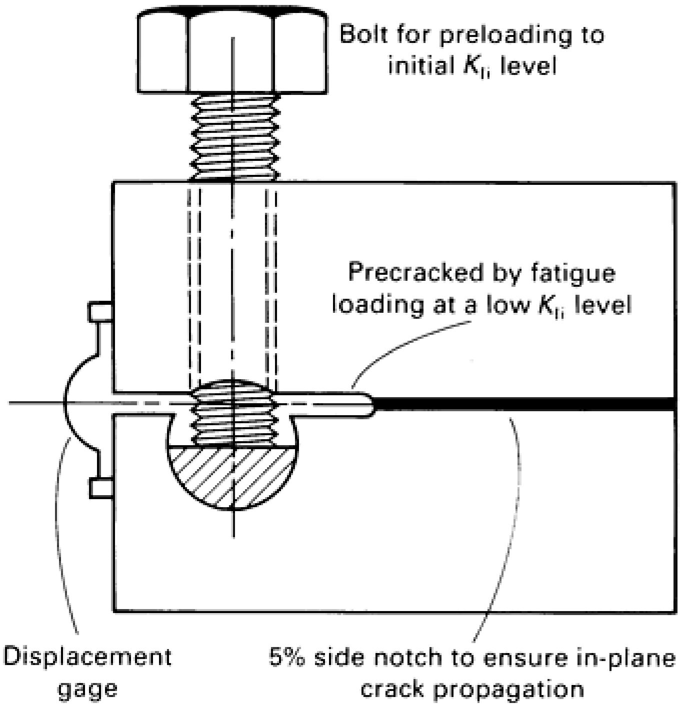

Fig. 3 Schematic showing basic principle of modified wedge-opening load test specimen

As subcritical crack extension occurs, stress intensity increases in the cantilever beam test and decreases in the wedge-opening load test (Fig. 4). Generally, the threshold stress intensity measured with the wedge-opening load test is lower than that measured with the cantilever beam test (Ref 12). The advantage of the wedge-opening load test is that only one specimen is required to measure K_{IHE}.

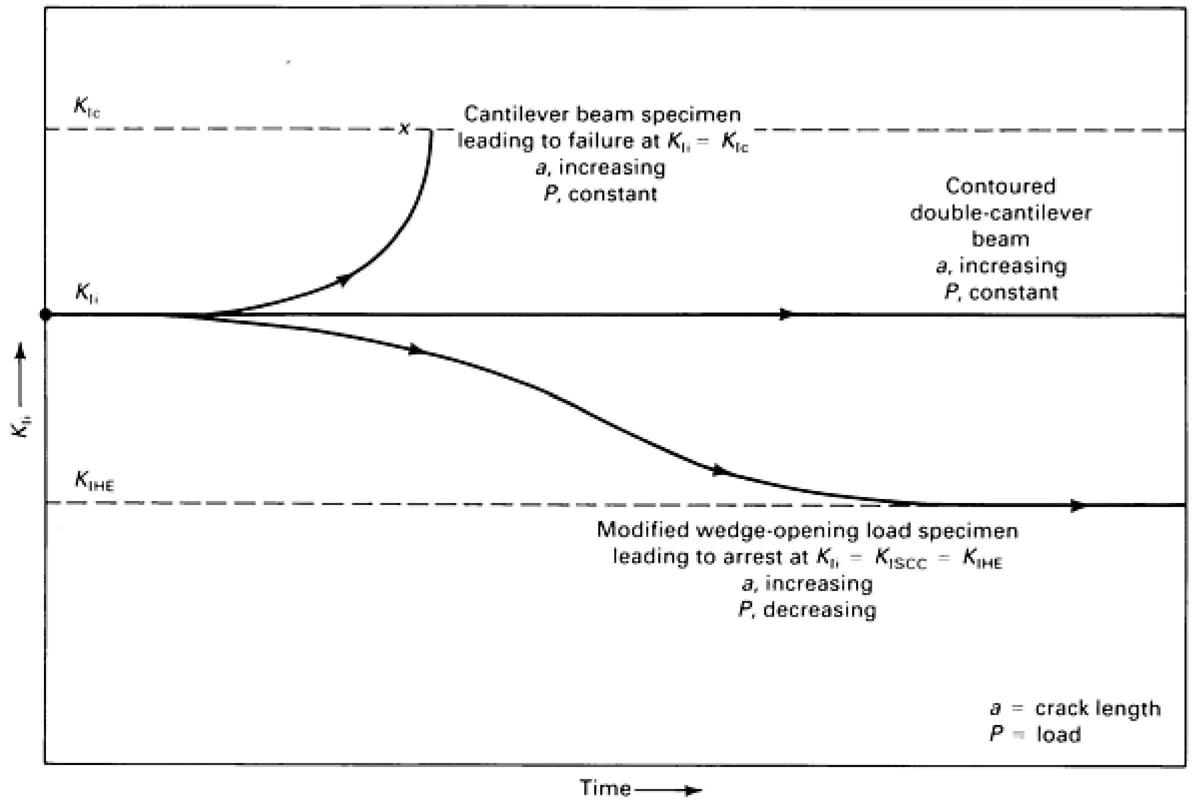

Fig. 4 Influence of time, crack extension, and load on stress-intensity behavior of modified wedge-opening load, cantilever beam, and contoured double-cantilever beam test specimens. Source: Ref 10

In long-term tests, it is essential to ensure that the concentration and the composition of the environmental solution do not change over time. For example, evaporation may cause the solution level to drop the crack line of the specimen; this would render the test invalid.

Figure 5 shows the results of wedge-opening load and cantilever beam tests on 25.4-mm (1-in.) thick iron-nickel-cobalt alloy steel specimens. The data imply that the wedge-opening load K_{IHE} crack arrest result is the lower limit for the cantilever beam K_{IHE} threshold.

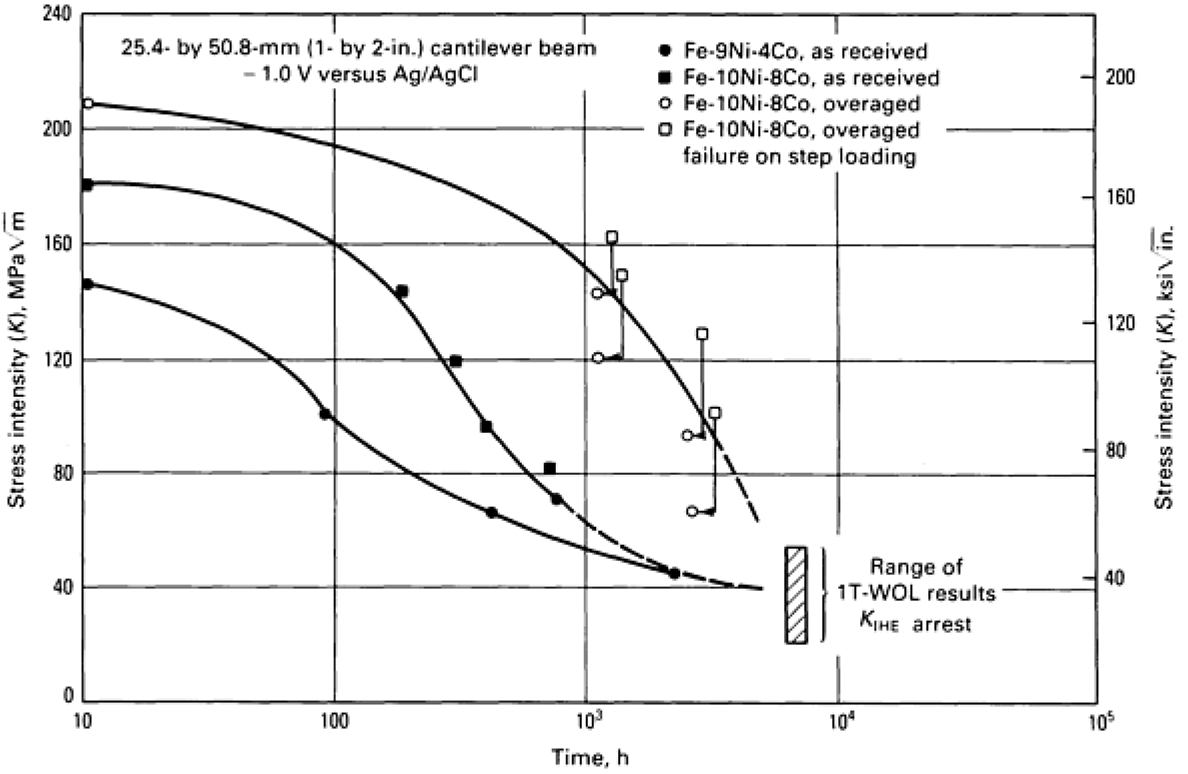

Fig. 5 Comparison of single-edge-notched cantilever beam and wedge-opening load test results for hydrogen embrittlement cracking of iron-nickel-cobalt steels. Source: Ref 13

The open circles in Fig. 5 represent "no fracture" at various exposure times for an overaged Fe-10Ni-8Co alloy in a cantilever beam test. The open squares indicate failure at increased stress intensities, following step loading at various exposure times at the lower stress intensity. The results suggest that increasing the load during the test produces more aggressive hydrogen embrittlement conditions than a constant load.

This may be due to the possible formation of an oxide film on the surface. When the load is increased, the oxide film is broken, exposing fresh metal, and more hydrogen is produced at the crack tip. For this reason, the test should use a rising load, because the constant-load cantilever beam test does not provide worst-case (fresh metal exposed) loading conditions.

The data also suggest that the cantilever beam test can generate an artificially high K_{IHE} threshold, depending on the time limit selected. If the test had been terminated at 200 h rather than at 5000 h, the reported K_{IHE} values from the cantilever beam test (Fig. 5) would have been four times higher than those measured after the longer time period. Similarly, if insufficient time is allowed in the wedge-opening load test, the incubation period may not be exceeded, and no crack growth will result.

Both testing methods require costly and time-consuming steps and result in a parameter, K_{IHE}, whose design significance is questionable. However, the parameter does provide a relative ranking of susceptibility to hydrogen embrittlement or, more generally, SCC.

The contoured double-cantilever beam test is used to measure crack growth rate at a constant stress intensity factor. This test simplifies the calculation of stress intensity by using a contoured specimen so that stress intensity is proportional to the applied load and is independent of the crack length. Under a constant load, stress intensity also remains constant with crack extension. For the test geometry shown in Fig. 6, the stress intensity factor equals 20 times the load ($K = 20P$).

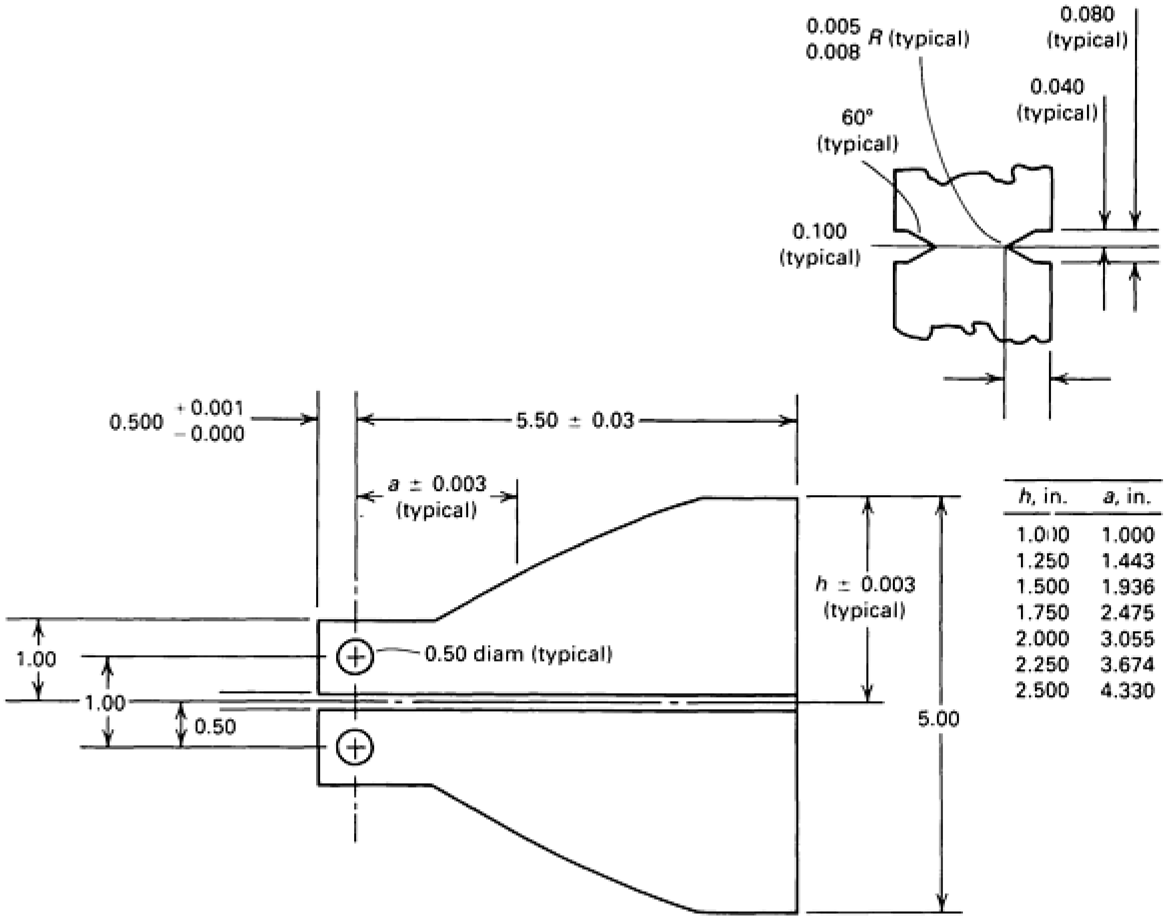

Fig. 6 Dimensions and configuration for double-cantilever beam test specimen. Specimen contoured to $3a^2/h^3 + 1/h = C$, where C is a constant. All values given in inches (1.0 in. = 25.4 mm)

Data on hydrogen embrittlement can be obtained with subthickness specimens (Ref 14), even in excess of the ASTM requirement of $K^2_{max} < 0.4\ B/YS^2$ (where B is the thickness and YS is the yield strength of the specimen), by using side grooves. Side grooves additional constraint on the material being tested. They also enable the maintenance of a plane-strain condition in a thin specimen by enhancing stress triaxiality. This method has been extensively used to study the effect of heat treatment (hardness) and environment on the hydrogen stress cracking of AISI 4340 steels (Fig. 7).

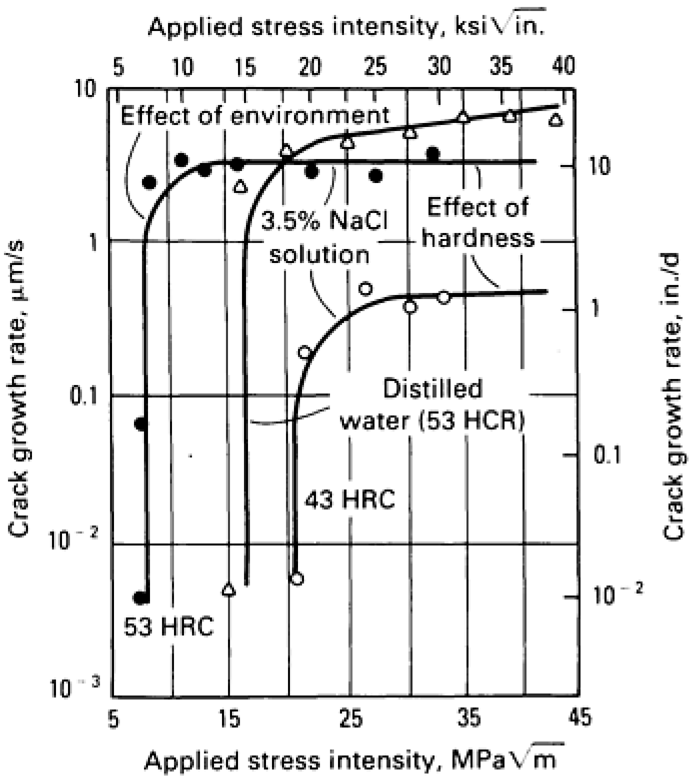

Fig. 7 Hydrogen embrittlement crack growth rate as a function of applied stress intensity for two different hardnesses and environments for an AISI 4340 steel contoured double-cantilever beam test specimen.

The contoured double-cantilever beam test has also been used to study the stress history effect that produces an incubation time before hydrogen stress cracking. Figure 8 shows that incubation time is dependent on the type of steel. A decrease in the stress intensity factor from 44 to 22 MPa $\sqrt{m}$(40 to 20 ksi $\sqrt{in.}$) may change the incubation time from less than 1 h for AISI 4340 steel to about 1 year for type D6-AC steel.

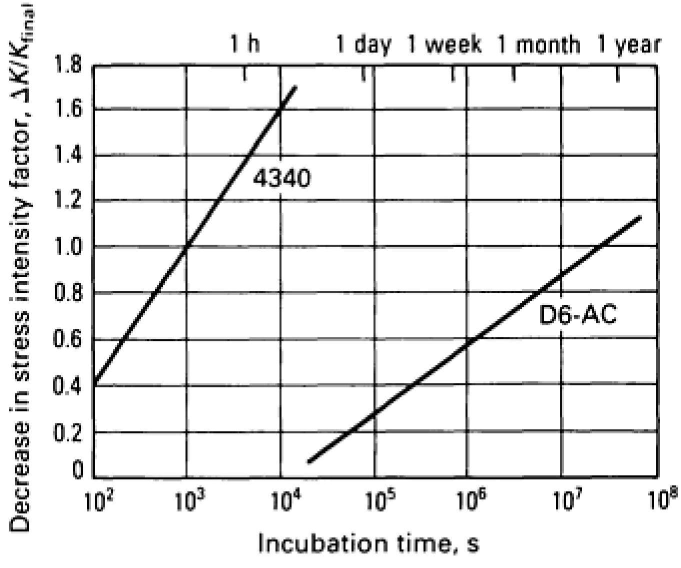

Fig. 8 Incubation time for crack growth in AISI type 4340 and type D6-AC steel contoured double-cantilever beam test-specimens as a function of decrease in stress intensity. Source: Ref 15

Three-Point and Four-Point Bend Tests. The contoured double-cantilever beam test uses a constant load to maintain a constant stress intensity factor with crack extension. The same effect can be produced by using a three- or four-point bend test under displacement control. These tests use heavily side-grooved Charpy V-notch specimens (Fig. 9). Because crack-opening displacement is constant as the crack extends, the load decreases; therefore, there is a slight initial increase in stress intensity to a maximum value that drops slightly as the ratio of crack depth to specimen width exceeds 0.5. Typically, stress intensity is constant within a small range. Figure 10 compares the change in stress intensity factor with crack extension as a function of load control to that of displacement control for a three-point bend specimen.

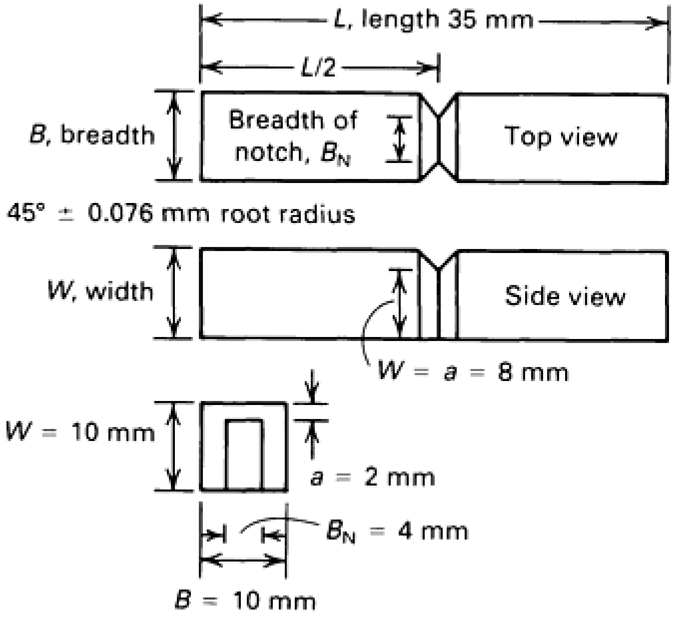

Fig. 9 Side-grooved Charpy V-notch test specimen used for three- and four-point bend tests

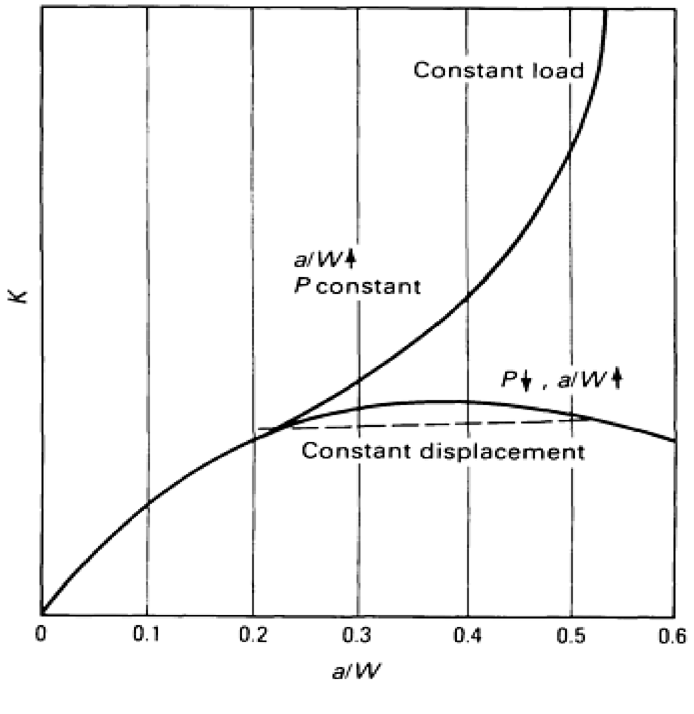

Fig. 10 Change in stress intensity factor with crack extension as a function of load control and displacement control for a three-point bend specimen

The rising step-load test provides a stress intensity that is different at each load but that remains constant with crack extension as each load level is sustained. Crack initiation is signaled by a drop in load (Fig. 11). The rising step-load test was developed as an accelerated low-cost test for measuring the resistance of steels (particularly weldments) to hydrogen embrittlement (Ref 13, 17). The threshold obtained by this method could be slightly higher if the test duration of each load is too short, but the test duration can be extended near the initiation loads in duplicate tests in order to obtain a more accurate measurement.

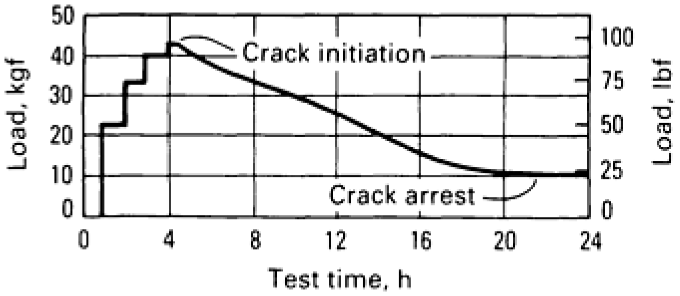

Fig. 11 Typical load-time record for four-point rising step-load test. Source: Ref 16

To index susceptibility to hydrogen-assisted cracking, the test should last no longer than 24 h, and the hydrogen source should reflect the most aggressive environment. In one experiment, a 3.5% sodium chloride solution was selected to simulate seawater, and a cathodic potential of -1.2 V versus SCE was used to generate hydrogen in order to reproduce the extreme conditions of sacrificial anodic protection generally found on a ship hull.

A Charpy specimen was chosen because such specimens are small and easy to machine and handle. In this test, however, the specimen was modified. Instead of using fatigue precrack, the notch-root radius was machined to less than 7.6 μm (3 mils). This was done to lower the cost and to give less ambiguous environmental conditions at the crack tip. Also, hydrogen cracks nucleate below the surface.

The specimen was deeply side grooved, a common practice used in crack growth rate tests to prevent the crack from branching. Side grooves are also used in crack-opening displacement or *J*-integral testing in order to cause load displacement curves to increase monotonically to fracture by inducing a highly triaxial stress field at the crack tip. Because a Charpy specimen is small, deep side grooves produce a triaxial stress field at the notch, and thus promote crack initiation. The extent of the side grooving is such that the remaining ligament is only 40% of the original thickness. The modified Charpy specimen dimensions are shown in Fig. 9.

The specimen was loaded by means of beams and an instrumented bolt (Fig. 12). Four-point bending under constant displacement control and stress intensity produced crack growth. Once cracking initiated at the notch (a/W = 0.2, where a is crack length and W is width of the specimen), arrest did not occur until the crack was nearly through the specimen. The load was manually increased at 1-h intervals. An environmental chamber encompassed the specimen and included a potentiostat to produce hydrogen while under stress.

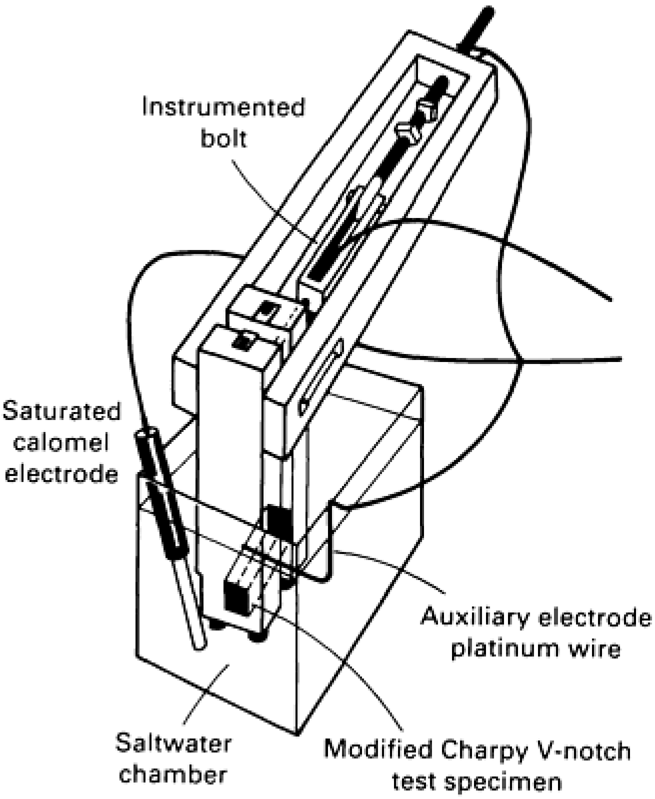

Fig. 12 Loading frame used for rising step-load test

The rising step-load test was used to evaluate high-strength HY ship steels and weldments in an environment simulating seawater under conditions of cathodic protection commonly employed to protect ship hulls (Ref 17). Samples from the heat-affected zone (HAZ) and other locations in the weld metal were tested. Interlayer gas tungsten arc heating was evaluated as a means of providing a refined, homogeneous, tempered microstructure with improved resistance to HSC. As a baseline, HY-130 and HY-180 steels were compared.

Figure 13 plots rising step-load test results for HY-130 and HY-180 base metals, in addition to combinations of modified HY steel compositions and programmed-cooling-rate thermal cycles for the base metal and the weld wire. The vertical axis is a plot of a parameter derived from the specimen strength ratio in ASTM E 399--that is, $6\,P_{max}/B(W - a)^2$YS, where P_{max} is the maximum load that the specimen is able to sustain, B is the specimen thickness, W is the specimen width, a is the crack length, and YS is the yield strength in tension. For the data shown in Fig. 13, P_{max} was replaced by the crack initiation load. The horizontal axis is a ratio of K_{IHE}/YS, which was measured in a separate test program with cantilever beam and wedge-opening load specimens.

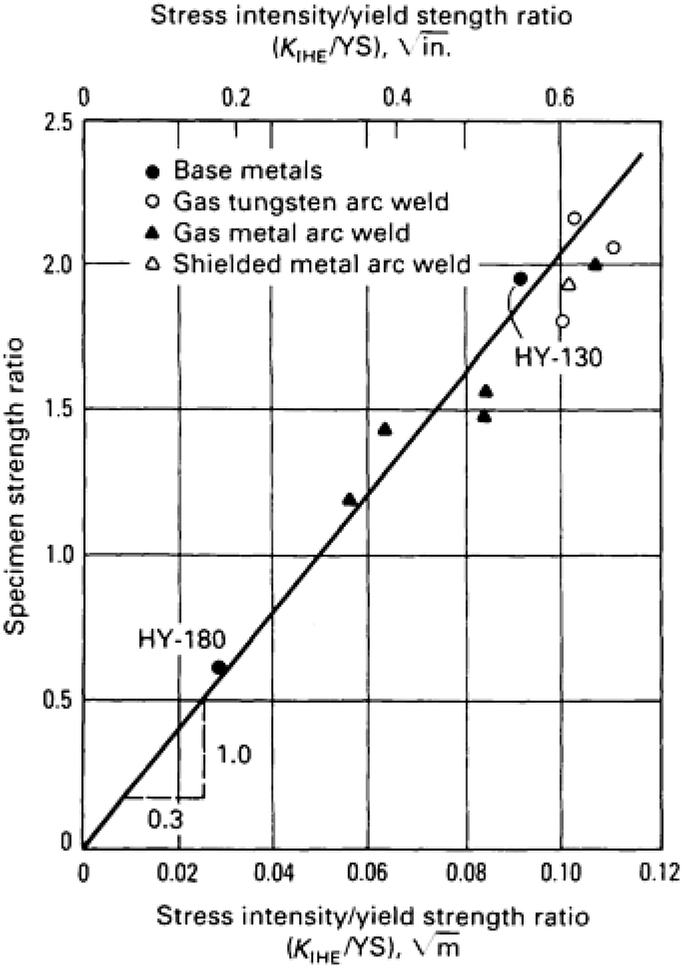

Fig. 13 Analytical correlation of strength ratio with threshold stress intensity data

The resistance to hydrogen embrittlement of the two base metals and six locations in HY-130 weldments was ranked by using this testing method. Test results showed that HY-180 is more susceptible to HSC than HY-130 and that the resistance to hydrogen embrittlement of specimens taken from the HAZ and the fusion line is consistently higher than that of weld metal specimens. The resistance of the weld metal is affected by grain structure; interlayer gas tungsten arc reheating homogenized the weld structure, but it did not temper the weld metal. Specimens from the gas tungsten arc reheated weldment consistently exhibited higher hardness and lower resistance to hydrogen embrittlement than similar specimens from the standard HY-130 weld metal (Ref 12, 17).

The disk-pressure testing method measures the susceptibility to hydrogen embrittlement of metallic materials under a high-pressure gaseous environment (Ref 18). The test is used for the selection and quality control of materials, protective coatings, surface finishes, and other processing variables.

In this test, a thin disk of the metallic material to be tested is placed as a membrane in a test cell and subjected to helium pressure until it bursts. Because helium is inert, the fracture is caused by mechanical overload; no secondary physical or chemical action is involved. An identical disk is placed in the same test cell and subjected to hydrogen pressure until it bursts. Metallic materials that are susceptible to environmental hydrogen embrittlement fracture under a pressure that is lower than the helium-burst pressure; materials that are not susceptible fracture under the same pressure for both hydrogen and helium. The ratio, S_{H_2}, between the helium-burst pressure, P_{He}, and the hydrogen-burst pressure, P_{H_2}, indicates the susceptibility of the material to environmental hydrogen embrittlement:

$$S_{H_2} = \frac{P_{He}}{P_{H_2}}$$

If S_{H_2} is equal to or less than 1, the material is not susceptible to environmental hydrogen embrittlement. When S_{H_2} is greater than 2, the material is considered to be highly susceptible. At values between 1 and 2, the material is moderately susceptible, with failure expected after long exposure to hydrogen; therefore, the material must be protected against exposure.

A compilation of test results is shown in Fig. 14. The alloys having little or no sensitivity are 7075-T6 aluminum; Haynes 188 (cobalt base); beryllium copper (copper base); types 304, 316, and 310 austenitic stainless steel; type 430 ferritic steel; and age-hardened austenitic A 286 steel. Titanium-base alloy Ti-6A1-4V exhibits moderate sensitivity. Alloys with high sensitivity are Haynes 25 (cobalt base) and iron-base alloys, including medium- and high-strength steels. Conventional testing methods, such as the cantilever beam, wedge-opening load, and contoured double-cantilever beam tests, have also been adapted for testing in high-pressure gaseous hydrogen environments.

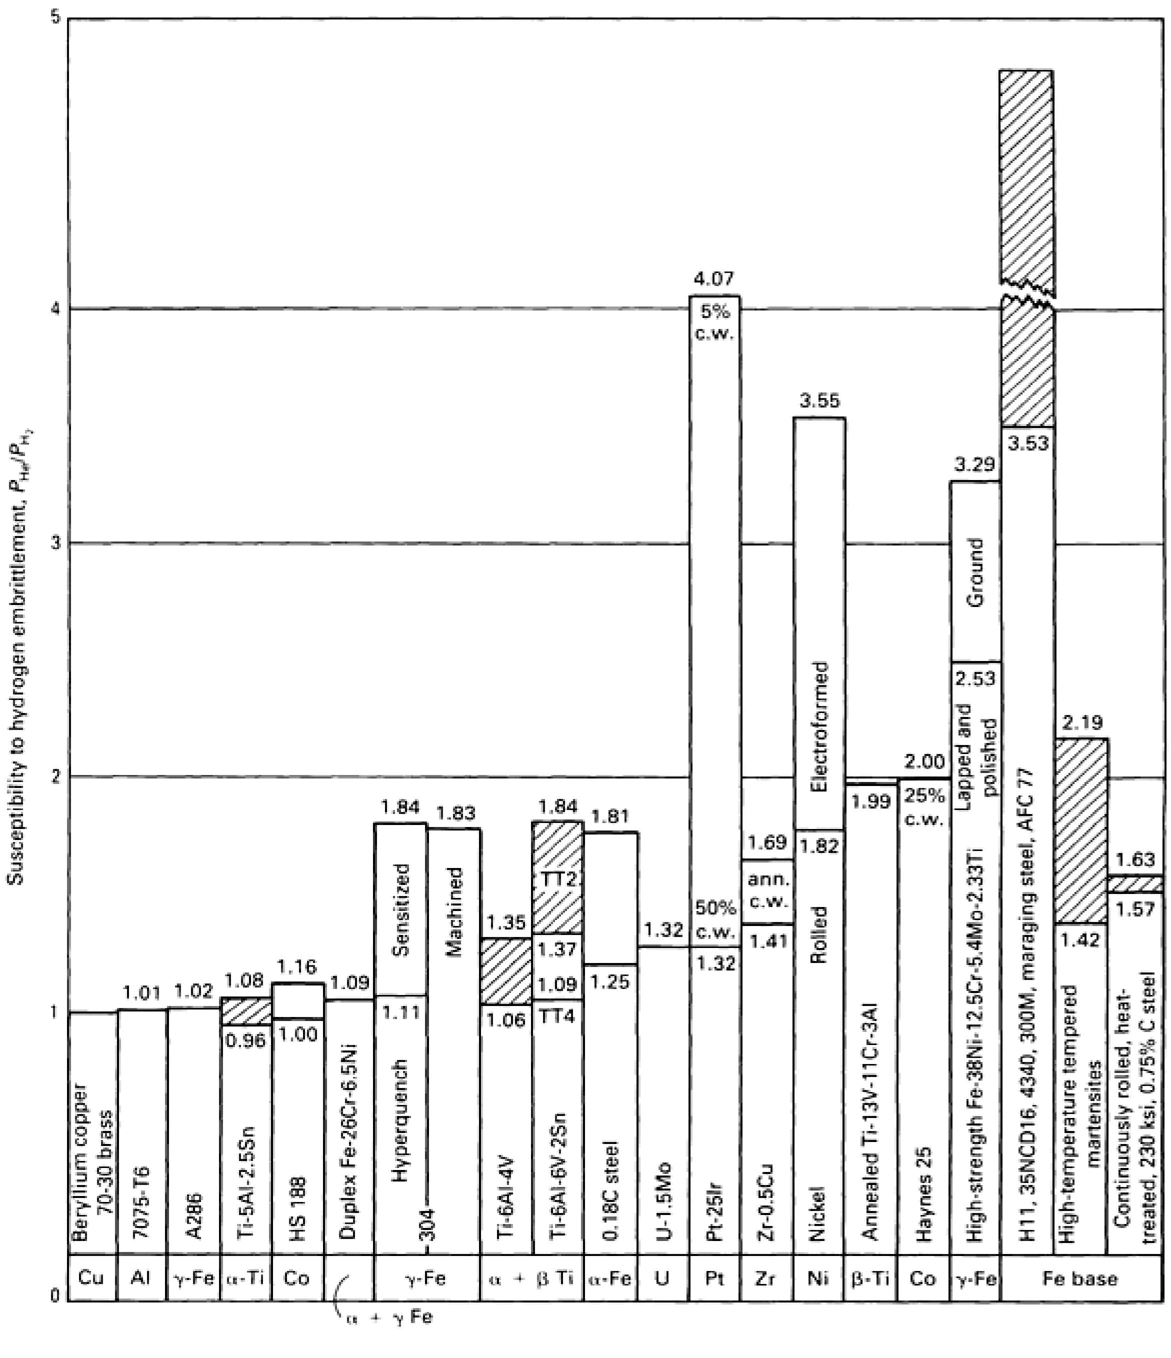

Fig. 14 Relative hydrogen susceptibility of various metals and alloys tested at a rate of 65 bars/min at room temperature. c.w., cold worked; ann., annealed. Source: Ref 18

Slow strain rate tensile tests can be used to evaluate many product forms, including plate, rod, wire, sheet, and tubing, as well as welded parts. Smooth, notched, or precracked specimens can be used. The principal advantage of this standardized test is that the susceptibility to hydrogen stress cracking (HSC) for a particular metal-environment combination can be rapidly assessed (Ref 19).

A variety of specimen shapes and sizes can be used; the most common is a smooth bar tensile coupon, as described in ASTM E 8 (Ref 20). The specimen is exposed to the environment and is stressed under displacement control. For stainless steel in chloride solution, the strain rate is 10^{-6}/s. One or more of the following parameters are applied to the tensile test at the same initial strain rate:

- Time to failure
- Ductility, as assessed, for example, by reduction of area or elongation to fracture
- Maximum load achieved
- Area bounded by a nominal stress-elongation curve or a true stress/true strain curve

Additional information on slow strain rate tensile tests can be found in the article "Evaluation of Stress-Corrosion Cracking" in this Volume.

Potentiostatic Slow Strain Rate Tensile Testing. Studies have been conducted on the use of dissociated water under potentiostatic conditions that produce hydrogen on the surface of the tensile test specimen while under slow strain rate displacement control. Results suggest that hydrogen is the most significant parameter in stress cracking under the conditions of hydrogen sulfide SCC found in oil fields (Ref 21).

Interpretation of Test Results

The phenomenon of hydrogen embrittlement or SCC is very complex. The test results depend on environmental conditions (potential, pH, oxygenation level, temperature, environment), material and melting procedure (air, vacuum, electroslag remelting, vacuum arc remelting, and so on); test specimen geometry (notched tensile or bend specimens, cantilever beam specimen, wedge-opening specimen), and specimen preparation (crush grinding, fatigue precracking). Therefore, evaluation of the test results, on a quantitative scale, is impossible. The purpose of the test is to address a very specific set of conditions.

The existing standard, ASTM F 519, is based on the assumption that air-melted AISI 4340 at 53 ± 1 HRC is a worst-case condition. If no fracture occurs in this specimen after 200 h at 75% of the notched strength, then other 4340 steels processed by alternate melting processes (even steels with higher hardness levels because of vacuum melting) will not have residual levels of atomic hydrogen that would produce sustained load failure in the environment of concern. Data to support this claim are shown in Fig. 15, which shows the extreme susceptibility of air melted 4340 steel as compared to electroslag remelted or vacuum arc remelted 4340 steel. This test is not intended to be a relative susceptibility test, nor is it intended to be used with any material other than air-melted 4340 according to MIL S-5000E.

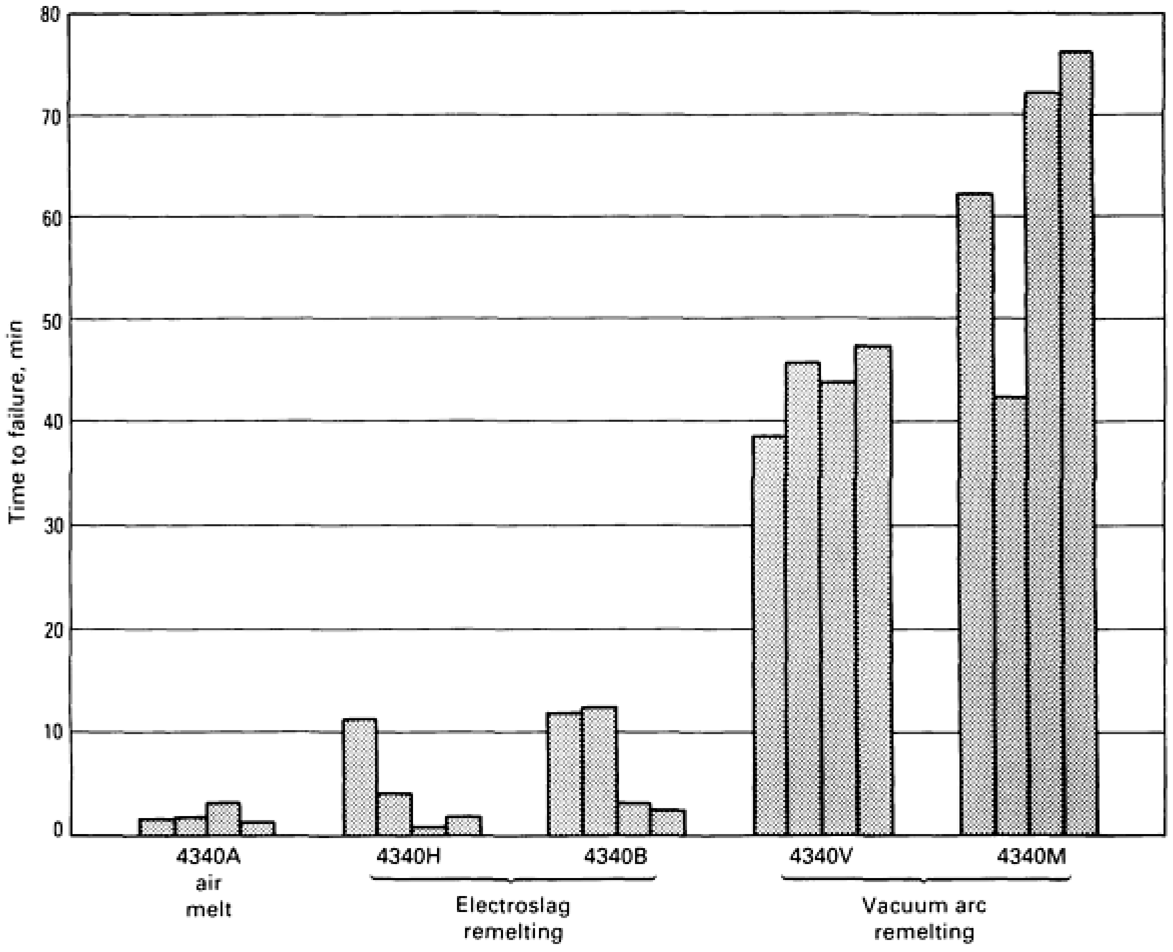

Fig. 15 Time to failure for AISI 4340 high-strength steels with an ultimate tensile strength range of 1790-2070 MPa (260-300 ksi) using ASTM F 519, Type 1c bend specimens. Source: Ref 22

This quality control method suffers from the fact that manufacturing-induced stress in the part might not be the same as in the representative test coupon. This is why stress relief before plating is advised. If the coupon is stress free but the parts have a high residual stress, the coupons will pass the 200-h sustained load test, but the parts, which might have cracked during plating, may inadvertently be put into service. Conversely, if care is not taken in the manufacturing of the coupons and if high residual stresses are introduced, the coupons will fail the 200-h sustained load test, but the parts will be stress or crack free. Based on the latter situation, all of these acceptable parts would be discarded. Obviously, before such action is taken, the parts themselves are generally tested.

To prevent any misrepresentation of test sampling with separately manufactured test coupons, the hardware itself is often tested directly, such as in the case of fasteners or springs, and the use of representative test coupons is completely avoided. The problem with testing actual hardware is twofold. First, the test is destructive and therefore can be costly, depending on the type of hardware being evaluated, and second, the method of applying the stress and the magnitude of the applied stress are not always easily obtained. It can often be very dangerous to reuse parts that have been proof tested by the application of a stress above the anticipated service stresses. Revising these parts can produce conditions that adversely affect structural integrity by consuming a large portion of the life of the part instead of ensuring its longevity.

Prevention and Control

The potential for hydrogen embrittlement must be evaluated before any prevention and control procedures are implemented (Ref 23). The sources of hydrogen must be examined with regard to three possibilities: the manufacture of the steel, the manufacture and processing of the steel part, and the environmental service conditions of the steel part. A source of hydrogen and a sufficient stress must exist in order for hydrogen embrittlement to occur. If either condition is eliminated, hydrogen embrittlement will not occur.

From a control viewpoint, the attempt is to eliminate the hydrogen or to ensure that no hydrogen is introduced during the manufacture and processing of the steel. It is then anticipated that no problem will exist in service. This approach focuses on the hydrogen embrittlement process that has classically been referred to as internal hydrogen embrittlement. This possibility is introduced during the manufacture and processing of the steel. Once the part is in service, any potential hydrogen embrittlement failure can result from hydrogen produced from a corrosion reaction or from the steel operating in high-pressure hydrogen. This is referred to as environmental hydrogen embrittlement.

Hydrogen embrittlement failures are prevented by controlling the amount of hydrogen introduced during the manufacture and processing of the hardware. Consideration must be given to the amount of hydrogen introduced during the melting of the steel, the manufacture of the part, and the in-service environment, which should also include cleaners and paint strippers. The necessary controls are covered in ASTM F 519. The major difficulty appears to involve identifying the manufacturing-induced residual stresses that result from heat treatment and, especially, welding (if it is part of the manufacturing process). Much more attention must be given to evaluating the potential for hydrogen embrittlement failures in the presence of residual stresses. The source of the residual stress must be identified in each piece of production hardware, or the assumption of high residual stresses in the manufactured part, especially in welded structures, must be included in the design analysis.

The usefulness of the threshold stress intensity K_{IHE} parameter has yet to be established. Its main function appears to be its use in designing against the service-induced or application-induced possibilities of hydrogen embrittlement failures. This can be done only by controlling the applied stress and geometrical factors, such as root radius, in order to maintain the effective applied stress intensity at a level that is below threshold for subcritical crack growth in a given environment. This approach is a relatively new frontier for technological advancement in that the method of measuring K_{ISCC} has not yet been standardized and its significance in design has not yet been completely understood.

Evaluation of Corrosion Fatigue

Donald O. Sprowls, Consultant

Introduction

A FREQUENT CAUSE of the premature fracture of structural components (see Fig. 1 in the article "Evaluation of Stress-Corrosion Cracking" in this Volume) is corrosion fatigue cracking (CFC), which is not limited to certain metallurgical conditions of the metal or to critical environmental species, as are other forms of environmentally assisted cracking. Classical CFC and stress-corrosion cracking (SCC) failures (which may be clearly distinguished by fractographic features) are separated by a spectrum of behaviors dictated by a large number of conditions related to the metallurgical condition of the material, the method of stressing, the electrochemistry of the metal/environment system, and the interaction kinetics.

Relationship Between CFC and SCC

Figure 1 illustrates a conceptual interrelationship of corrosion fatigue, stress corrosion, and hydrogen embrittlement used in Ref 1 in a discussion of the current understanding of the mechanisms of stress corrosion and corrosion fatigue. The most serious practical situations involving ductile alloy/environment systems are in the crosshatched regions, which indicate the combination of any two failure mechanisms, and especially in the center, in which all three phenomena interact. Although much research in this area has been published in recent years (Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11), many unanswered questions remain. One researcher has concluded that the danger of cracking in practical situations and the applicability of various testing techniques can be assessed from a mechanistic base as well as from the existing foundation of empirical experience (Ref 1). Some of the experimental evidence relating CFC to SCC will be cited in later sections of this article that discuss specific aspects of corrosion fatigue testing.

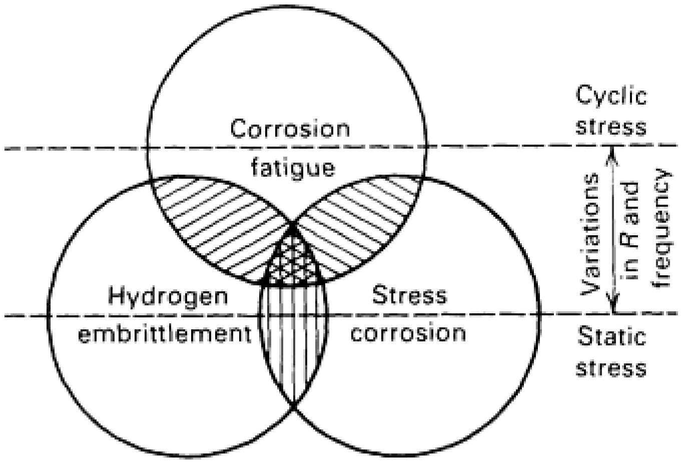

Fig. 1 Venn diagram illustrating the interrelationship among stress corrosion, corrosion fatigue, and hydrogen embrittlement. Source: Ref 1

Prediction of Corrosion Fatigue Life

According to a recent assessment of standards for CFC and SCC, the methodology for the interpretation and use of standard test method data for environmental cracking is not well developed. Moreover, to the extent that the two phenomena can interact synergistically under some conditions, existing approaches to standard test development may produce nonconservative data in some cases (Ref 12). Similarly, according to another researcher, the research and testing community is still unable to deliver a scientific basis for a reliable estimate of fatigue life for all conceivable load and environmental combinations, despite the estimated billions of dollars spent on fatigue (Ref 13).

Therefore, the designer may rely on experience with similar components in service rather than a laboratory evaluation of mechanical test specimens. Laboratory tests, however, are essential for understanding fatigue behavior, and current studies with fracture mechanics test specimens are beginning to provide satisfactory design criteria.

Types of Corrosion Fatigue Tests

Laboratory corrosion fatigue tests can be classified as either cycles to failure (crack initiation) or crack propagation tests. In cycles to failure testing, specimens or parts are subjected to the number of stress cycles required for CFC to initiate and subsequently grow large enough to produce failure. Such data are usually obtained by testing smooth or notched specimens. With this type of testing, however, it is difficult to distinguish between CFC initiation life and CFC propagation life.

In crack propagation testing, fracture mechanics methods are used to determine the crack growth rates of preexisting cracks under cyclic loading. Preexisting cracks or sharp defects in a material reduce or may eliminate the crack initiation portion of the fatigue life of the component. Both types of testing are important; however, it appears that crack initiation is of more significance in the failure process of relatively thin sections, while crack growth appears to dominate thick-section component endurance (Ref 14).

The usual approach to corrosion fatigue testing is to perform a state-of-the-art fatigue test in the presence of the environment of interest. This article will emphasize important factors that should be recognized and controlled in corrosion fatigue tests and will provide references to published standard methods and recommended practices. Information on the planning and design of fatigue tests and the statistical analysis of test results is available in the article "Fatigue Data Analysis" in *Mechanical Testing,* Volume 8 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Standards and Recommended Practices for Fatigue Testing

Only a few standardized procedures for fatigue testing are available because many of the testing machines are custom built. However, several types of fatigue-testing machines, testing methods, and test specimens are accepted as standard. In the United States, the American Society for Testing and Materials (ASTM) issues voluntary standards and recommended practices. Those related to fatigue testing are:

- ASTM E 206, "Standard Definitions of Terms Relating to Fatigue Testing and the Statistical Analysis of Fatigue Data"
- ASTM E 466, "Standard Practice for Conducting Constant Amplitude Axial Fatigue Tests of Metallic Materials"
- ASTM E 467, "Standard Practice for Verification of Constant Amplitude Dynamic Loads in an Axial Load Fatigue Testing Machine"
- ASTM E 468, "Standard Practice for Presentation of Constant Amplitude Fatigue Test Results for Metallic Materials"
- ASTM E 513, "Standard Definitions of Terms Relating to Constant Amplitude Low-Cycle Fatigue Testing
- ASTM E 606, "Standard Practices for Constant Amplitude Low-Cycle Fatigue Testing
- ASTM E 647, "Standard Test Method for Constant-Load-Amplitude Fatigue Crack Growth Rates above 10^{-8} m/Cycle"
- ASTM E 739, "Standard Practice for Statistical Analysis of Linear or Linearized Stress-Life (S-N) and Strain-Life (ε-N) Fatigue Data"
- ASTM E 742, "Standard Definitions of Terms Relating to Fluid Aqueous and Chemical Environmentally Affected Fatigue Testing"
- ASTM E 912, "Definitions of Terms Relating to Fatigue Loading"

Cycles to Failure Tests

Cycles to failure (crack initiation) tests are procedures in which a specimen or part is subjected to cyclic loading to failure. A large portion of the total number of cycles in these tests is spent initiating the crack. Although cycles to failure tests conducted on small specimens do not precisely establish the fatigue life of a large part, such tests do provide data on the intrinsic fatigue crack initiation behavior of a metal or alloy. As a result, such data can be used to develop criteria to prevent fatigue failures in engineering design. Examples of the use of small-specimen fatigue test data can be found in the basis of the fatigue design codes for boilers and pressure vessels; complex welded, riveted, or bolted structures; and automotive and aerospace components.

Fatigue-Testing Regimes

The magnitude of the nominal stress on a cyclically loaded component is often measured by the amount of overstress, that is, the amount by which the nominal stress exceeds the fatigue limit or the long-life fatigue strength of the material used in the component. The number of load cycles that a component under low overstress can endure is high; therefore, the term high-cycle fatigue is often applied. Because high-cycle fatigue tests require uninterrupted operation for long periods of time, test machines that are simple and reliable are used. Either constant-load amplitude or constant deflection tests can be conducted.

As the magnitude of the nominal stress increases, the initiation of multiple cracks is more likely. Also, spacing between fatigue striations, which indicate the progressive growth of the crack front, is increased, and the region of final fast fracture is increased in size.

Low-cycle fatigue is the regime characterized by high overstress. The commonly accepted dividing line between high-cycle and low-cycle fatigue is considered to be between 10^4 and 10^5 cycles. In practice, this distinction is made by determining whether the dominant component of the strain imposed during cyclic loading is elastic (high cycle) or plastic (low cycle), which in turn depends on the properties of the metal as well as the magnitude of the nominal stress.

Different test techniques may be required for the control and monitoring of low-cycle fatigue tests. Typically, strain-controlled tests (constant strain amplitude) are used.

In routine low- and high-cycle fatigue crack initiation testing, complete fracture of a small specimen is generally the failure criterion. Approximately 30 to 40% of the low-cycle fatigue life and about 80 to 90% of the high-cycle fatigue life measured by cycles to failure involve nucleation of the dominant fatigue crack that eventually causes failure.

Loading Parameters

Most laboratory fatigue testing is done either with axial loading or in bending, thus producing only tensile and compressive stresses. The stress is usually cycled between a maximum and a minimum tensile stress or between a maximum tensile stress and a maximum compressive stress. The latter is considered a negative tensile stress, is given an algebraic minus sign, and is therefore known as the minimum stress.

Applied stresses are described by three parameters. The mean stress, S_m, is the algebraic average of the maximum and minimum stresses in 1 cycle, $S_m = (S_{max} + S_{min})/2$. In the completely reversed cycle test, the mean stress is zero. The range of stress, S_r, is the algebraic difference between the maximum and minimum stresses in 1 cycle, $S_r = S_{max} - S_{min}$. The stress amplitude, S_a, is one-half the range of stress, $S_a = S_r/2 = (S_{max} - S_{min})/2$.

During a fatigue test, the stress cycle is usually maintained constant so that the applied stress conditions can be written $S_m \pm S_a$, where S_m is the static or mean stress, and S_a is the stress amplitude, which is equal to half the stress range. The nomenclature used to describe test parameters involved in cyclic stress testing is shown in Fig. 2.

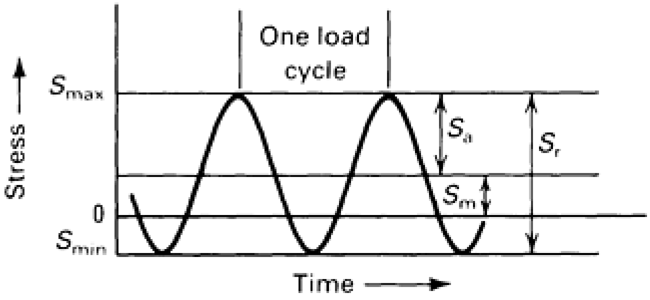

Fig. 2 Nomenclature used to describe test parameters involved in cyclic stress testing

The stress ratio is the algebraic ratio of two specified stress values in a stress cycle. Two commonly used stress ratios are the ratio A of the stress amplitude to the mean stress ($A = S_a/S_m$) and the ratio R of the minimum stress to the maximum stress ($R = S_{min}/S_{max}$).

If the stresses are fully reversed, the stress ratio R becomes -1; if the stresses are partially reversed, R becomes a negative number less than 1. If the stress is cycled between a maximum stress and no load, R becomes 0. If the stress is cycled between two tensile stresses, R becomes a positive number less than 1. A stress ratio R of 1 indicates no variation in stress, making the test a sustained-load SCC test rather than a corrosion-fatigue test.

Presentation of Fatigue Data

High-cycle fatigue data are presented graphically as stress, S, versus cycles to failure, N, in S-N, diagrams or S-N curves.

***S-N* Curves.** The results of fatigue cycles to failure tests are usually plotted as maximum stress, minimum stress, or stress amplitude versus number of cycles, N, to failure, using a logarithmic scale for the number of cycles. Stress is plotted on either a linear or a logarithmic scale. The resulting plot of the data is termed an S-N curve. Three typical S-N curves are shown in Fig. 3.

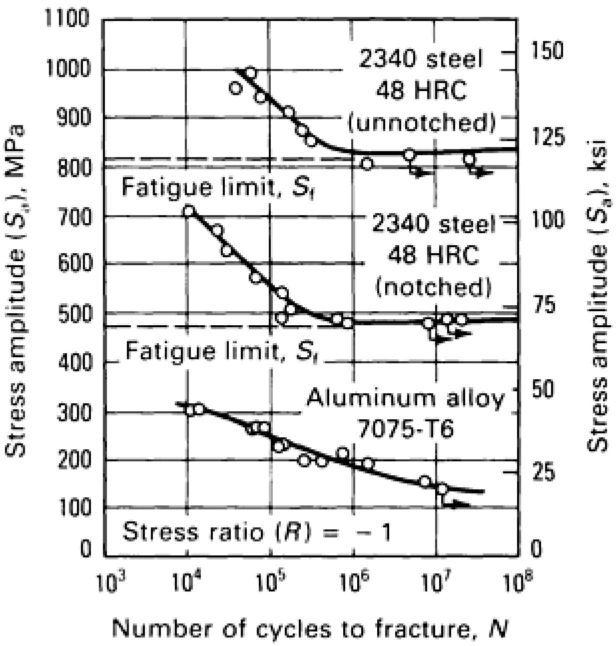

Fig. 3 Typical *S-N* curves for constant amplitude and sinusoidal loading

Fatigue Limit and Fatigue Strength. The horizontal portion of an *S-N* curve represents the maximum stress that the metal can withstand for an infinitely large number of cycles with 50% probability of failure. This maximum stress is known as the fatigue (endurance) limit, S_f. Most nonferrous metals do not exhibit a fatigue limit. Instead, their *S-N* curves continue to drop at a slow rate at high numbers of cycles, as shown by the curve for aluminum alloy 7075-T6 in Fig. 3.

For these types of metals, fatigue strength, rather than fatigue limit, is reported. Fatigue strength is the stress to which the metal can be subjected for a specified number of cycles. Because there is no standard number of cycles, each table of fatigue strengths must specify the number of cycles for which the strengths are reported. The fatigue strength of nonferrous metals at 10^8 or 5×10^8 cycles is sometimes erroneously called the fatigue limit.

Low-Cycle Fatigue. For the low-cycle fatigue region ($N < 10^4$ cycles), tests are conducted with controlled cycles of elastic plus plastic (total) strain range, rather than with controlled load or stress cycles. Under controlled-strain testing, fatigue life behavior is represented by a log-log plot of the total strain range, $\Delta\epsilon_t$, versus the number of cycles to failure (Fig. 4).

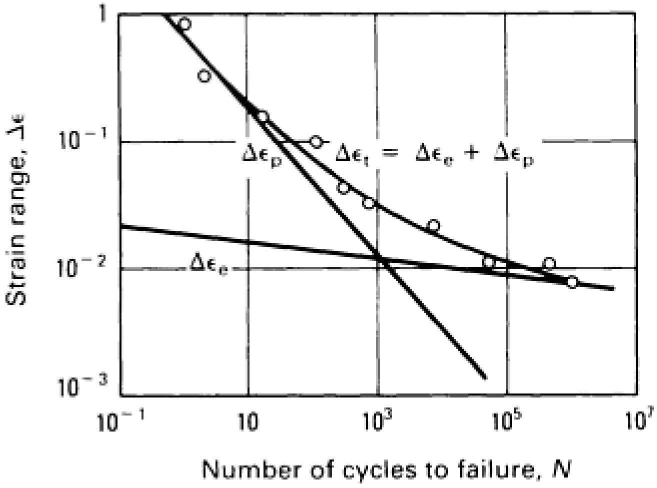

Fig. 4 Typical plot of strain range versus cycles-to-failure for low-cycle fatigue.

The total strain range may be separated into elastic and plastic components. For many metals and alloys, the elastic strain range, $\Delta\epsilon_c$, is equal to the stress range divided by the modulus of elasticity. The plastic strain range, $\Delta\epsilon_p$, is the difference between the total strain range and the elastic strain range.

When lines of curves are presented with fatigue data, the equation and the method of the fit should be indicated. Any presentation of corrosion fatigue data should include the following pertinent information, when applicable, regarding the material and the test:

- Material identification (product form)
- Tensile strength
- Orientation of the specimen
- Surface condition
- Notch description (stress concentration factor)
- Type of fatigue test (mode of loading)
- Controlled test parameters
- Stress ratio
- Stress cycle frequency
- Stress wave shape
- Test temperature and environment

Fatigue Test Specimens

A typical fatigue test specimen has three areas: the test section and the two grip ends. The grip ends are designed to transfer load from the test machine grips to the test section and may be identical, particularly for axial fatigue tests. The transition from the grip ends to the test area is designed with large, smoothly blended radii to eliminate any stress concentrations in the transition.

The design and type of specimen used depend on the fatigue-testing machine used and the objective of the fatigue study. The test section in the specimen is reduced in cross section to prevent failure in the grip ends and should be proportioned to use the middle to upper ranges of the load capacity of the fatigue machine, that is, to avoid very low load amplitudes where sensitivity and response of the system are decreased. Several types of fatigue test specimens are illustrated in Fig. 5.

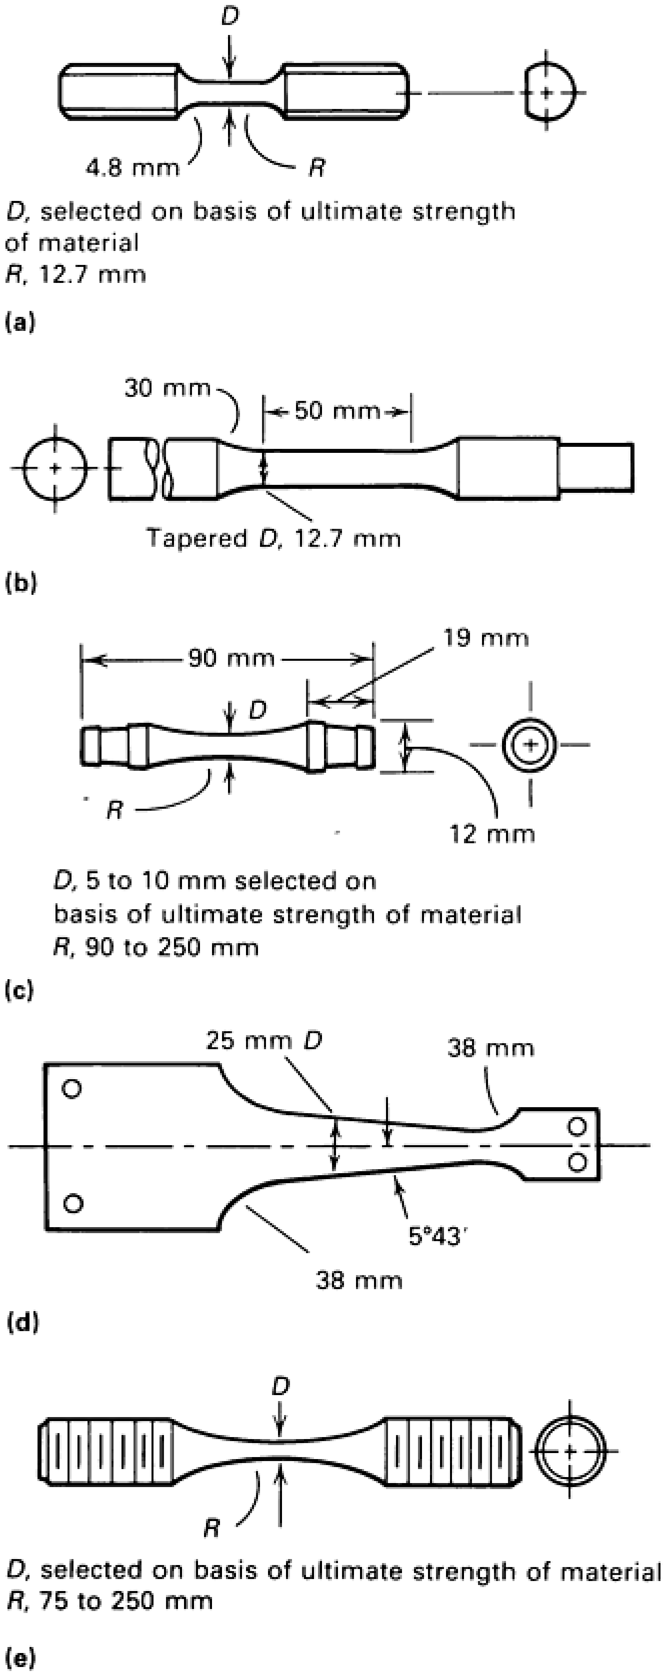

Fig. 5 Typical fatigue test specimens. (a) Torsional specimen. (b) Rotating cantilever beam specimen. (c) Rotating beam specimen. (d) Plate specimen for cantilever reverse bending. (e) Axial loading specimen

Cylindrical Specimens. Three types of specimens with circular cross sections are commonly used:

- Specimens with a continuous radius between the grip ends with the minimum diameter at the center (Fig. 5c and e); referred to as hourglass specimens
- Specimens with tangentially blending fillets between the test section and the grip ends (Fig. 5a)
- Specimens for use in cantilever beam loading with tapered diameters proportioned to produce nominally constant stress along the test section (Fig. 5b)

The design of the grip ends depends on the machine design and the gripping devices used. Round specimens for axial fatigue machines may be threaded, buttonhead, or constant-diameter types for clamping in V-wedge pressure grips.

For rotating-beam machines, short, tapered grip ends with internal threads are used, and the specimen is pulled into the grip by a draw bar. A long constant-diameter grip end shank is used on machines with lathe-type collet chucks as grips. Torsional fatigue specimens are generally cylindrical; however, there is usually a flat or keyway in the grip ends to transmit torque from the machine into the specimen (Fig. 5a).

Flat Sheet and Plate Specimens. Generally, flat specimens for either axial or bending fatigue tests are reduced in width in the test section, but may have thickness reductions. The most commonly used types include:

- Specimens with tangentially blending fillets between the test section and the grip ends; used in both axial and bending fatigue tests
- Specimens with a continuous radius between the grip ends; also used in both axial and bending fatigue tests
- Specimens for use in cantilever reverse bending tests with tapered widths (Fig. 5d).

Flat specimens are generally clamped in flat wedge-type grips, or they can be held with a stiff bolted clamp/joint friction grip for reversed axial loading. Pin loading can be used when compression loads are not encountered. When pin loading is used, the holes drilled in the grip end must be designed to avoid shear or bearing failures at the holes, tensile failure between the holes at maximum load, and fatigue cracking at the holes in the grip end. In the axial fatigue testing of flat sheet specimens, the test length must be designed to prevent premature buckling of the specimen.

Effect of Test Specimen Size (Ref 15)

It is difficult to predict the fatigue performance of large machine members directly from the results of laboratory tests on small specimens. In most cases, a size effect exists; that is, the fatigue strength of large members is lower than that of small specimens. Precise determination of this phenomenon is difficult. It is extremely difficult to prepare geometrically similar specimens of increasing diameter that have the same metallurgical structure and residual stress distribution throughout the cross section. The problems in fatigue testing of large specimens re considerable, and few fatigue machines can accommodate specimens with a wide range of cross sections.

Changing the size of a fatigue specimen usually results in variations of two factors. First, increasing the diameter increases the volume or surface area of the specimen. The change in amount of surface is significant because fatigue failures usually initiate at the surface. Second, for plain or notched specimens loaded in bending or torsion, an increase in diameter usually decreases the stress gradient across the diameter and increases the volume of material that is highly stressed.

Experimental data on the size effect in fatigue typically show that the fatigue limit decreases with increasing specimen diameter. The data for steel shafts tested in reversed bending given in Table 1 show that the fatigue limit can be appreciably reduced in large section sizes.

Table 1 Effect of specimen size on the fatigue limit of normalized plain carbon steel in reversed bending

Specimen diameter		Fatigue limit	
mm	**in.**	**MPa**	**ksi**
7.6	0.30	248	36
38	1.50	200	29
152	6.00	144	21

Source: Ref 16

No size effect was found for smooth fatigue specimens of plain carbon steel with diameters ranging from 5 to 35 mm (0.2 to 1.4 in.) when tested in axial tension-compression loading (Ref 17). However, when a notch was introduced into the specimen, so that a stress gradient was produced, a definite size effect was observed. Therefore, it can be concluded that a size effect in fatigue is primarily due to the existence of a stress gradient.

The fact that large specimens with shallow stress gradients have lower fatigue limits supports the concept that a critical value of stress must be exceeded over a given finite depth of material for failure to occur. This appears to be a more realistic criterion of size effect than the ratio of the change in surface area to the change in specimen diameter. The importance of stress gradients in size effect explains why correlation between laboratory results and service failure is often poor. Actual failures in large parts are usually directly related to stress concentrations, either intentional or accidental, and it is usually impossible to duplicate the same stress concentration and stress gradient in a small laboratory specimen.

Effect of Stress Concentration

Fatigue strength is significantly reduced by the introduction of a stress raiser, such as a notch, hole, or corrosion pit. Because actual machine elements invariably contain such stress raisers as fillets, keyways, screw threads, press fits, and holes, fatigue cracks in structural parts usually initiate at such geometrical irregularities.

An optimal means of minimizing fatigue failure is the reduction of avoidable stress raisers through careful design and the prevention of accidental stress raisers by careful machining and fabrication. Stress concentration can also arise from surface roughness and metallurgical stress raisers, such as porosity, inclusions, local overheating in grinding, and decarburization. Some of these conditions will be discussed in the section "Surface Effects and Fatigue" in this article.

The effect of stress raisers on fatigue is generally studied by testing specimens containing a notch, usually a V-notch or a U-notch. The presence of a notch in a specimen under uniaxial load introduces three effects:

- There is an increase or concentration of stress at the root of the notch
- A stress gradient is set up from the root of the notch toward the center of the specimen
- A triaxial state of stress is produced at the notch root

The ratio of the maximum stress in the region of the notch (or other stress concentration) to the corresponding nominal stress is the stress concentration factor, K_t. In some situations, values of K_t can be calculated by using the theory of elasticity or can be measured by using photoelastic plastic models. Values for K_t are reported in Ref 18, 19, 20, and 21.

The effect of notches on fatigue strength is determined by comparing the *S-N* curves of notched and unnotched specimens (Fig. 3). The data for notched specimens are usually plotted in terms of nominal stress based on the net cross section of

the specimen. The effectiveness of the notch in decreasing the fatigue limit is expressed by the fatigue notch factor, K_f. This factor is the ratio of the fatigue limit of unnotched specimens to the fatigue limit of notched specimens.

For materials that do not exhibit a fatigue limit, the fatigue notch factor is based on the fatigue strength at a specified number of cycles. Values of K_f have been found to vary with the severity of the notch, the type of notch, the material, the type of loading, and the stress level. The published values of K_f are subject to considerable variability and should be carefully examined for their limitations and restrictions. However, two general trends are usually observed for test conditions of completely reversed loading. First, K_f is usually less than K_t, and second, the ratio of K_f/K_t decreases as K_t increases.

The notch sensitivity of a material in fatigue is expressed by a notch sensitivity factor, *q:*

$$q = \frac{K_f - 1}{K_t - 1} \quad \textbf{(Eq 1)}$$

A material that experiences no reduction in fatigue due to a notch ($K_f = 1$) has a factor of $q = 0$, but a material in which the notch has its full theoretical effect ($K_f = K_t$) has a factor of $q = 1$. However, q is not a true material constant, because it varies with the severity and type of notch, the size of the specimen, and the type of loading. As shown in Fig. 6, notch sensitivity increases with tensile strength. Therefore, it is sometimes possible to decrease fatigue performance by increasing the hardness or tensile strength of a material.

Surface Effects and Fatigue

Fatigue properties are generally very sensitive to surface conditions. Except in special cases involving internal defects or case hardening, all fatigue cracks initiate at the surface. Factors that affect the surface of a corrosion-fatigue specimen can be divided into four categories:

- Surface roughness or stress raisers at the surface
- Changes in the properties of the surface metal
- Changes in the residual stress condition of the surface
- Corrosion

Surface Roughness. In general, fatigue life increases as the magnitude of surface roughness decreases. Decreasing surface roughness minimizes local stress raisers. Therefore, special attention must be given to the surface preparation of fatigue test specimens. Typically, a metallographic finish, free of machining grooves and grinding scratches is required. Figure 7 illustrates the effects that various surface conditions have on the fatigue properties of steel.

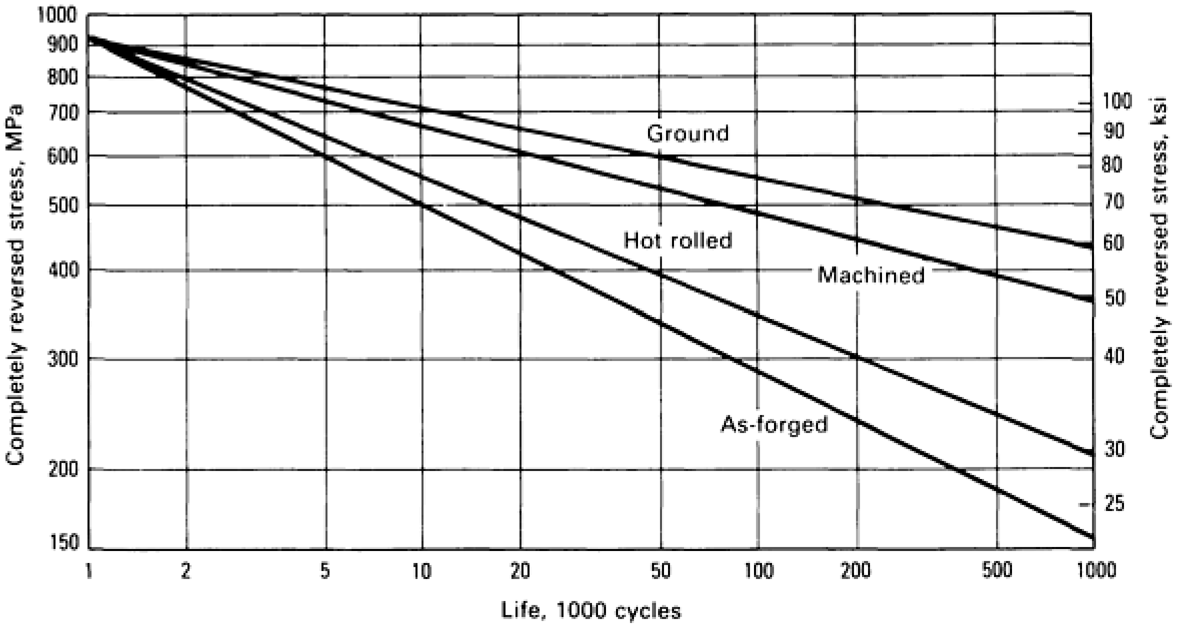

Fig. 7 Effect of surface conditions on the fatigue properties of steel (302 to 321 HB)

Changes in Surface Properties. Because fatigue failure is dependent on surface condition, any phenomenon that changes the fatigue strength of the surface material will greatly alter fatigue properties. Decarburization of the surface of heat-treated steel is particularly detrimental to fatigue performance. Similarly, the fatigue strength of aluminum alloy sheet is reduced when a soft aluminum coating (cladding) is applied to the stronger age-hardenable aluminum alloy sheet.

Marked improvements in fatigue properties can result from the formation of harder and stronger surfaces on steel parts by carburizing and nitriding (Ref 23). However, because favorable compressive residual stresses are produced in the surface by these processes, the higher fatigue properties are not exclusively due to the formation of higher-strength material on the surface. The effectiveness of carburizing and nitriding in improving fatigue performance is greater when a high stress gradient exists (as in bending or torsion) than in an axial fatigue test.

The greatest increase in fatigue performance occurs in notched fatigue specimens that are nitrided. The amount of strengthening depends on the diameter of the part and the depth of surface hardening. Improvements in fatigue properties similar to those caused by carburizing and nitriding may also be produced by flame hardening and induction hardening. In surface-hardened parts, failure initiates at the interface between the hard case and the softer core, rather than at the surface.

Electroplating of the surface generally decreases the fatigue limit of steel because the platings inherently contain cracks. The particular plating conditions used to produce an electroplated surface can have a significant effect on fatigue properties because large changes in the residual stress, adhesion, porosity, and hardness of the plate can be produced. Anodized coatings on aluminum alloys can be similarly detrimental to fatigue strength.

Surface Residual Stresses. Processing, such as grinding, polishing, and machining, that work hardens or increases residual stress on the surface can influence fatigue strength, although there is no generalization that predicts the extent of improved fatigue strength that can be derived from work hardening and residual stress. Compressive residual surface stresses generally increase fatigue strength, but tensile residual surface stresses do not. There may be a gradual decrease in residual stress if the cyclic stresses cause some plastic deformation. Compressive residual surface stress provides greater improvement in the fatigue strength of harder materials (such as alloy spring steel). In softer materials (such as low-carbon steel), work hardening effectively improves fatigue strength.

In a notched high-strength steel, the beneficial effect of prestretching and the detrimental effect of precompression are much greater than in a plain carbon steel because of the type of residual stress present at the notch. A compressive residual stress introduced during quenching from a tempering temperature will increase the fatigue strength, particularly in notched specimens.

In general, residual stresses are introduced by the poor fit of structural parts, a change in the specific volume of a metal accompanying phase changes, a change in shape following plastic deformation, or thermal stresses resulting from rapid temperature changes, such as occur in quenching. The influence of residual stress on fatigue strength is similar to that of an externally applied static stress. A static compressive surface stress increases the fatigue strength, and static tensile surface stress reduced it.

Specimen Preparation. Because both fatigue crack initiation and corrosion are typically surface dependent, proper machining and surface preparation of test specimens is critical. Unless care is taken, scatter caused by variable surface conditions will mask the scatter that is typical for the material being studied.

One of the primary aims of corrosion-fatigue testing is the comparison of materials. Therefore, uniform preparation procedures must be established. Machining operations must not alter the surface structure of the metal; therefore, heat generation, heavy cutting, and severe grinding are prohibited. For as-machined surfaces, the final machining should be transverse to the plane of stress. Transition fillets must be blended into the test area without steps or undercutting. Surface polishing using metallographic techniques is preferred for smooth specimens, in which machining marks are removed by a sequence of grinding steps.

The final polishing is not a buffing operation, but a cutting operation that uses lapping compounds or aluminum oxide powder in a liquid medium to remove grinding scratches. For flat sheet or plate specimens, edges should be slightly rounded and ground to eliminate nicks, dents, cuts, and sharp edges, which cause early crack initiation.

Environmental Effects and Fatigue

In corrosion fatigue, the magnitude of the cyclic stress and the number of times it is applied are not the only critical loading parameters. Time-dependent environmental effects are also of primary importance. When failure occurs by corrosion fatigue, stress cycle frequency, stress wave shape, stress amplitude, and stress ratio all affect the cracking processes, depending on the resistance to SCC of the material.

Environmental Effects on Fatigue Strength. For any given material, the fatigue strength, or fatigue life at a given value of maximum stress, generally decreases in the presence of an aggressive environment. This effect varies widely, depending primarily on the characteristics of the material/environment combination. The environment affects the probability of fatigue crack initiation, crack growth rate, or both. For many materials, the stress range required to cause fatigue failure diminishes progressively with increasing time and with the number of cycles of applied stress.

A corrosive environment can clearly reduce the crack initiation time by any form of localized attack to form a stress concentration. Corrosion attack would clearly be favored at new unfilmed metal surfaces formed at a persistent slip band. A clear example of the importance of stress concentration due to corrosion is illustrated in Fig. 8. which shows fatigue endurance results for plain and notched specimens of a 13% Cr ferritic steel in distilled water and salt water. These environments are seen to cause a massive reduction in the endurance limit of the smooth specimens but only a relatively modest effect on the notched specimens. The importance of surface finish and the adverse effect of corrosion, even when only allowed to occur before a fatigue test, is of course well known and included in standard texts on fatigue design (Ref 25).

Effect of Frequency and Stress Wave Form. In nonaggressive environments, cyclic frequency generally has little effect on fatigue behavior. On the other hand, in aggressive environments, fatigue strength is strongly dependent on frequency. Corrosion fatigue strength (endurance limit at a prescribed number of cycles) will generally decrease as the cyclic frequency is decreased. This effect is most important at frequencies less than 10 Hz.

The frequency dependence of corrosion fatigue is thought to result from the fact that the interaction of a material with its environment is essentially a rate-controlled process. Low frequencies, especially at low strain amplitudes or when there is substantial elapsed time between changes, in stress levels, allow time for interaction between material and environment; high frequencies do not, particularly when high strain amplitude is also involved.

The effect of stress frequency on low-cycle corrosion fatigue is also very dependent on susceptibility to SCC. For example, at low intermediate frequencies, material sensitive to SCC fractured by the propagation of fatigue cracks, but at lower frequencies, damage due to SCC during the period of maximum strain became greater and the fatigue strength at extremely low frequencies was markedly decreased. For materials that are insensitive to SCC, failure was due to the propagation of CFC in the entire range of stress frequencies tested (0.02 to 17.3 cycles/min, or cpm) (Ref 26).

Historically, CFC is not considered to be a problem at very high frequencies. However, a new ultrasonic frequency corrosion fatigue testing system has been developed for examining the corrosion fatigue strength of engineering materials in the very high cycle regime (10^9 to 10^{10} cycles) typical of many design lifetimes. Central to this resonant fatigue-testing system is a high-efficiency large-displacement, piezoelectric transducer that operates at a frequency of 20 kHz; this enables the accumulation of large numbers of cycles within a reasonable amount of time. The apparatus, environmental controls, and testing method are described in Ref 27.

Experimental 20-kHz and low-frequency corrosion fatigue results obtained with this method for a number of engineering materials, including a 12% Cr stainless steel, show similar reductions in fatigue limit at a specified number of cycles,

despite the difference in frequency. This results holds for a variety of aqueous environments with and without electrochemical controls imposed during testing. The data illustrate the capabilities of the ultrasonic corrosion fatigue technique and are analyzed to assess its advantages and limitations.

In some cases, corrosion fatigue strength is strongly affected by the stress wave form as well as by the stress frequency. The period of zero stress, the period during which the stress changes, and the period of application of maximum stress in a single cycle each have an effect on the specimen life. The damaging effect of the period during which the stress is changing is greatest, while the protective effect of the stress-free time decreases the corrosion fatigue damage.

Effect of Stress Amplitude. In general, a low amplitude of cyclic stress favors relatively long fatigue life, permitting greater opportunity for involvement of the environment in the fatigue process. However, environmental interaction may be insignificant unless the strain rate is in a critical range for SCC in certain alloy/environment systems.

Stress amplitude must be considered together with mean stress and frequency. Low stress levels may allow more time for environmental interaction, but if the frequency is high, the crack tip may not be exposed to the environment for a time sufficient for the corrosion processes to do significant damage.

Crack Propagation Tests

In large structural components, the existence of a crack does not necessarily imply imminent failure of the part. Significant structural life may remain in the cyclic growth of the crack to a size at which a critical failure occurs. The objective of corrosion fatigue crack propagation testing is to determine the rates at which subcritical cracks grow under cyclic loading before reaching a size that is critical for fracture under specified environmental conditions.

The article "Environmental Effects on Fatigue Crack Propagation" in *Mechanical Testing,* Volume 8 of *ASM Handbook,* formerly 9th Edition *Metals Handbook* contains information on the effects of environmental variables. Detailed information on specimen types, crack-measuring techniques, fatigue crack growth data analysis, and fracture mechanics is also available in Volume 8. The following discussion contains many excerpts from these excellent articles.

Fracture Mechanics Approach to Corrosion Fatigue

Fracture mechanics provides the basis for many modern fatigue crack growth studies. The growth or extension of a fatigue crack under cyclic loading is principally controlled by maximum load and stress ratio. However, as in crack initiation, there are a number of additional factors that may exert a strong influence, especially with the presence of an aggressive environment. Most CFC growth rate investigations attempt to follow the general provisions of standard test method ASTM E 647.

In this constant-load-amplitude method, crack length is measured visually or by an equivalent method as a function of elapsed cycles, and these data are subjected to numerical analysis to establish the rate of crack growth. Crack growth rates are then expressed as a function of crack tip stress intensity range ΔK, which is calculated from expressions based on linear-elastic stress analysis.

Background information on the rationale for employing linear-elastic fracture mechanics for this purpose is given in Ref 28. Expressing the crack growth rate da/dN as a function of ΔK provides results that are independent of specimen geometry, and this enables the exchange and comparison of data obtained from a variety of specimen configurations and loading conditions. Moreover, this feature enables da/dN versus ΔK data to be used in the design and evaluation of engineering structures. It is important in the generation of CFC growth data, however, that there be judicious selection, monitoring, and control of mechanical, chemical, and electrochemical test variables in order to ensure that the data are truly applicable to the intended use.

Results of fatigue crack growth rate tests for many metallic structural materials have shown that complete da/dN versus ΔK curves have three distinct regions of behavior (Fig. 9). In an inert (or benign) environment, the rate of crack growth depends strongly on K at K levels approaching K_c or K_{Ic} at the high end (Region III) and at levels approaching an apparent threshold, ΔK_{th}, at the lower end (Region I), with an intermediate Region II that depends on some power of K or ΔK of the order of 2 to 10 (Ref 28). This is described by the power-law relationship:

$$\frac{da}{dN} = C(\Delta K)^n \qquad \text{(Eq 2)}$$

where C and n are constants for a given material and stress ratio. In an aggressive environment, the CFC growth curve can be quite different from the pure fatigue curve, depending on the sensitivity of the material to the given environment and the occurrence of various static stress fracture mechanisms. The environmental effects are quite strong above some threshold for SCC (K_{ISCC}) and may be negligible below this level. In addition, certain loading factors, such as cyclic frequency, stress ratio, and stress wave form, can have marked effects on the crack growth curves in aggressive environments. Therefore, a variety of curves can be expected from the broad range of material-environment-loading systems that will produce various CFC behaviors.

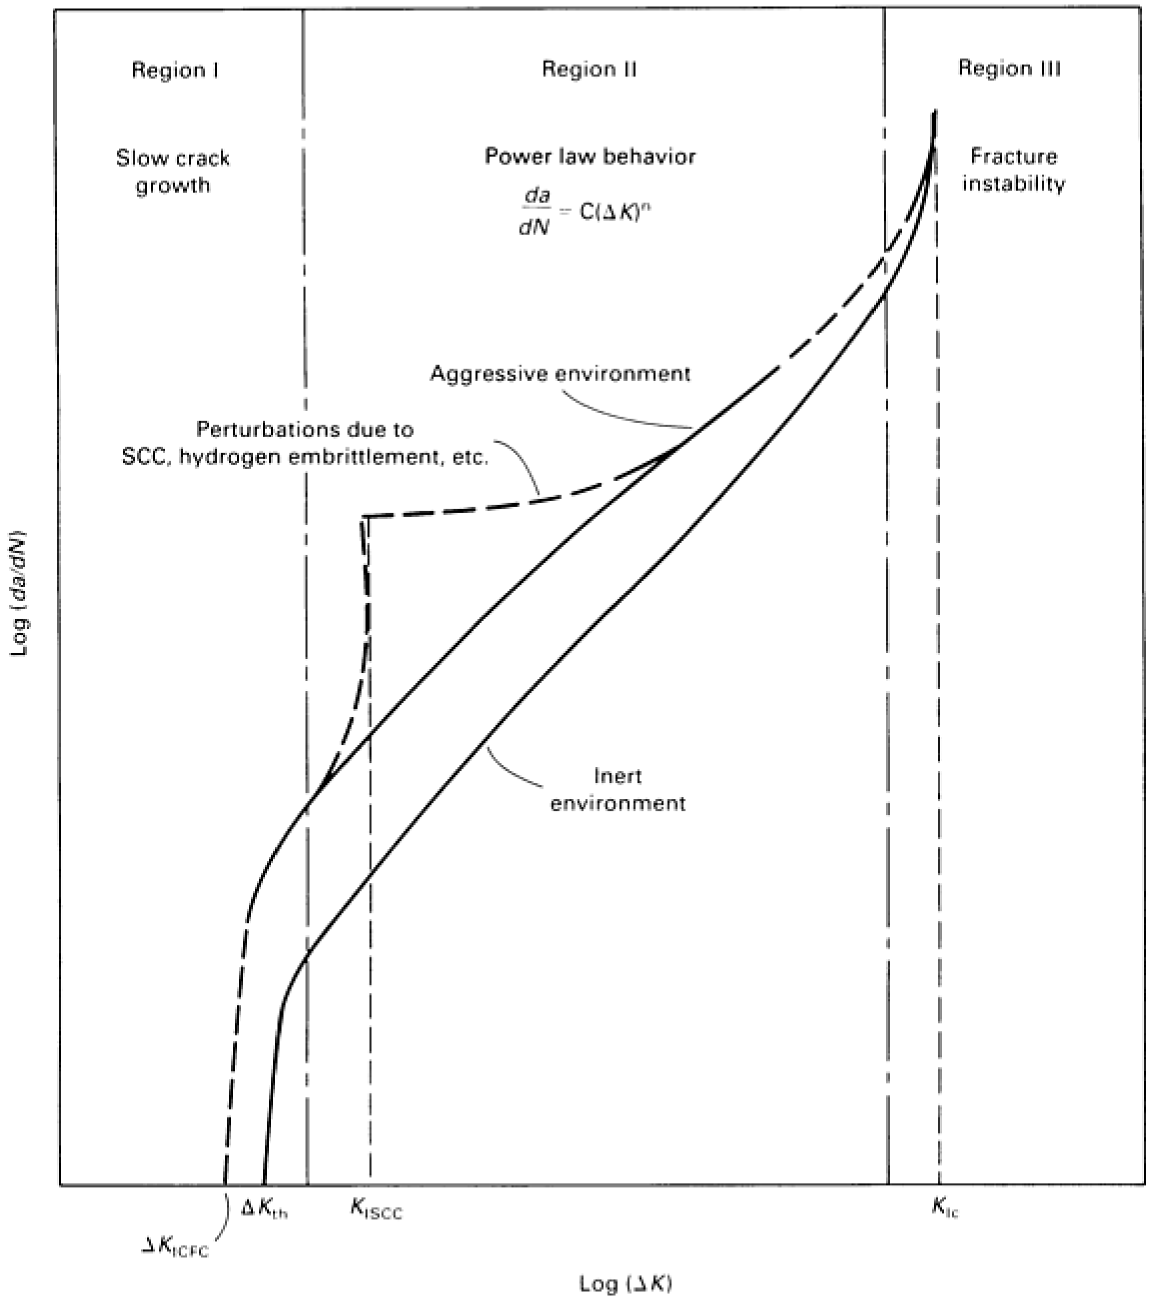

Fig. 9 Corrosion fatigue crack propagation rate as a function of the cyclic crack tip stress intensity factor. Source: Ref 29

Figure 10 shows an example of a high-strength aluminum alloy with a high resistance to SCC. This alloy had a CFC growth rate ranging up to one order of magnitude higher in 3.5% sodium chloride (NaCl) solution than that in dry air. These data also illustrate the similar behavior when tested with either a *K*-increasing (remote load) or a *K*-decreasing (wedge force) loading method.

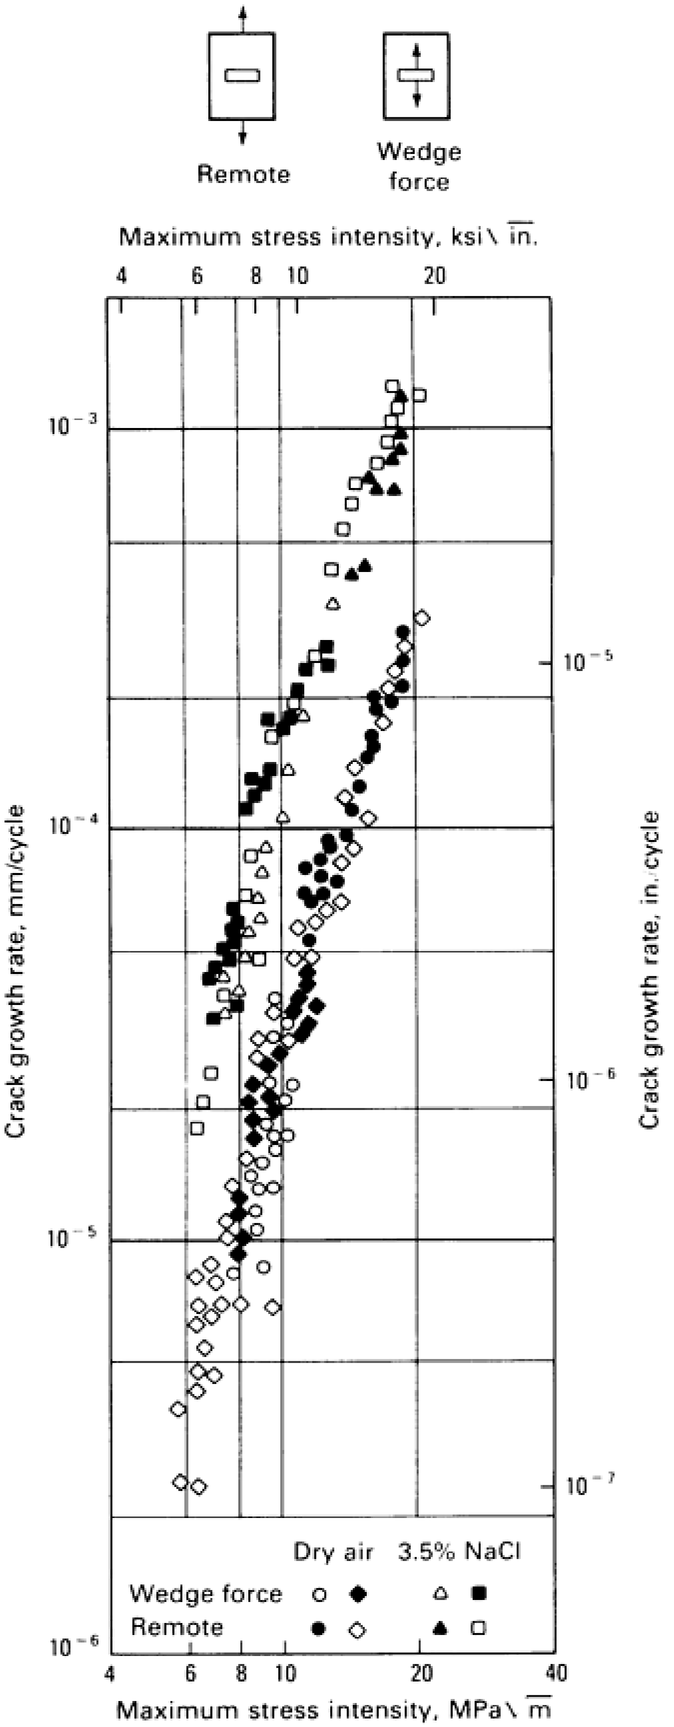

Fig. 10 Crack tip stress intensity control of fatigue crack propagation in 7075-T6 aluminum alloy sheet--long-transverse loading. Remote and wedge force methods of loading specimens in aqueous 3.5% sodium chloride

environment and benign dry air environment. Source: Ref 30

Corrosion fatigue growth rate versus stress intensity data have been extensively produced (Ref 2, 3, 4, 5, 6, 7, 8, 31, and 32) and can be used for mitigating corrosion fatigue from several perspectives. These laboratory crack growth rate data are scalable quantitatively for predicting component performance. The *da*/*dN* versus ΔK curve for a given material and environment is integrated in conjunction with the stress intensity solution for a component in order to predict life (Ref 28). A specific example reported in Ref 33 is illustrated in Fig. 11. The predicted 85-year life of a welded pipe is based on week-long laboratory measurements of *da*/*dN* versus ΔK for steel in an oil environment.

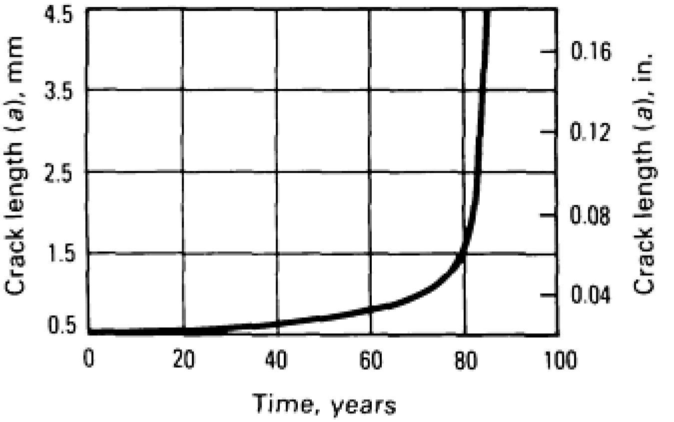

Fig. 11 Predicted fatigue crack extension from a weld toe crack in an API 5LX52 carbon steel pipeline carrying hydrogen sulfide contaminated oil. Temperature: 23 °C (73 °F). Source: Ref 33

Alloy development for optimized corrosion fatigue resistance, defined in terms of *da*/*dN* versus ΔK for different metallurgical conditions, is directly related to component life goals based on fracture mechanics. Similarly, the effects of mechanical and chemical variables on corrosion fatigue and component performance are defined through measured changes in growth rate at different applied stress intensity levels.

Crack growth rate data are important to fundamental studies of corrosion fatigue mechanisms. The fracture mechanics approach isolates crack propagation from initiation in terms of a precise near-tip mechanical driving force. ΔK. Crack growth rates are related directly to the kinetics of mass transport and the chemical reaction that constitute embrittlement. As shown in Fig. 12, prediction of the effect of loading frequency on crack growth rate in salt water (normalized to vacuum) identifies important rate-limiting crack tip electrochemical reactions. Modeling and measurements in Fig. 12 provide a sound basis for extrapolating short-term laboratory data in order to predict long-term component cracking.

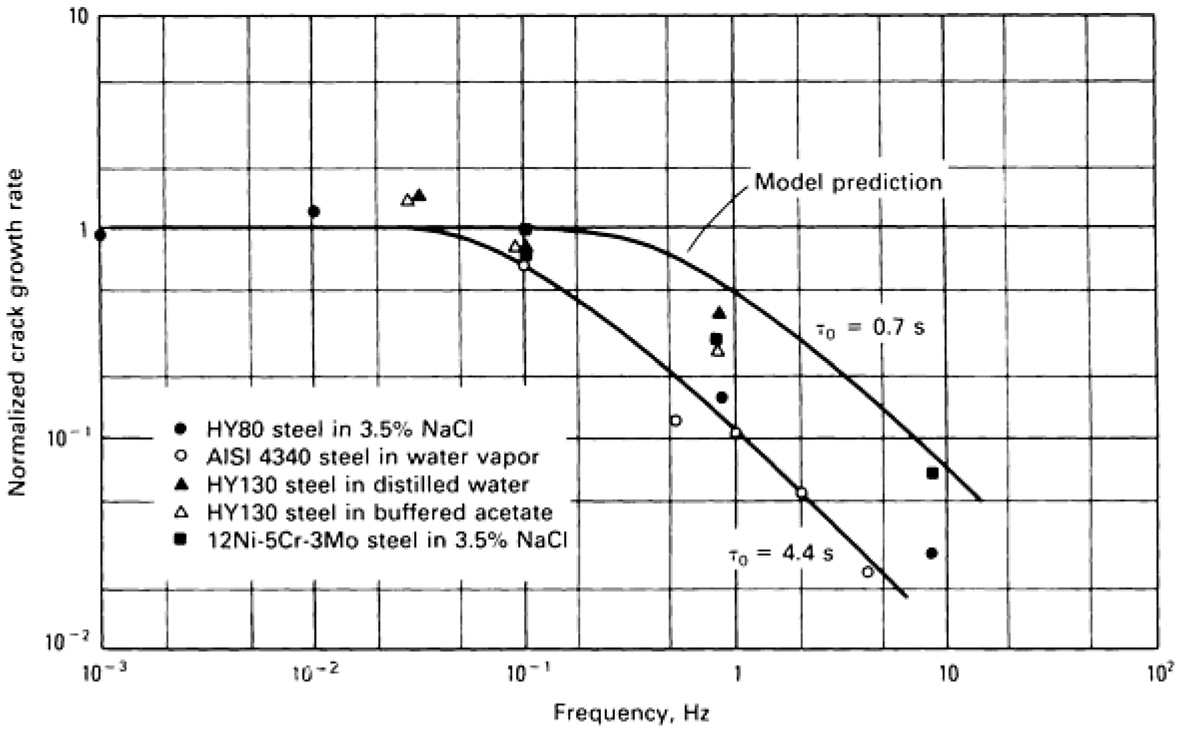

Fig. 12 Modeled effect of loading frequency on corrosion fatigue crack growth in alloy steels in an aqueous chloride solution. The determination of the normalized crack growth rate and the time constants, τ_0, from the model can be found in Ref 34.

The fracture mechanics approach to corrosion fatigue may be invalidated by several factors. Discussion in this article is limited to crack growth in conjunction with net section elastic loading and small-scale plasticity confined to the crack tip. Studies of crack growth under large-scale cyclic plasticity have not been extended to consider environmental effects (Ref 35, 36). Also, stress intensity provides a mechanical description of similitude, which may not completely describe crack growth due to interacting chemical and mechanical driving forces.*

Investigations of this phenomenon are currently underway. Results indicate that simple K-based approaches can be comprised for (1) small corrosion fatigue cracks below 5 mm (0.2 in.), cases in which varying crack shape and load transients alter crack chemistry and embrittlement, and (3) situations in which surface roughness or corrosion products impede crack displacement (Ref 37, 38, 39). References 35, 36, 37, 38, and 39 should be consulted if an application includes plasticity, small crack, load transient, or crack closure effects.

Variables Influencing Corrosion Fatigue

Although corrosion fatigue phenomena are diverse and specific to the environment, several variables are known to influence crack growth rate. The following factors must be considered in any study of corrosion fatigue:

- Stress intensity range
- Load frequency
- Stress ratio
- Aqueous environment electrode potential
- Environment composition
- Alloy composition, microstructure, and yield strength

Moreover, the effects of such variables, as temperature, load history and waveform, stress state, and environment composition may be unique to specific materials and environments.

Stress Intensity Range. Corrosion fatigue crack growth rates generally increase with increasing stress intensity; however, the precise dependence varies markedly. It is incorrect to assume that the three regimes (near threshold, power law, and fast fracture; see Fig. 9) of fatigue cracking observed for benign environments simply shift to higher crack speeds at all ΔK levels. Although such behavior may actually occur, as illustrated in Fig. 10 for the aluminum/dry air system, the data provided in Fig. 13 and 14 are more typical of complex stress intensity dependencies for aggressive environments.

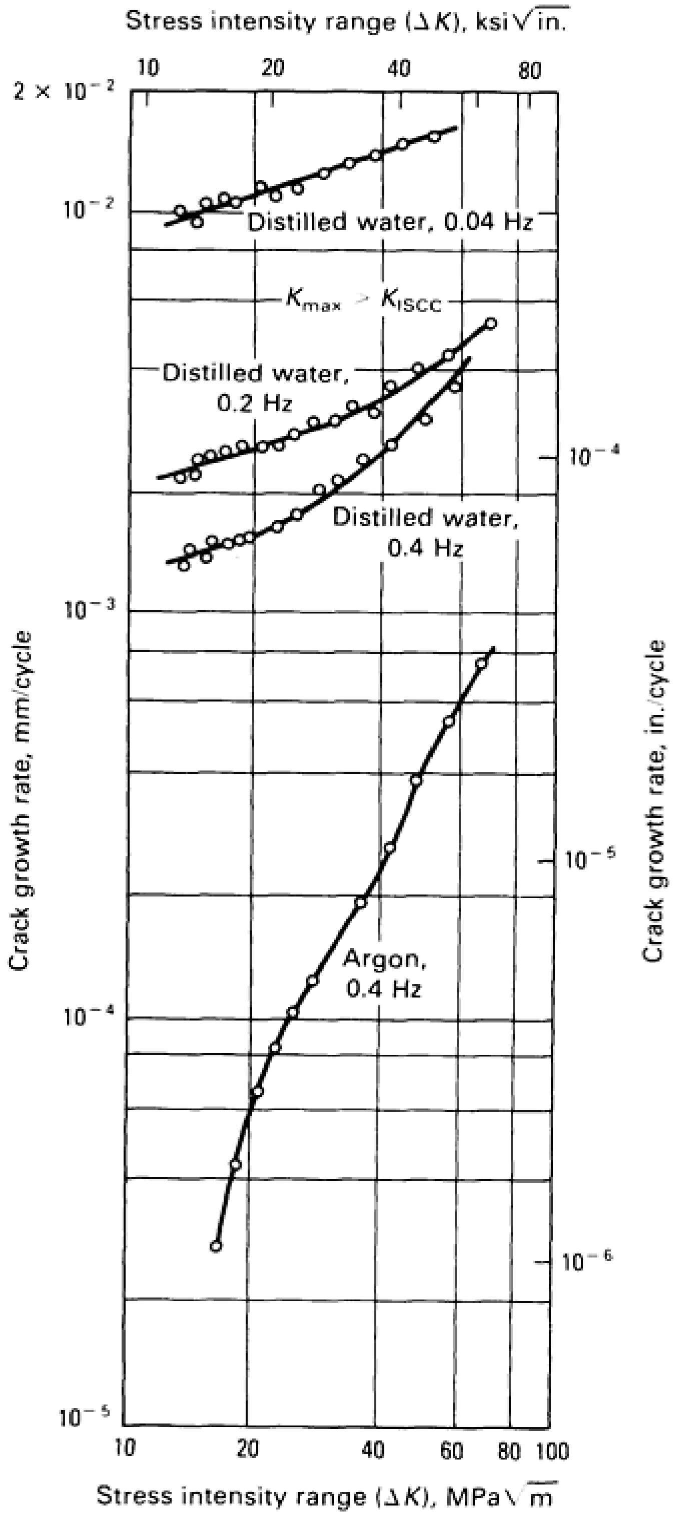

Fig. 13 Effect of stress intensity range and loading frequency on corrosion fatigue crack growth in ultrahigh-strength 4340 steel exposed to distilled water at 23 °C (73 °F). Source: Ref 40

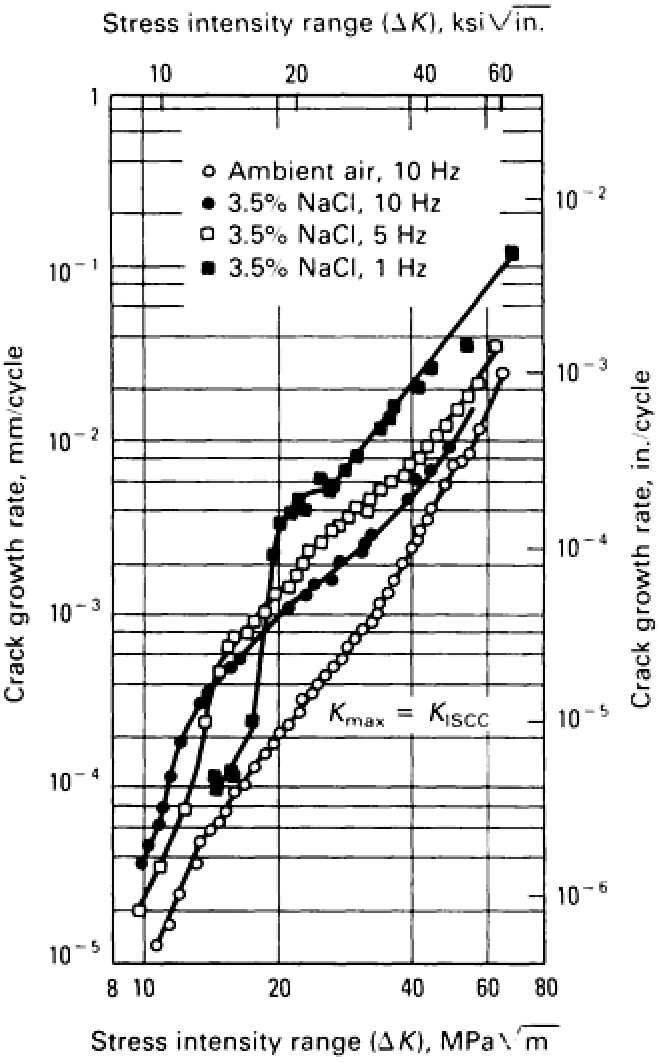

Fig. 14 Effects of stress intensity and frequency on corrosion fatigue in Ti-6Al-4V in aqueous sodium chloride at 23 °C (73 °F). Stress ratio: *R* = 0.1. Source: Ref 41

Materials that are extremely environment sensitive, such as ultrahigh-strength steel in distilled water (Fig. 13), are characterized by high crack growth rates that are influenced less by ΔK. Time-dependent corrosion fatigue crack growth occurs predominantly above the threshold stress intensity for static load cracking and is modeled through linear superposition of SCC and inert environment fatigue rates (Ref 28, 34). Time-dependent crack growth is the part of the crack extension that is attributable to the constant or rising-load portion of the cyclic load cycle, when SCC and hydrogen embrittlement mechanisms may be operative. Therefore, such factors as stress wave form and stress hold-time are particularly significant under such circumstances.

Cycle-dependent corrosion fatigue crack propagation often occurs below the threshold for time-dependent stress corrosion (Ref 41). Typical ΔK dependencies for this mode of cracking are complex, as illustrated in Fig. 14 for Ti-6Al-4V exposed to aqueous sodium chloride. The mechanistic implications of the various stress intensity dependencies are detailed in Ref 28, 41, and 42. The influences of such variables as frequency, stress ratio, and metallurgical factors depend on the proportions of time- and cycle-dependent corrosion fatigue.

Frequency. Cyclic load frequency is the most important variable that influences corrosion fatigue for most material, environment, and stress intensity conditions. The rate of environmental cracking above that produced in vacuum generally increases with decreasing frequency. Frequencies exist above which corrosion fatigue is diminished. The dominance of frequency is directly related to the time dependence of the mass transport and chemical reaction steps required for environmental cracking. Basically, insufficient time is available for chemical embrittlement at rapid loading rates;

damage is only mechanical and is equivalent to crack growth in vacuum. It is impossible to predict the frequency range at which corrosion fatigue is severe, because of the numerous chemical processes. It is also difficult to extrapolate short-term (high-frequency) laboratory crack growth rate data in order to predict long-term component performance.

The literature provides qualitative guidance in terms of frequency effects on corrosion fatigue. Crack growth in environmentally sensitive materials stressed above the stress-corrosion threshold proceeds at rapidly increased rates with decreasing frequency, as illustrated in Fig. 13. The frequency effect is predicted through the integration of static load data throughout each fatigue cycle (Ref 34). For such systems, the chemical contribution to fatigue cracking is suppressed above 0.5 to 5 Hz, with higher critical frequencies associated with more aggressive environments and sensitive microstructures.

Frequency effects on cycle-dependent cracking are complex and unpredictable. The data given in Fig. 12 and 14 provide typical examples. For steels in salt water (Fig. 12), corrosion fatigue is suppressed at about 10 Hz. Crack speed increases with decreasing frequency and reaches a plateau between 0.5 and 0.1 Hz. In contrast, corrosion fatigue in Ti-6Al-4V occurs at loading frequencies at least as high as 10 Hz (Fig. 14).

Stress Ratio. The rates of corrosion fatigue crack propagation generally are increased by higher stress ratios. The deleterious effect of increased stress ratio is illustrated in Fig. 15 for carbon steel stressed cyclically in pressurized nuclear reactor water at 288 °C (550 °F). The extent of the corrosion fatigue effect relative to dry air increased from about a factor of four at low R (0.11 to 0.24) to as much as 20- to 30-fold at high R (0.61 to 0.71) (Ref 43). Corrosion fatigue in this system probably proceeds by repeated passive film formation and rupture. Increased stress ratio at constant ΔK results in increased crack tip strain and strain rate, enhanced film rupture, and therefore increased corrosion fatigue crack propagation (Ref 44).

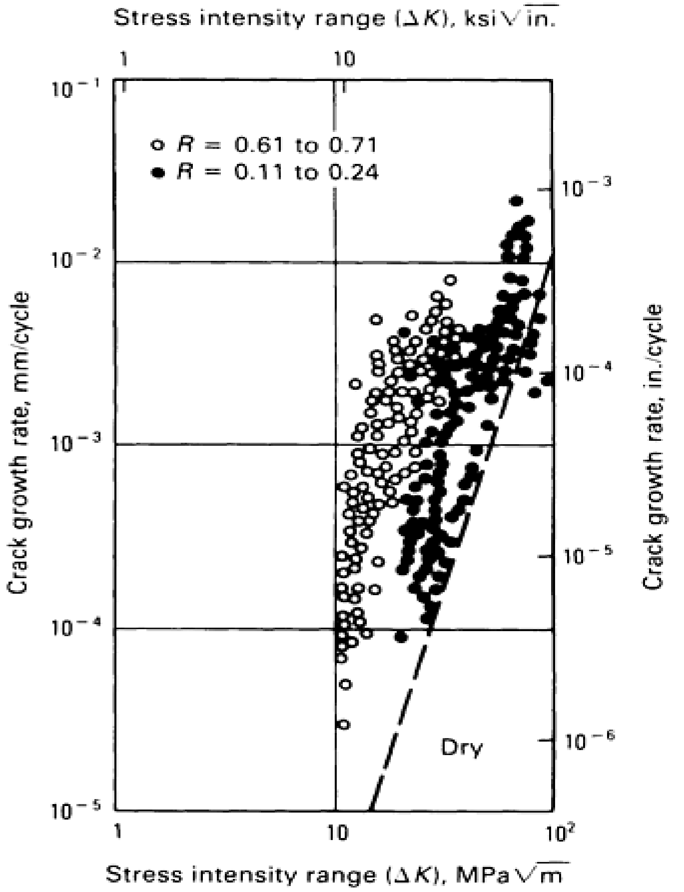

Fig. 15 Effect of stress ratio on corrosion fatigue crack propagation in ASTM A533 B and A508 carbon steels exposed to pressurized high-purity water at 288 °C (550 °F). Frequency: 0.017 Hz. Average behavior in air is represented by the dashed line labeled "Dry." Source: Ref 43

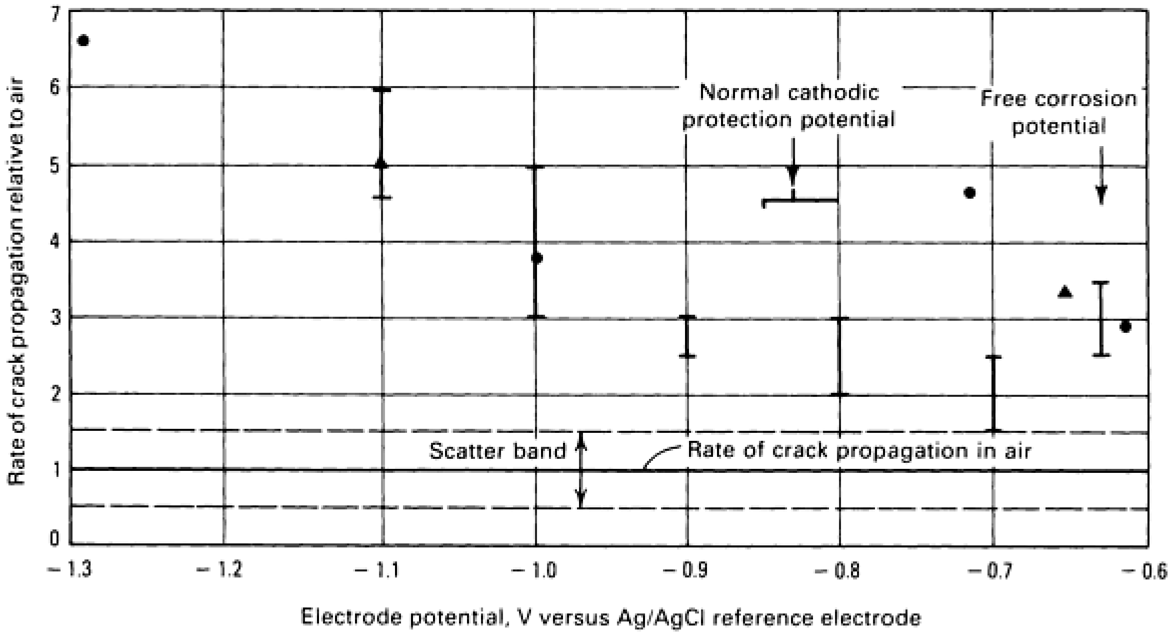
Electrode Potential. Like loading frequency, electrode potential strongly influences rates of corrosion fatigue crack propagation for alloys in aqueous environments. Controlled changes in the potential of a specimen can result in either the complete elimination or the dramatic increase of fatigue cracking. The precise influence depends on the mechanism of the environmental effect and on the anodic or cathodic magnitude of the applied potential.

For ferrous alloys that crack by hydrogen embrittlement when stressed in aqueous solutions, corrosion fatigue is increased by high cathodic polarization from the free corrosion potential. Specific data are given in Fig. 16 for three steels stressed at constant ΔK in aqueous chloride (Ref 35, 45, 46). For each steel, the crack growth rate in salt water is about three times faster than that reported for air at the free corrosion potential and is enhanced by a factor of five at a very high cathodic potential. For the low-strength BS4360:50D grade, intermediate potentials appear to be mildly beneficial. Corrosion fatigue parallels electrode potential induced changes in the amount of cathodically evolved hydrogen in the crack tip. Precise modeling of this reaction sequence is complex and only partially completed (Ref 47).



Material tested	Symbol	Yield strength		Environment	Ref
		MPa	**ksi**		
BS4360:50D	I	450	65	Seawater	44
HY80	•	600	85	3% NaCl	45

Fig. 16 Effect of applied electrode potential on corrosion fatigue crack propagation in several steels exposed to seawater or 3% sodium chloride at constant ΔK between 20 and 40 MPa $\sqrt{m}$ (18 and 36 ksi $\sqrt{in.}$). Temperature: 23 °C (73 °F); frequency: 0.1 Hz; stress ratio: *R* = 0.1

Electrode potential control can suppress corrosion fatigue for alloys that crack through anodic dissolution/film rupture or anion adsorption mechanisms (Ref 48). For example, corrosion fatigue of austenitic stainless steel in chloride solutions at elevated temperatures is probably suppressed by polarization active to the critical potential for SCC.

Another example is illustrated in Fig. 17. Aluminum alloy 7079-T651 is degraded by corrosion fatigue in several aqueous halide solutions at the free corrosion potential. Compared to dry argon, cracking in potassium iodide is enhanced by more than an order of magnitude. The CFC growth rate was further increased by anodic polarization above about -0.6 V versus standard hydrogen electrode, but is suppressed by cathodic polarization.

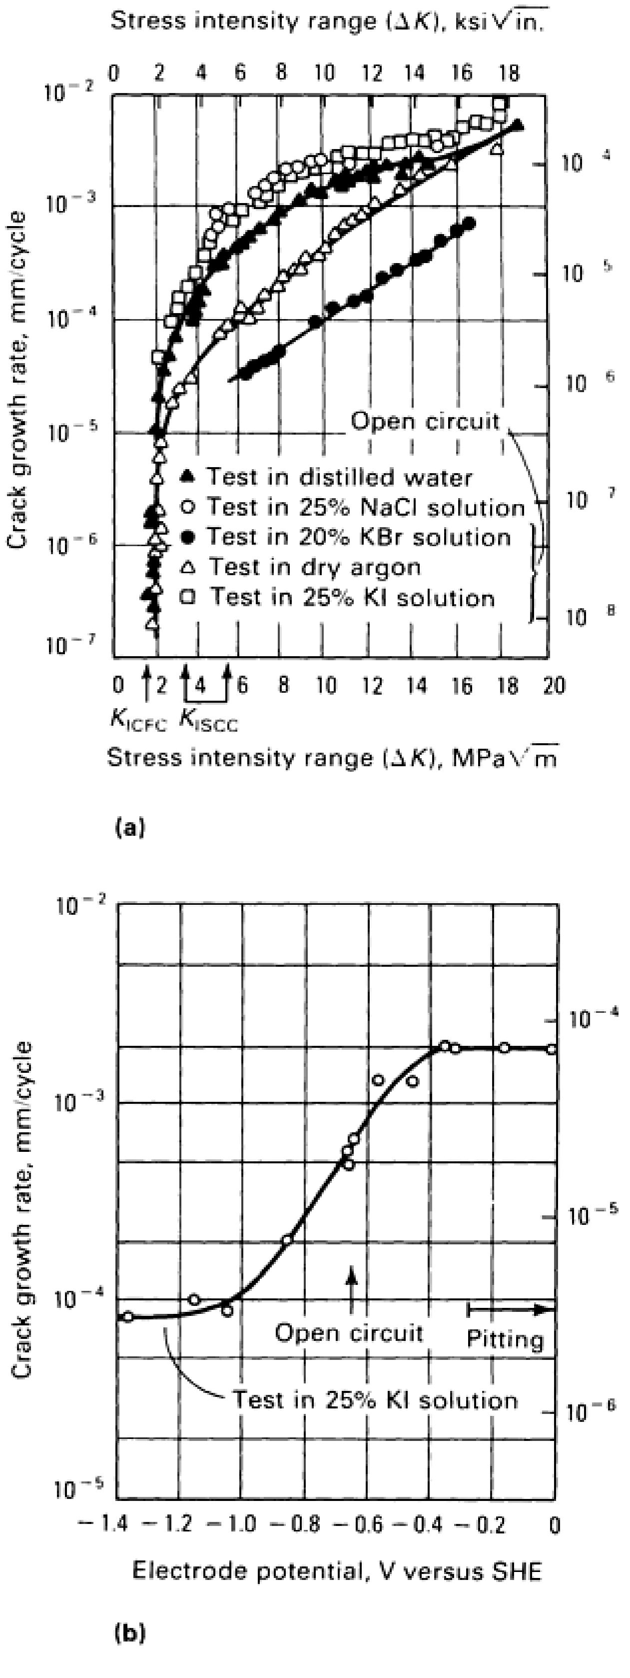


Fig. 17 Corrosion fatigue behavior of aluminum alloy 7079-T651 plate (S-L orientation). Temperature: 23 °C (73 °F); frequency: 4 cycles/s; stress ratio: R = 0. (a) Effect of stress intensity range on crack growth rate. K_{ICFC} and a range of K_{ISCC} are indicated at the bottom. (b) Effect of electrode potential at ΔK of 6.7 MPa $\sqrt{m}$ (6 ksi $\sqrt{in.}$) in 25% potassium iodide solution. Source: Ref 49

Electrode potential should be monitored and, if appropriate, maintained constant during corrosion fatigue experimentation. Apparent effects of variables, such as the dissolved oxygen content of the solution, flow rate, ion concentration, and alloy composition on corrosion fatigue, can often be traced to changing electrode potential.

Crack Closure Effects. Premature crack surface contact during unloading, or crack closure, can greatly reduce rates of fatigue crack propagation. The true (or effective) crack tip driving force is reduced below the applied ΔK because of the reduced crack tip displacement range. Closure phenomena are produced by a variety of mechanisms and are particularly relevant to fatigue crack propagation in the near-threshold regime, after large load excursions, or for embrittling corrosive mechanisms, as reviewed in Ref 37, 50, and 51.

Two mechanisms of crack closure are relevant to corrosion fatigue. Rough, intergranular crack surfaces, typical of environmental embrittlement, promote crack closure because uniaxially loaded cracks open in a complex three-dimensional mode, thus allowing for surface interactions and load transfer. Roughness-induced closure is most relevant to corrosion fatigue at low ΔK and at stress ratio levels at which absolute crack opening displacements (0.5 to 3 μm) are less than fractured grain heights (5 to 50 μm).

Alternatively, crack closing is impeded by dense corrosion products within the pulsating fatigue crack. For mildly oxidizing environments, such as moist air, this closure mechanism is relevant at low stress intensity levels and contributes to the formation of a threshold, as described in Ref 51.

For corrosive bulk environments, cracking at high ΔK values may be retarded below growth rates observed for air or vacuum due to corrosion product formation within the crack. The engineering significance of beneficial crack closure influences depends on the stability of the corrosion product during complex tension-compression loading and fluid conditions. The beneficial effects of environmentally induced crack closure are reported in the literature for several material environment systems.

An example of crack closure is presented in Fig. 18 for ASTM A471 steel exposed to either moist air or steam at 100 °C (212 °F). Crack growth is reduced for the latter environment because of crack surface oxidation and enhanced closure. It should be noted that oxide-induced closure influences cracking even at a relatively high stress ratio of 0.35. The data presented in Fig. 18 were obtained at a high loading frequency of 100 Hz. Chemically enhanced crack growth is essentially precluded.

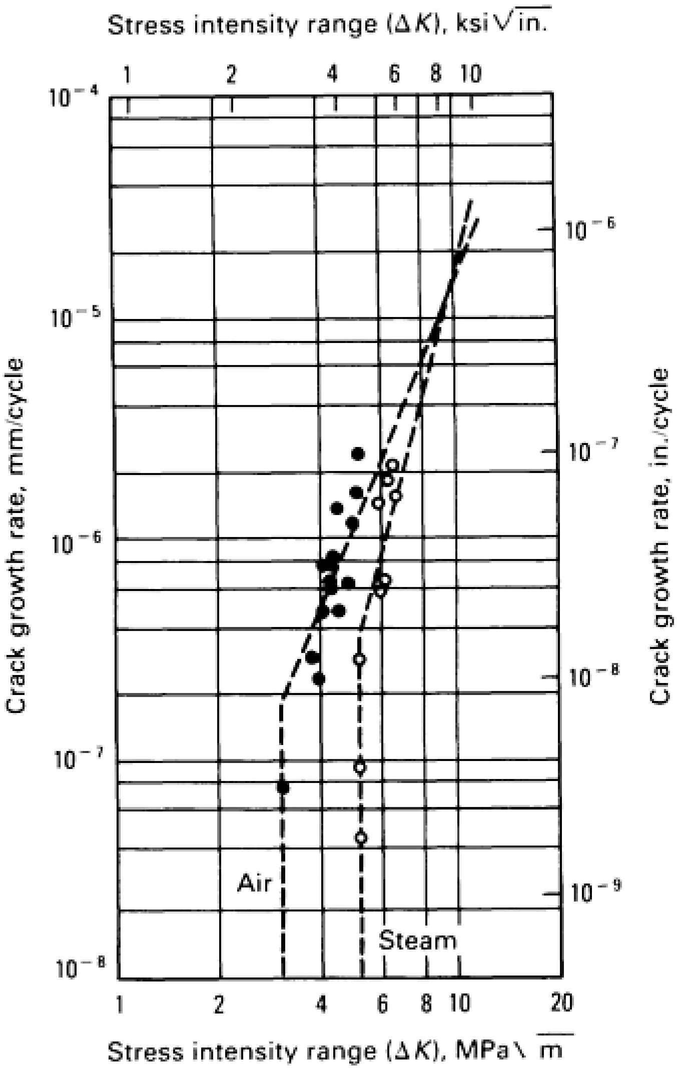

Fig. 18 Corrosion fatigue crack propagation in ASTM A471 steel exposed to moist air and steam. Temperature: 100 °C (212 °F); frequency: 100 Hz; stress ratio: *R* = 0.35. Source: Ref 52

Crack growth at lower frequencies could be deleteriously influenced by metal embrittlement and beneficially influenced by increased oxide formation and closure. The complexity of predicting environmentally enhanced cracking is clear, as emphasized by data given in Fig. 19 for a 2.25Cr-1Mo steel (ASTM A542, class 3) stressed in dry hydrogen at 23 °C (73 °F). At high ΔK levels and low loading frequencies, cracking was accelerated in hydrogen as compared to moist air; this is due to classical hydrogen embrittlement. For low stress intensities, cracking was also increased by hydrogen exposure; however, the effect is not due to hydrogen embrittlement because of the rapid loading frequencies. Oxides form on crack surfaces through a fretting mechanism during cycling in air, and crack growth rates are reduced by oxide-induced closure. However, oxide formation is precluded for cycling in pure hydrogen, crack closure is absent, and growth rates are increased relative to those in moist air. Equally rapid rates of fatigue cracking have been reported for low ΔK cycling in hydrogen and in helium. Equal rates of cracking are observed for hydrogen, helium, and moist air at high *R* levels where closure is absent (Ref 50, 51).

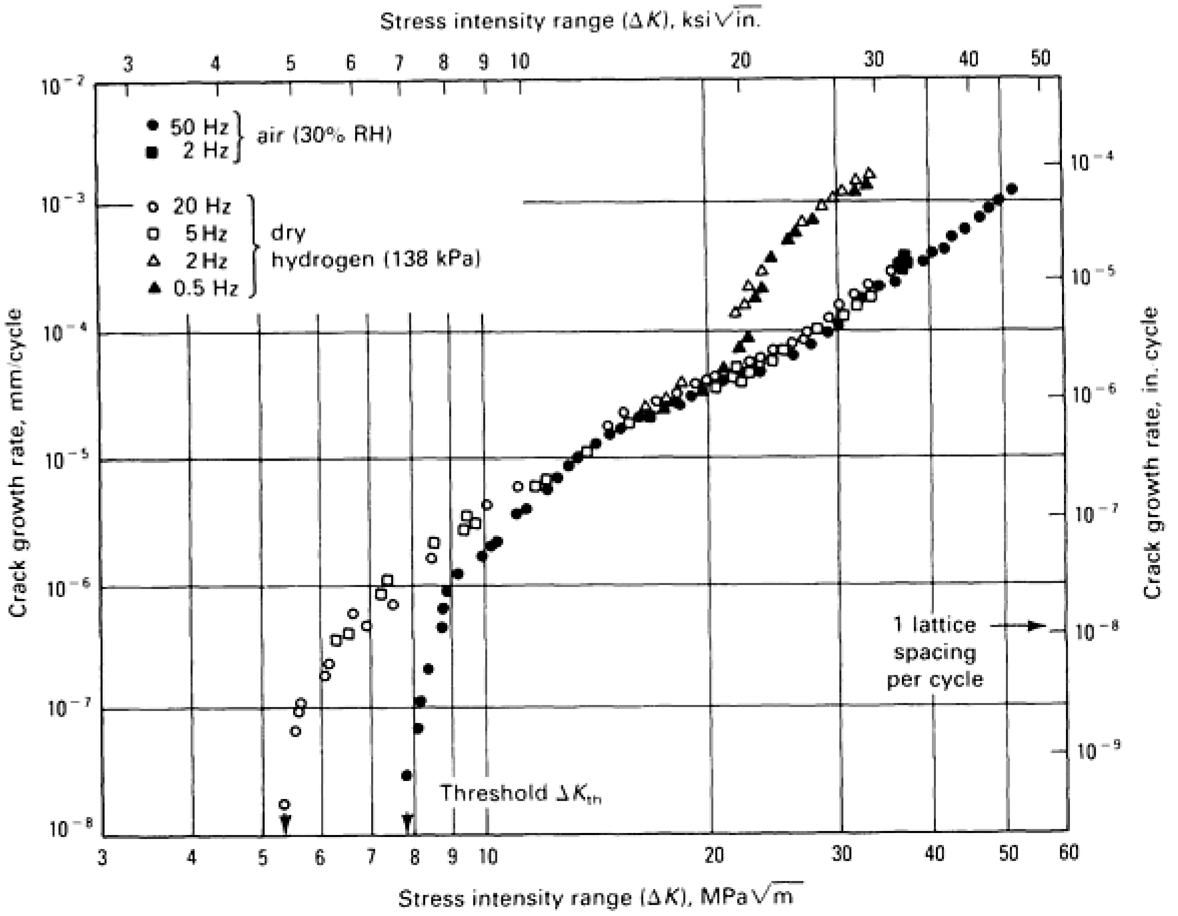

Fig. 19 Corrosion fatigue in 2.25Cr-lMo pressure vessel steel in dry hydrogen at 23 °C (73 °F) due to hydrogen embrittlement at high ΔK and to reduced oxide-induced closure at low ΔK. Stress ratio: R = 0.05. Source: Ref 50

CFC Growth Characterization

Experimental characterizations of corrosion fatigue crack propagation are complicated by the numerous variables that influence the failure process. Both the mechanics of loading and the composition of the environment must be controlled. Standard methods of measurement and fracture mechanics analysis of fatigue crack propagation in benign environments can be found in ASTM Standard E 647.

Four problem areas are relevant to corrosion fatigue experimentation. First, the environment must be contained about the cracked specimen without affecting loading, crack monitoring, or specimen-environment composition. Parameters such as environmental purity, composition, temperature, and electrode potential must be monitored and controlled frequently.

Second, the deleterious effect of low cyclic frequency dictates that crack growth rates be measured at low frequencies (often <0.2 Hz); this leads to long test times--often several days to weeks. Load-control and crack-monitoring electronics and environment composition must be stable throughout long-term testing.

Third, crack length must also be measured for calculations of stress intensity and crack growth rate. Optical methods are often precluded by the environment and test chamber. Indirect methods, which are based on specimen compliance (Ref 53) or electrical potential difference (Ref 54), have been successfully applied to the monitoring of crack growth in a wide variety of hostile environments. Experimental and analytical requirements, however, are complex for indirect crack monitoring.

Nonvisual techniques will often have greater accuracy and less variability in crack length measurement than optical observations. In addition, the nonvisual techniques are generally more consistent and reliable, especially where long periods of unattended testing are anticipated. Beyond that, nonvisual techniques are absolutely essential where the test

temperature or the environment prohibits direct visual observations. The nonvisual method is more precise than visual techniques, and it allows for automation of the test beyond the mere acquisition of the crack growth rate data (Ref 55, 56).

Finally, specimen geometry and size requirements for ΔK-based crack propagation data, which are scalable to components through similitude, have not been established completely for subcritical crack growth. In-plane yielding must be limited to the crack tip by ensuring that net section stress is below yield and that the maximum plastic zone size, defined as approximately 0.2 $(K_{max}/\sigma_{YS})^2$, is much less (for example, 10- to 50-fold) than the uncracked ligament. Specimen thickness, as it influences the degree of plane-strain constraint, and crack size, as it influences the chemical driving force, may affect corrosion fatigue crack speeds. Currently, such effects are unpredictable; specimen thickness and crack geometry must be treated as variables.

CFC Growth in Specific Environments

Corrosion fatigue studies in aqueous solutions and gaseous environments at ambient temperatures present fewer problems experimentally than many of the other environments considered in this article. Nevertheless, simulation of practical conditions in relation to a specific engineering application requires careful consideration if the data are to be relevant. Similarly in an academic investigation, comparison of the results of different pieces of work is possible only if the mechanical, metallurgical, and chemical variables are properly characterized and controlled. It is often the case, however, that the most frequent problem in determining the validity of corrosion fatigue data lies with the control and monitoring of the bulk environment chemistry and the monitoring and recording of the electrochemical potential in aqueous solutions.

Corrosion fatigue crack growth data are required for practical engineering applications in many diverse and specialized environments. An excellent overview of the following eight specific types of environments is given in the article "Environmental Effects on Fatigue Crack Propagation" in *Mechanical Testing,* Volume 8 of *ASM Hanbook,* formerly 9th Edition *Metals Handbook* and will not be repeated in this article:

- Vacuum and gaseous environments at ambient temperatures
- Vacuum and oxidizing gases at elevated temperatures
- Aqueous solutions at ambient temperatures
- Acidified chloride environments at ambient and elevated temperatures
- High-temperature pure water under aerated conditions
- High-temperature pure water under deaerated conditions
- Liquid-metal environments
- Steam or boiling water with contaminants

Evaluation of Crevice Corrosion

R.M. Kain, LaQue Center for Corrosion Technology, Inc.

Introduction

CREVICE CORROSION is a form of localized corrosion that primarily affects passive-type alloys. Stainless steels, particularly those with little or no molybdenum, are especially prone to crevice corrosion. In neutral and acidic chloride-containing environments, higher-alloyed stainless-type materials and related nickel-base alloys may also be susceptible in some cases. Although other alloy systems, such as aluminum, copper, and titanium, may also be susceptible to crevice-related corrosion, testing and test development have primarily focused on assessing the behavior of the stainless-type alloys. Much of this attention has been associated with the identification and development of more resistant alloys for marine applications and in certain process industries, such as pulp and paper. Over the years, diverse crevice corrosion testing methodologies have evolved and continue to find significant utility in simple immersion studies, electrochemical testing, and mathematical modeling.

Early experience with stainless steel in seawater, for example, revealed that localized corrosion occurred beneath marine barnacles and other deposits. Comparative immersion tests of available stainless alloys also produced crevice corrosion beneath insulating washers on test racks. Simple testing and service experience both revealed considerable variability in stainless steel performance. Recognizing the limitations of the 300-series stainless steels, alloy producers saw potential markets for new, corrosion-resistant marine alloys. Several high-molybdenum austenitic (some with nitrogen enhancement), duplex, and superferritic alloys were subsequently developed. Prior to these developments, a number of alloy 20-type stainless alloys (20% Cr) that gained acceptance in the chemical-processing industry were also considered for marine service. This was particularly true in the case of cast stainless pump and valve materials. The merits of high-molybdenum nickel-base alloys, such as alloy 625 and alloy C-276, were recognized early, but use was generally limited to high-performance applications.

Few alloy development laboratories had access to natural seawater. Those researchers who used seacoast test facilities were often left to the mercies of seemingly long-term natural exposure in order to obtain data. Both situations prompted the use and development of laboratory screening tests. Some used simple salt solutions or recipes simulating ocean water. It was recognized for some time that the environment within the crevice was different from that of the bulk environment. Oxygen differential cells could be established between cathode surfaces exposed to oxygenated seawater and anodic crevice areas. Others recognized that hydrolysis reactions within crevices could produce changes in pH and chloride concentration in the crevice environments. As such, investigators sought the use of ferric chloride ($FeCl_3$) solutions to simulate crevice conditions. Results could now be obtained within a matter of days rather than months or years of natural exposure testing. The development of economical and reliable electrochemical test equipment also provided another tool for investigators.

Aspects of Crevice Corrosion Testing

This article will discuss a number of the more frequently used crevice corrosion testing procedures. It is recognized, however, that other techniques exist and that their merits should be examined.

Because crevices are real space dimensions between mating materials, use of the term artificial crevice test is discouraged in favor of descriptors that identify the crevice former as naturally occurring (for example, a barnacle) or man-made (for example, a washer). The use of the latter as either a metal or nonmetal device can recreate the geometry of some fabricated crevices, but not all. Similarly, a man-made crevice former device may or may not reproduce the conditions generated by attachment and growth of a barnacle.

Another aspect of crevice corrosion test selection is based on the two accepted phases of crevice corrosion; initiation and propagation. Initiation refers to the breakdown of passivity and the actual occurrence of crevice corrosion as determined by some finite degree of propagation or penetration. Under some conditions, breakdown may be followed by repassivation without any outward evidence of attack. For a given alloy-environment combination, the occurrence of crevice corrosion is highly dependent on the crevice geometry. Tighter crevices are more conducive to promoting breakdown, but this factor may affect the propagation behavior of materials in different ways (Ref 1). Environmental factors may affect the rate of crevice corrosion propagation. Although natural and synthetic seawater, for example, will both cause AISI type 316 and other stainless alloys to initiate, different rates of propagation are likely to occur (Ref 2). The overall size of the specimen in relation to the crevice area can also affect propagation behavior. Regardless of the purpose of crevice corrosion testing, the investigator should be aware that these and many other factors could affect test results. A number of metallurgical, environmental, and geometrical factors that affect crevice corrosion are discussed in the section "Crevice Corrosion" of the article "Localized Corrosion" in this Volume.

Guidelines for Crevice Corrosion Testing

ASTM Specification G 78 provides guidance in the conduct of crevice corrosion tests for stainless steels and related nickel-base alloys in sea-water and other chloride-containing environments (Ref 3). This guide does not promote any particular test technique, but advises the reader to be aware that crevice corrosion test results can be affected by a number of interrelated factors. In particular, attention is advised in the area of crevice geometry and specimen preparation. Importantly, Ref 3 points out that the occurrence or absence of crevice corrosion in a given test is no assurance that it will or will not occur under other conditions. This is especially true if the test conditions do not consider factors that may affect initiation and/or propagation behavior. Laboratory screening tests play a valuable role in the ultimate use of stainless materials in corrosive environments. Laboratory immersion tests and electrochemical studies are important tools for investigating the effects of alloy content and environmental variables. However, test results should be used judiciously so as not to limit materials that may not meet artificially contrived conditions selected to accelerate results.

Immersion Tests

Depending on accessibility, laboratory immersion tests may be able to utilize natural or actual process environments. This provides a convenient opportunity to study, for example, the effects of temperature, crevice geometry, and such factors as surface finish. These tests can be conducted at marine corrosion test centers and at laboratories associated with chemical-processing facilities.

Whether preparing samples for field or laboratory exposures, the researcher must be sure to provide flat-parallel surfaces for attachment of the crevice formers. Two such formers, one to each side of a test panel, are generally attached with a corrosion-resistant fastener. A consistent level of tightness should be used to minimize variability in crevice gap. The mechanical properties of some nonmetallic materials used to form crevices may relax with time. In some cases, this may be sufficient to render the crevice ineffective. Some materials are more deformable than others (for example, polymer versus ceramic) and may allow for greater tightness (smaller crevice gap). Crevice formers may vary in size and may take the shape of continuous annular washers and O-rings or of some type of serrated or multiple-crevice assembly.

To gain a greater appreciation of alloy performance, the researcher should test several different types and sizes of crevice-forming materials whenever possible. Similarly, if different product forms (plate, pipe, casting, and so on) are to be used in service, differences in thermomechanical processing and finishing may influence corrosion resistance. Heavily pickled materials, for example, may not have the same surface composition and roughness as an as-rolled product. For specific applications, the metallurgical condition of the material should be representative of that in service. If alloying effects are to be investigated, it may be advisable to test with a common surface finish. Conversely, if competitive alloys are to be compared, both as-produced and ground surfaces should be tested.

Specific Crevice Corrosion Tests

Spool Specimen Test Racks. A considerable amount of crevice corrosion data have been obtained from test rack exposures of candidate alloys in various process streams and other industrial environments. Simple tetrafluoroethylene (TFE) fluorocarbon sleeves and washers, intended primarily as electrical insulating spacers between candidate alloy specimens, have proved to be effective crevice formers. Test results for metal coupons and spool disk specimens have identified the occurrence of crevice corrosion and the extent of penetration incurred during the exposure period. Although these and other tests lack definition with regard to actual times to initiation and rates of propagation, they are nonetheless quite effective in screening materials for further consideration.

One area in which test rack exposures have been extensively used is the pulp and paper industry. For example, Ref 4 discusses results from bleach plant exposure in which crevice corrosion susceptibility was identified for 24 of the 26 alloys tested. However, the crevices found in bleach plant washers may be less severe than those on the test specimens. This is supported by the observation that some materials that exhibited less than 0.4 to 0.46 mm (15 to 18 mils) of crevice penetration in a 3-month test have actually performed satisfactorily in service for up to 20 years. More information on the use of test rack exposure tests is available in the article "In-Service Monitoring" in this Volume.

Ferric Chloride Tests. The ferric chloride test described in ASTM G 48 involves exposure to a highly oxidizing acid chloride environment (Ref 5). Crevices are created at sites of contact with TFE-fluorocarbon blocks secured by rubber bands. A test is generally conducted at 22 or 50 ± 2 °C (72 or 120 ± 3.5 °F) for 72 h.

The pH of the standard 6% $FeCl_3$ solution is about 1.2 and is less than the pH of the critical crevice solution, which can cause a breakdown of passivity for type 304 and type 316 stainless steels. Critical crevice solution compositions for these alloys with respect to pH and chloride concentration have been identified at levels of pH 2.0 at 1.5 M Cl^- and pH 1.7 at 3.5 M Cl^-, respectively (Ref 6). Use of $FeCl_3$ eliminates the time factor for development of the aggressive crevice solution from the neutral pH of, for example, a chloride-containing natural water. The crevice prevents oxygen from maintaining the passive film. The combination of pH and high Cl^- will lower the breakdown or critical potential for pitting, while the presence of the ferric ions (Fe^{3+}) maintains the potential of the alloy in this critical region.

More resistant alloys do not exhibit a breakdown potential in the domain associated with Fe^{3+} reduction at ambient temperature. In some cases, the Fe^{3+} serves as a chemical potentiostat and holds the corrosion potential well within the passive region in the absence of oxygen. Increasing the $FeCl_3$ solution temperature to 50 °C (120 °F), for example, promotes breakdown and allows for ranking of more resistant alloys. Figure 1 shows schematically the polarization characteristics for stainless steels exposed to $FeCl_3$.

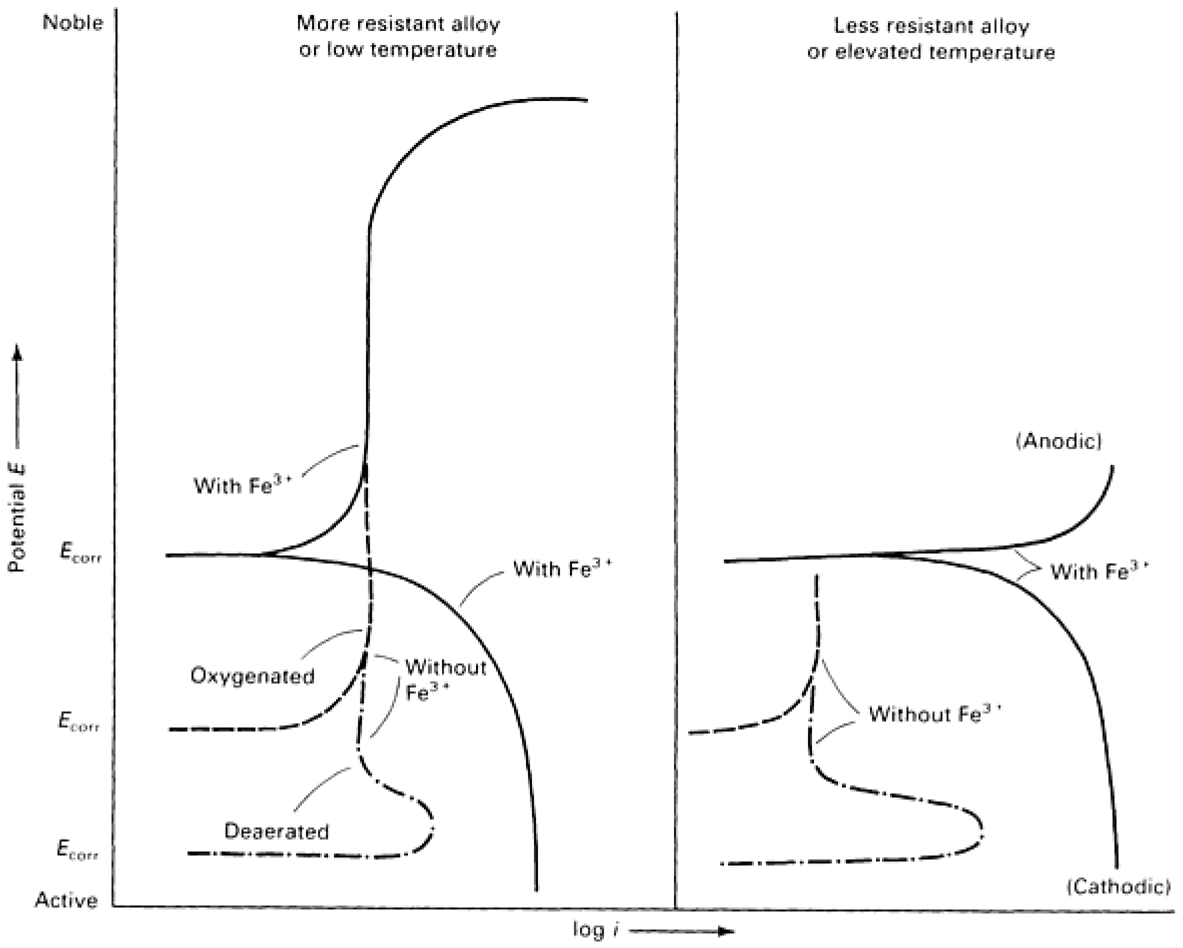

Fig. 1 Schematic showing the polarization characteristics of stainless-type materials in an acid chloride solution with and without Fe^{3+}

Materials Technology Institute Tests. The Materials Technology Institute of the Chemical Process Industry (MTI) has identified five corrosion tests for iron- and nickel-base corrosion resistant alloys (Ref 7). The results of these tests are intended to provide a reasonable assessment of the probable utility of new alloys in a variety of corrosive environments. Two of the methods address resistance to crevice corrosion. Method MTI-2 proposes alloy ranking on the merits of increased critical crevice temperature, and method MTI-4 fosters a concept of critical chloride concentration. Both methods are concerned with initiation resistance; neither method provides guidance in the area of crevice corrosion propagation.

Method MTI-2, originating from ASTM G 48, also involves the use of a 6% $FeCl_3$ solution for determining the relative resistance of alloys to crevice corrosion in oxidizing chloride environments. In the MTI procedure, crevices are formed by the application of two serrated TFE washers, each having 12 plateaus or contact sites in which corrosion may initiate. The washers, one on each side, are initially secured at a specified torque of 0.28 N · m (2.5 in. · lb). The critical crevice temperature is determined by increasing the $FeCl_3$ temperature in 2.5 °C (4.5 °F) increments within the range of 0 to 100 °C (32 to 212 °F) and by noting the closest temperature that produces attack (less than 0.025 mm, or 1 mil) in depth within a 24-h test period. Specimens are disassembled and inspected after each increment. The number of sites incurring this degree of attack is also reported, along with the minimum temperature for initiation. Results for materials with a standard surface finish (wet 80-grit or dry 120-grit) can be compared with recommended controls of type 316 stainless steel and alloy C-276.

Table 1 provides critical crevice temperature data for a number of nickel alloys. As described in Ref 8, some differences in test procedure were considered in regard to $FeCl_3$ makeup and specimen surface conditioning. In contrast to the specified MTI procedure, the modified procedure involved fresh surface grinding between exposure at each temperature increment. Reportedly, this minimized scatter and lowered the critical crevice temperature. Differences in critical crevice

temperature as a function of procedure increased with increased alloy content. This is shown in Fig. 2 for the four alloys common to all three tests. Considering the diverse composition with respect to molybdenum content, it is reasonable to expect a similar ranking in $FeCl_3$ regardless of procedure.

Table 1 Critical crevice temperature data for various alloys evaluated for 24-h periods in 6% $FeCl_3$ (10% $FeCl_3 \cdot 6H_2O$) using MTI and modified MTI procedures

Data are compared to literature critical crevice temperature values obtained in testing in 10% $FeCl_3$ (not hexahydrate).

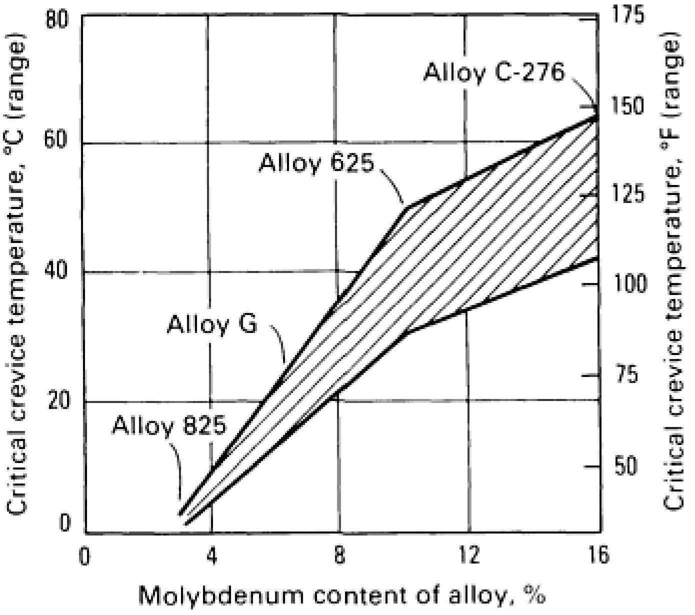

Fig. 2 Molybdenum content versus critical crevice temperature range for several nickel-base alloys. The range of critical crevice temperatures was obtained by varying test procedure.

The value of this ranking with regard to service expectation remains limited. Some agreement has been cited among critical crevice temperature and specific seawater test data (Ref 9, 10), but this agreement does not take into account the effect of crevice geometry and the interrelationship with the natural environment. Although increasing $FeCl_3$ temperature (for example, from 25 to 50 °C, or 77 to 120 °F) is certainly detrimental, the same is not necessarily true in seawater when bulk oxygen levels decline with increasing temperature and when biological factors may be altered (Ref 11).

Method MTI-4 uses increases in neutral bulk Cl^- concentration at eight levels ranging from 0.1 to 3.0% NaCl to establish a minimum (critical) Cl^- concentration in order to produce crevice corrosion at room temperature (20 to 24 °C, or 68 to 75 °F). The MTI-4 method is consistent with MTI-2 in the area of specimen requirements, crevice assembly procedure, and evaluation technique. The recommended test period, however, is 1000 h, and suggested controls are type 304 and 316 stainless steel.

Both methods are acceptable screening tools and are well suited for alloy development purposes. Method MTI-2, for example, has been frequently used to demonstrate the beneficial effects of chromium and molybdenum in promoting resistance to crevice corrosion initiation. However, extension of either method beyond its intended scope may be misleading. In the case of MTI-4, for example, differences in crevice geometry from that of the serrated washer could significantly alter resistance to a given bulk Cl^- concentration. Tighter and/or larger crevices could promote initiation at lower Cl^- levels (Ref 12). Use of the serrated washer identified earlier, for example, has produced crevice initiation at Cl^- levels as low as 100 to 300 mg/L in a matter of a few days when assembled at an initial torque of 8.5 N · m (75 in. · lb) (Ref 13). As noted in the section "Crevice Corrosion" of the article "Localized Corrosion" in this Volume, initiation at metal-to-metal sites can sometimes promote more rapid initiation and at lower Cl^- levels in comparison to nonmetal-to-metal crevices of comparable geometry.

Multiple-Crevice Assembly Testing

Background. Since its inception in the mid-1970s, the multiple-crevice assembly test has been one of the most popular and most controversial procedures available for evaluating the crevice corrosion resistance of stainless steels and related alloys. Although frequently cited in the literature, its present status is that of an acknowledged test method in the Standard Guide covered by ASTM G 78. Multiple-crevice assembly devices generally consist of two serrated washers that provide a number of plateau-contact sites when fastened to a sheet or plate specimen. The acetal resin washer multiple-crevice assembly shown in Fig. 3 contains 20 plateaus, thus producing a total of 40 sites on each specimen. Typically, triplicate

sheet or plate specimens are tested. The design shown is one of several in use that evolved from the multiple-crevice assembly originally developed by D.B. Anderson (Ref 14). Other multiple-crevice assemblies may have fewer plateaus of somewhat different size. Procedures generally call for attachment with an insulated, corrosion-resistant fastener and tightening in a reproducible manner with a calibrated torque wrench. The actual level of tightness may vary as a function of initial torque, crevice-forming material (that is, washer), and any relaxation. The fastener can also be used to attach the specimen to a suitable support and thus prevent the creation of any other undesirable crevice sites.

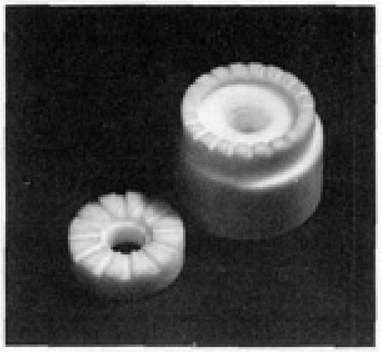

Fig. 3 Serrated washers used for multiple-crevice assembly testing

Multiple-crevice assemblies were developed as a rapid and economical screening tool for establishing resistance to crevice corrosion in natural seawater. Testing was specifically intended to be severe enough to produce some measure of alloy behavior before other factors, such as fouling and seasonal variation in temperature, could come into play. It was also desirable that the multiple-crevice assembly demonstrate recognized differences in alloy capabilities, such as those between type 304 and type 316 stainless steels, as well as the exceptional degree of performance expected of highly corrosion-resistant alloys. Unlike other crevice corrosion tests, the multiple-crevice assembly test relied solely on naturally occurring processes and required neither outside electrochemical nor chemical stimulation.

Because crevice corrosion appeared to be random in its occurrence, the creation of a number of identical crevice sites on a given set of specimens would provide the basis for statistical analysis. Therefore, the multiple-crevice design and the use of the probability concept gained appeal. Early concerns with geometrical factors primarily addressed the size of the specimen in terms of boldly exposed area (cathode) to shielded or crevice area (anode). Subsequent research, especially through mathematical modeling (Ref 15), showed that the occurrence of crevice corrosion was dependent on a number of interrelated factors but the probability concept suggested only a material (that is, alloy) property. Because such crevice geometry factors as crevice tightness could be overriding considerations, proponents and users of the multiple-crevice assembly generally abandoned the probability concept in describing the occurrence of crevice corrosion.

Examples of Use. The multiple-crevice assembly remains popular because it enables the investigator to report results in terms of initiation and propagation. For example, resistance to initiation can be expressed as the number of sides or sites or the percentage thereof exhibiting attack in a given test period. Because attack, when it occurs, is located at specific sites, penetration measurements can be made at each site and can be reported as a maximum depth. This can be accomplished by using an appropriate dial depth gage or microscope. Results have been reported as a range of these maximum values or their average value. Table 2, for example, lists data describing the effect of alloy molybdenum content on both initiation and propagation resistance for a series of controlled chemistry heats of a nickel-base alloy containing 30% Cr.

Table 2 Multiple-crevice assembly test results showing the beneficial effects of molybdenum in nickel-base alloys containing 30% Cr

Results of 30-day test in filtered, natural seawater at 30 °C (85 °F)

Alloy	Alloy molybdenum content, %	Initiation resistance			Penetration resistance			
		Time observed, h		**Average number of sites visibly corroded**	**Maximum depth**		**Average depth**	
		Earliest	**Average**		**mm**	**mils**	**mm**	**mils**

Source: Ref 16

(a) ND, not detected during 30-day test.

Other methods of data presentation have been used to describe crevice corrosion initiation and propagation behavior. Figures 4, 5, 6, and 7 show multiple-crevice assembly results plotted in bar graph form as mean values plus and minus one standard deviation of the percentage of sites initiated and maximum depth of attack. Figures 4 and 5 provide a ranking of alloys based on their resistance to crevice corrosion when tested in their respective mill conditions and with a common surface finish (120-grit SiC, wet ground). The second examples (Fig. 6 and 7) are used to illustrate the influence of the initial crevice assembly torque level. Observations on different materials responding to differences in crevice tightness help to explain further the apparent variability in multiple-crevice assembly tests and in other types of crevice tests.

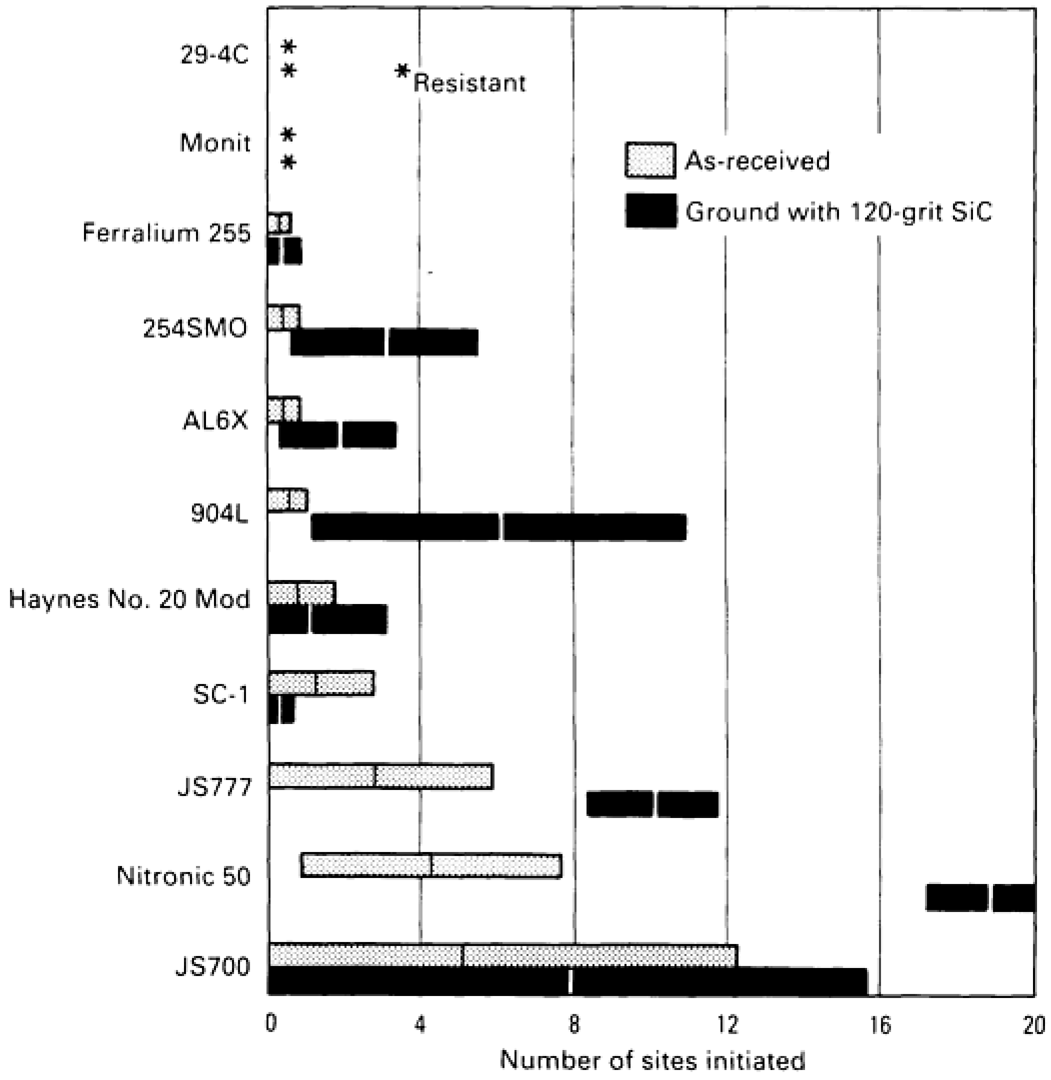

Fig. 4 Summary of number of initiated crevice sites beneath multiple-crevice assembly washers for a series of alloys tested in natural seawater. Bar graphs represent the mean values (plus and minus one standard deviation) for replicate 30-day tests of both as-received and ground (120-grit SiC) specimens. Assembly torque: 8.5 N · m (75 in. · lb)

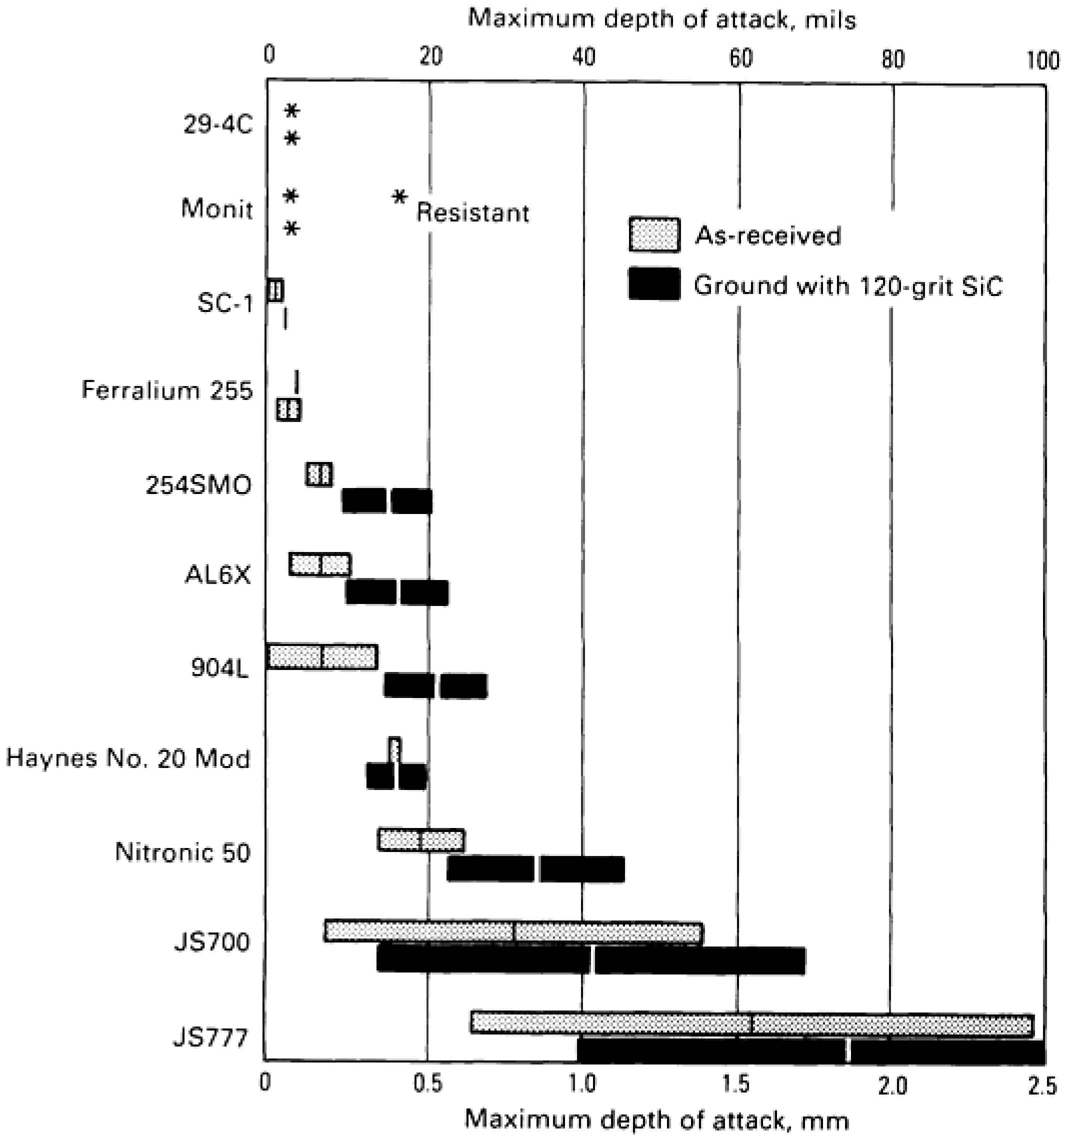

Fig. 5 Summary of maximum depth of attack beneath multiple-crevice assembly washers for a series of alloys tested in natural seawater. Bar graphs represent the mean values (plus and minus one standard deviation) for 30-day replicate tests on both as-received and ground (120-grit SiC) specimens. Assembly torque: 8.5 N · m (75 in. · lb)

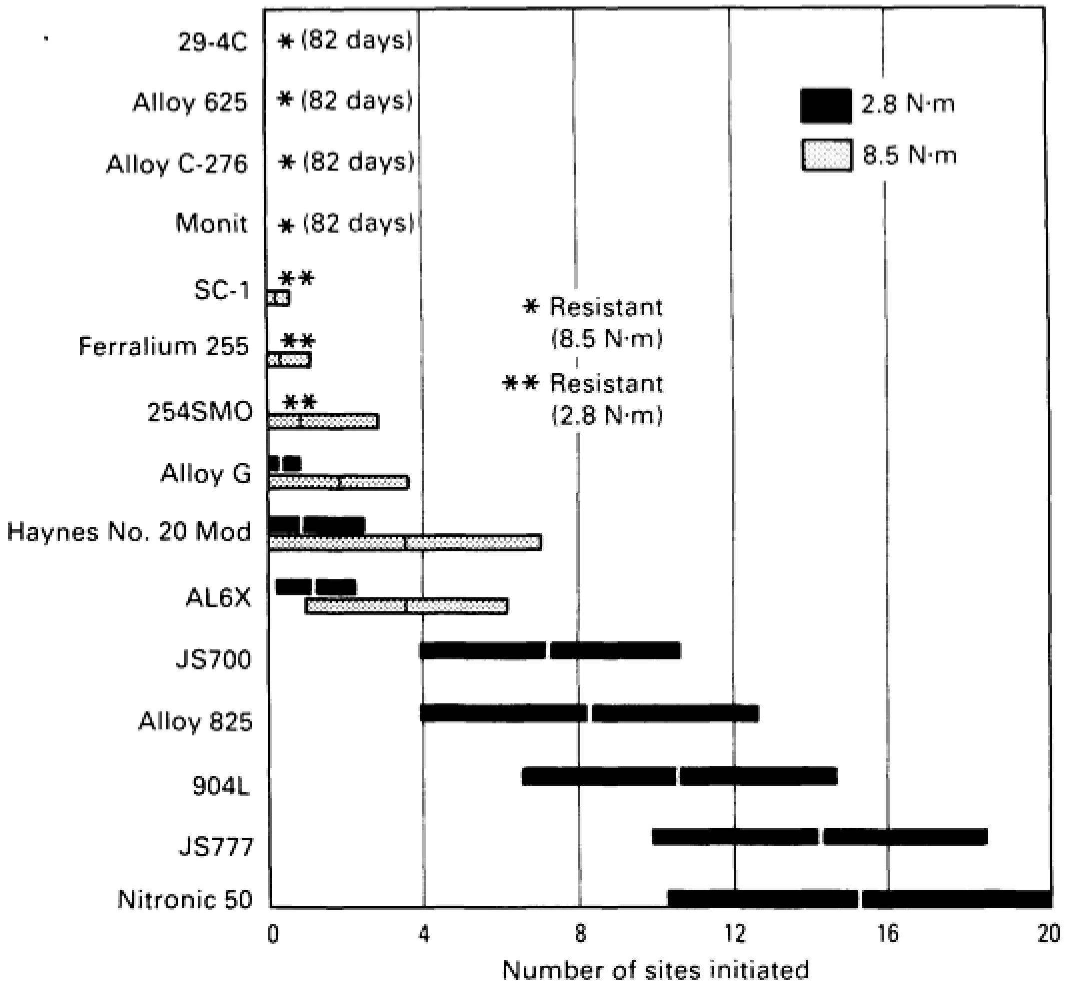

Fig. 6 Summary of number of initiated crevice sites beneath multiple-crevice assembly washers for a series of alloys tested in natural seawater. Bar graphs represent mean values (plus and minus one standard deviation) for replicate 60-day tests using an assembly torque of either 2.8 N · m (25 in. · lb) or 8.5 N · m (75 in. · lb). All specimen surfaces were ground with 120-grit SiC.

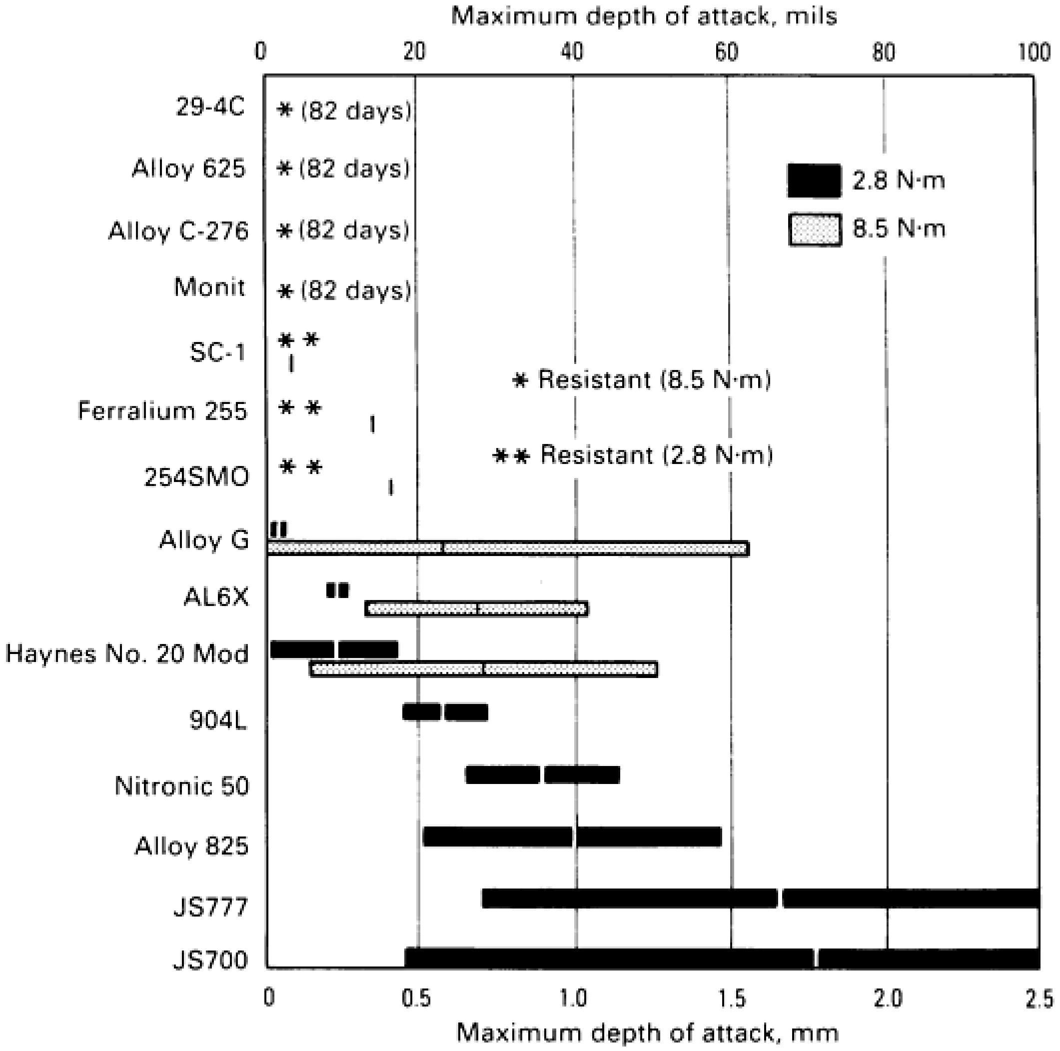

Fig. 7 Summary of maximum depth of attack beneath multiple-crevice assembly washers for a series of alloys tested in natural seawater. Bar graphs represent the mean values (plus and minus one standard deviation) for 60-day replicate tests conducted using an assembly torque of either 2.8 N · m (25 in. · lb) or 8.5 N · m (75 in. · lb). All specimen surfaces were ground with 120-grit SiC.

Furthermore, it has been postulated that the multiple-crevice assembly can produce a range of tight crevice gaps (Ref 17). This may vary depending on the actual degree of tightness at the time of exposure. As mentioned earlier, relaxation may be a factor in this regard. It has been shown that a multiple-crevice assembly made of acetal resin experiences more relaxation than, for example, assemblies of PTFE or ceramic (Ref 18). Despite this shortcoming, however, the acetal washers still provided the most severe conditions in comparative tests. Multiple-crevice assemblies of TFE are now widely use in variations of the ASTM G 48 and MTI $FeCl_3$ test procedures, replacing the certainly less controllable rubber band technique.

Variability. Because of the criticality of crevice geometry, some degree of variability should be expected in data not only from different sources but also from a single location or a single investigator. In this regard, several round robin, comparative test studies have ben conducted over the years. One such program involved exposure of several grades of stainless steel to pulp-bleaching environments. Testing was performed in accordance with a procedure developed by the National Association of Corrosion Engineers T-5H-6 Task Group ("Test Methods for Measuring Crevice Corrosion Rates"). Multiple exposures involved the use of a Rulon device similar to that shown in Fig. 3, but with somewhat larger plateaus. Participants used specimens of prescribed size and assembly torque of prescribed levels. Because the initiated sites were few and nonreproducible, it was concluded that the method was not useful in warm (up to 82 °C, or 180 °F), low-pH (1 to 5), low-chloride (50 to 2000 ppm) environments. However, this actually fits well with the premise that a range of tight crevice gaps exists with each assembly. Mathematical modeling has shown an interrelationship between

bulk chloride level and crevice gap. For the relatively small crevice depth of a plateau site and the low-level chlorides present in the bleach plant, only the tightest of crevice sites should be expected to initiate.

The above procedure evolved from that used in the American Society for Testing and Materials (ASTM) G1.09 Task Group round robin testing of multiple-crevice assemblies. In these tests, triplicate specimens with wet ground (120-grit SiC) surfaces were exposed for 30 days with multiple-crevice assemblies tightened to an initial torque of 8.5 N · m (75 in. · lb). Of the eight participants with access to natural seawater, seven were located on the U.S. eastern coast at latitudes ranging from Key West, FL, to New England. The eighth test location was situated on the coast of California. All except two sites provided some degree of filtration, and three were unable to provide temperature control. As expected, some differences in seawater chemistry (for example, chloride and dissolved oxygen) and ambient temperatures were reported.

Although the purpose of these tests was to identify the reproducibility of data for different classes of materials, an alloy ranking was also identified. None of the participants reported any incidence of crevice corrosion for nickel alloy C-276 (~15% Mo). On the other hand, at least one specimen of alloy G (~6% Mo) initiated attack at all eight test locations. Overall, the actual number of sites attacked as well as the range and maximum depth of penetration were both found to be quite minimal. For type 304 and type 316 stainless steels, however, crevice corrosion occurred on all specimens except for one of the 2% Mo containing type 316. From this general point of view, identification of alloy susceptibility was quite reproducible. However, in terms of the actual number of sites that initiated, much variability was identified, particularly on a location-to-location basis or a participant-to-participant basis.

Figure 8 shows a plot of the percentage of crevice sites that incurred visible attack after 30 days. Each data point represents a single specimen with 40 crevice sites. Test locations are identified on the basis of ascending order of initiation for type 304. Although results showed considerable variation from some locations to others, repeatability at each site was generally good to excellent in most cases. Three of the locations (1, 2, and 7) ranked type 316 as more resistant than type 304, as is typically assumed. Two other locations (3 and 5) showed mixed behavior, but still favored type 316; the opposite is shown by results from locations 4 and 6. As can be seen, results from location 8 actually showed greater initiation resistance for type 304.

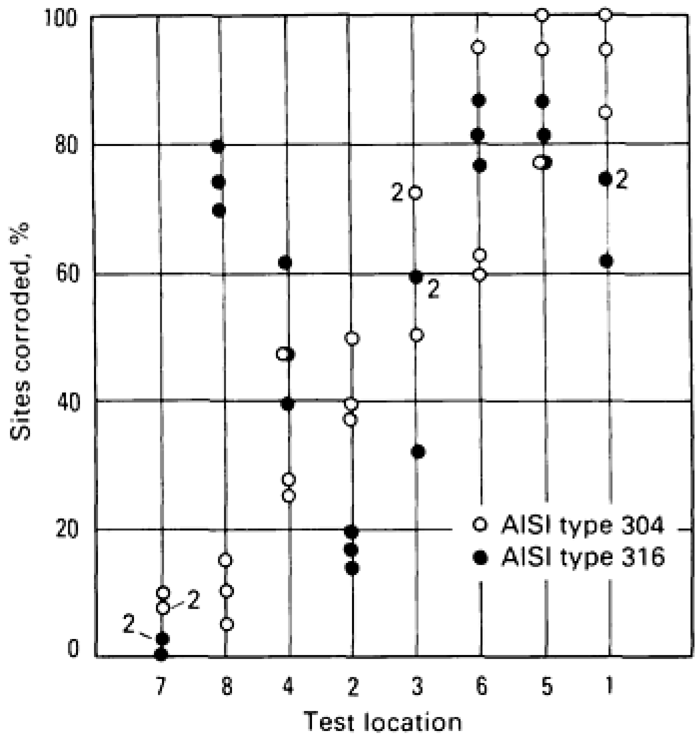

Fig. 8 Crevice corrosion initiation results from 30-day multiple-crevice assembly tests on triplicate specimens in natural seawater at various test sites (ASTM round robin). Source: Ref 3

Figure 9 shows the range of penetration incurred by both alloys at all eight test locations. With the exception of location 7, which consistently reported low incidences of attack, the range of penetration measured elsewhere was more or less comparable, considering the variation of two orders of magnitude in site-to-site propagation. On the basis of maximum depth of penetration seven of eight participants reported greater resistance for type 316.

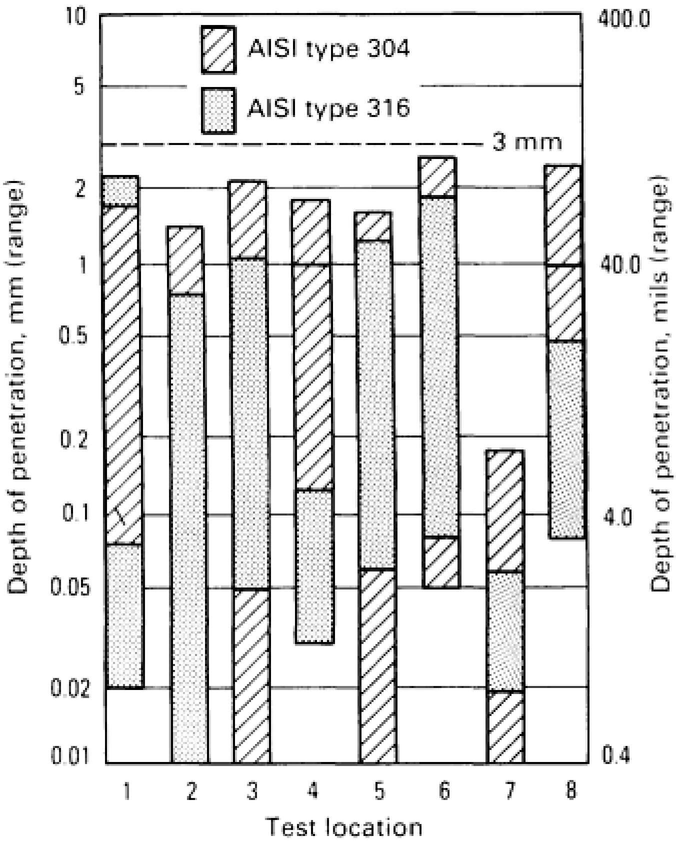

Fig. 9 Crevice corrosion propagation results from 30-day multiple-crevice assembly tests on triplicate specimens in natural seawater at various test sites (ASTM round robin)

Because of the variability in test results from this round robin, a second set of experiments with five participants was conducted at one of the test locations. Actual assembly and conduct of the test were performed by individuals with different degrees of experience as well as others with no prior experience in multiple-crevice assembly testing. All of the tests were conducted at the same time in seawater controlled at 25 ± 2 °C (77 ± 3.5 °F). The results of these tests are given in Fig. 10. Overall, the degree of variability is consistent with that observed from data provided from different test locations. Overall, penetrations measured in the latter test were comparable to those illustrated in Fig. 9.

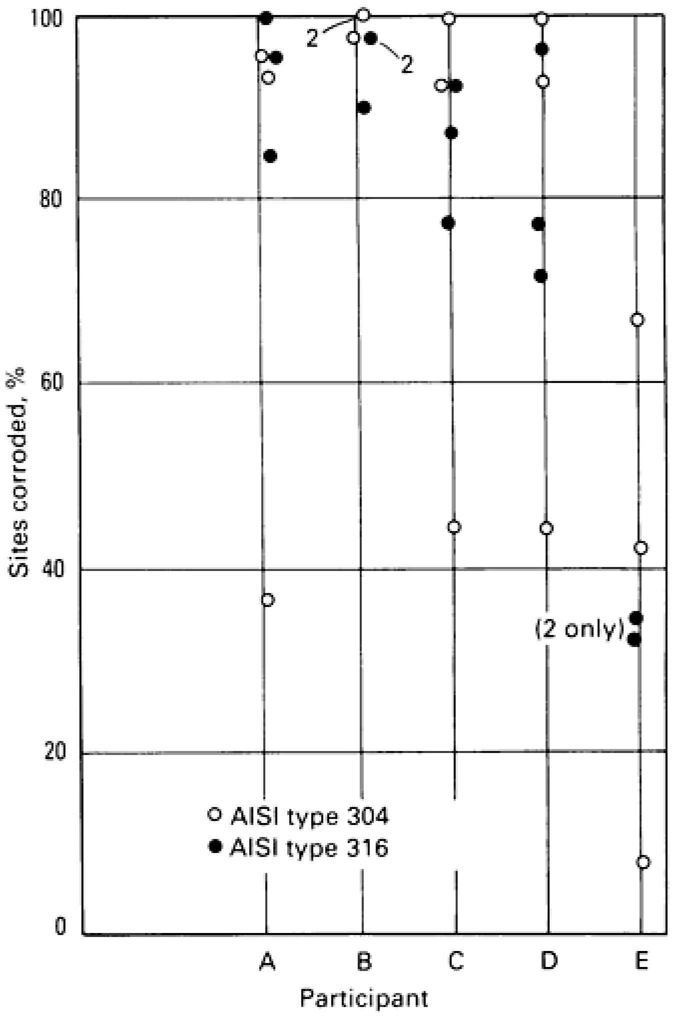

Fig. 10 Crevice corrosion initiation results from 30-day multiple-crevice assembly tests on triplicate specimens in natural seawater at site 5 in ASTM round robin

At least one other series of comparative tests has been performed (Ref 19). In this case, 13 participants used multiple-crevice assemblies in round robin testing of type 304 in 3.5% NaCl at 30 °C (85 °F). Crevice assembly design and initial torque were the same as the above ASTM Gl.09 procedure. Again, considerable variability was evident from one participant to another. Based on a percentage of total sites initiated out of 120 available, a range of 20 to 86% was reported. Although some expectations were noted, a number of individual participants reported good reproducibility among replicate specimens. In contrast to natural seawater, penetrations in 3.5% NaCl tests did not exceed 0.23 mm (9 mils). Average penetrations from triplicate specimens varied by only a few hundredths of a millimeter.

The degree of variability described above is likely to be encountered in any type of crevice corrosion test. When conducted in a conscientious manner, multiple-crevice assembly can generate meaningful results toward the ranking of alloys and can identify the effect of other exposure variables. The multiple-crevice assembly test cannot and should not be used to predict alloy performance under other conditions.

Other Tests. Simple immersion tests of materials of interest can be performed with a variety of crevice formers. In reality, this may be a more acceptable way of characterizing alloy performance than conducting numerous experiments targeted at a single parameter, such as critical crevice temperature. Specification ASTM G 78 shows a number of different types of crevice formers that have been applied to sheet and plate materials by different investigators. Other types may be more suited to other product forms, such as pipe and tubing. For example, the investigator may use different O-ring materials of different diameter and thickness to produce a range of geometries. Similarly, sleeves of nonmetallic tubing or nylon compression fittings could be used in an evaluation of tubular materials. Such devices may, for example, replicate the depth and tightness of a tube-tubesheet assembly but not the electrochemical reactions of dissimilar metals. Other

assemblies, for example, may replicate the geometry of an O-ring or gasket seal, but may not consider the full dynamic impact of a piping system. Use of any of these devices can be applied to materials other than stainless steel. The investigator should become familiar with the localized corrosion tendency of each family of alloys. Copper-base alloys, for example, typically exhibit attack adjacent to the mouth of the effective crevice area.

Electrochemical Tests

ASTM Standard Methods. The *Annual Book of ASTM Standards* identifies two practices for investigating localized corrosion. Standard Practice G 61 is recommended primarily for iron-, nickel-, or cobalt-base alloys (Ref 20). Crevices are formed on a 16-mm (0.63-in.) diam disk electrode by a TFE-fluorocarbon gasket/mounting assembly. The electrode is made the anodic member of a polarization cell containing a deaerated 3.5% NaCl solution. (This procedure has been used for other environments of interest.) After a 1-h period of free corrosion, the crevice electrode potential is increased in the noble direction at a scan rate of 0.6 V/h. The current measured and the potential charge are both continuously plotted (or data collected by computer for subsequent analysis). Upon reaching a current of 5 mA, the scan direction is reversed and continued to its potential of origin. Susceptibility to crevice corrosion is identified by the occurrence of hysteresis during the reverse scan. Relative alloy resistance can be established by comparing the forward and reverse scan potential-current domains with alloy C-276 and type 304 stainless steel standards. Specification ASTM G 61 provides standard polarization plots (forward and reverse scan) for comparison and equipment checkout. As with other crevice corrosion tests, some degree of variability is expected. In this test, several factors may affect results, most notably the actual time between specimen preparation and exposure as well as the degree of tightness used in assembling the electrode mount.

Nonstandard variations, such as use of different electrode assemblies and/or polarization scan rates, may significantly affect the measured response (Ref 21). Some correlation has been made between cyclic polarization tests according to ASTM G 61 and actual immersion tests in seawater (Ref 22). For the most part, cyclic polarization tests are able to differentiate between highly alloyed, resistant materials (for example, the high-molybdenum nickel-base alloys 625 and C276) and lower-alloy materials (for example, 300-series stainless steel). Many alloys with intermediate compositions may be less easily correlatable because they exhibit resistance to a broader range of environments (that is, Cl^- concentration and crevice geometry) than the 300-series stainless steels but less than that for nickel-base high-molybdenum alloys.

Another ASTM practice, F 746, describes procedures for testing the pitting and crevice corrosion of metallic surgical implant materials (Ref 23). Testing is again limited to making relative rankings of performance. The procedure calls for the use of a cylindrical electrode with crevices formed by a mounting compression gasket and an intentional crevice-forming collar. Corrosion is induced by a polarization step to +0.8 V versus the saturated calomel electrode (SCE). Provisions are established for current monitoring and subsequent potential-time increments. The test is designed to produce corrosion for a control electrode of type 316L stainless steel. Alloys can be compared relative to breakdown, propagation, or repassivation tendencies.

Other Potentiostatic and Potentiodynamic Polarization Tests. A potentiostatic test procedure identified with the Santron CTD 400 potentiostat is discussed in Ref 24. This technique, like the MTI procedure, identifies alloy crevice corrosion resistance according to an established critical crevice temperature. Tests have been conducted in neutral NaCl solution and synthetic seawater under constant applied potentials, for example, +600 mV versus SCE. In this automated test, the equipment is programmed to increase the solution temperature in 5 °C (9 °F) increments if a specific critical current level is not reached in a given period, for example, 15 to 20 min.

Test results obtained with the above method using 12-serration multiple-crevice assemblies are summarized in Table 3. Also given in Table 3 is a critical crevice temperature ranking determined in 72-h $FeCl_3$ tests according to ASTM G 48 (rubber band test) and another ranking based on the total number of sites initiated in 30-day natural seawater multiple crevice assembly (20 serrations) tests. The three procedures provided the same order of merit for only 3 of the 12 materials, numbers 1, 2, and 6. In several of the cases, at least two procedures provided the same ranking for a given alloy. In the Santron test, the noble potential is intended to mimic the redox potential of $FeCl_3$. In natural seawater, such potentials would never be achieved without chemical stimulation. Nickel-base chromium-molybdenum alloys, for example, may reach potentials of only +350 mV versus SCE in ambient temperature seawater (Ref 26).

Table 3 Initiation of crevice corrosion in immersion tests in seawater, $FeCl_3$, and synthetic seawater

All specimens were ground with 120-grit SiC.

Potentiodynamic polarization tests for crevice-free electrodes in a series of increasingly aggressive simulated crevice solutions have been used to rank alloys according to a criterion associated with anodic peak current density (Ref 27). Such information has been used in mathematical modeling to identify the localized environment that can cause breakdown of passivity and what conditions lead to its development (Ref 15). In addition, as shown in Fig. 11, a plot of the above log current versus pH has been used to characterize propagation resistance for several cast alloys (Ref 6). Alloy propagation behavior can be ranked according to the slope of the log *i*/pH plot.

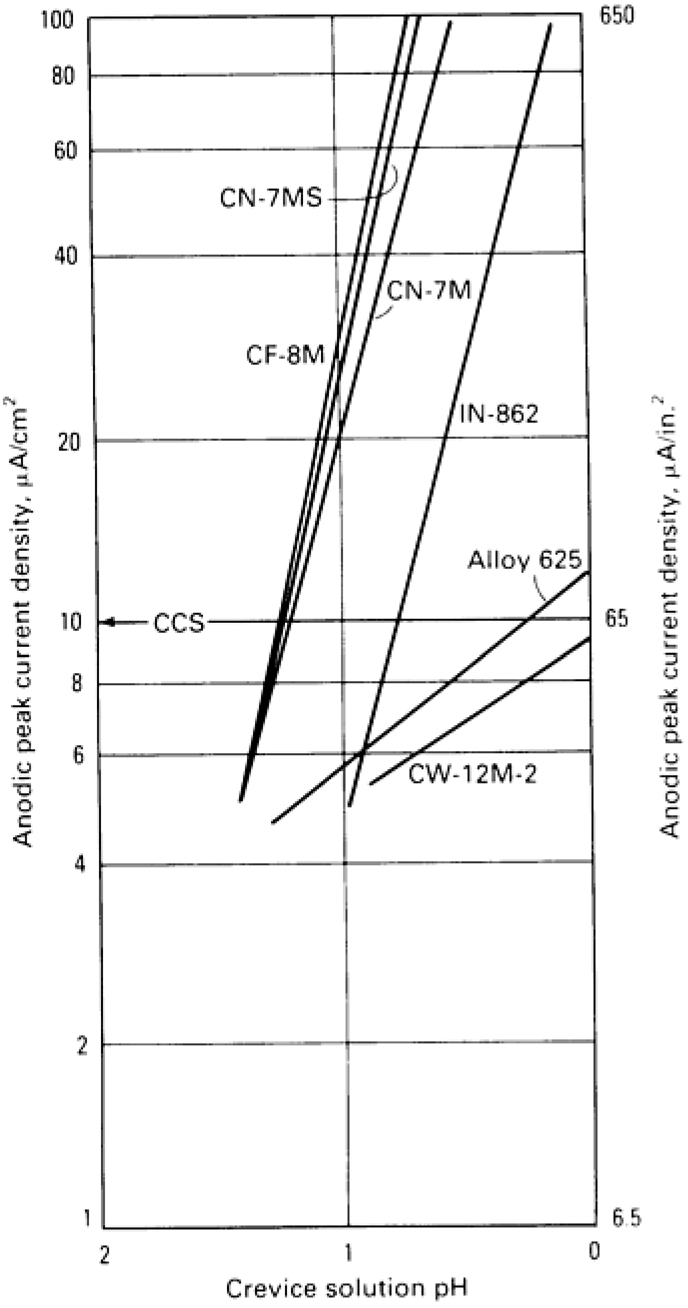

Fig. 11 Plot of anodic peak current density versus simulated crevice solution pH used to determine the composition (pH) of the critical crevice solution (CCS) according to the 10-μA/cm² (64.5-μA/in.²) criterion. Source: Ref 6

Remote Crevice Assemblies. An electrochemical procedure requiring no stimulation other than that provided by the bulk environment-alloy reaction has been described in the literature. These techniques have been identified as either remote crevice or remote cathode tests (Ref 28, 29). Remote crevice assembly tests involve the physical separation but electrical connection of a small anode or crevice member and a larger member (cathode). Both are exposed in the bulk

environment. Current between the two members can be monitored through a zero-resistance ammeter. The technique is quite capable of accurately identifying the time to initiation and subsequent propagation. Examples of its utility have been demonstrated in both natural seawater and other chloride-containing environments (Ref 2).

Unlike other techniques, this procedure has the capability of separating the initiation and propagation phases of crevice corrosion. This capability is summarized by the plot of corrosion current normalized for initiation time in Fig. 12. Results show very good reproducibility in both the trend of increasing current once initiation has occurred as well as the magnitude of current. The total charge (coulombs) reflects the total amount of propagation, which is directly proportional to mass loss due to crevice corrosion.

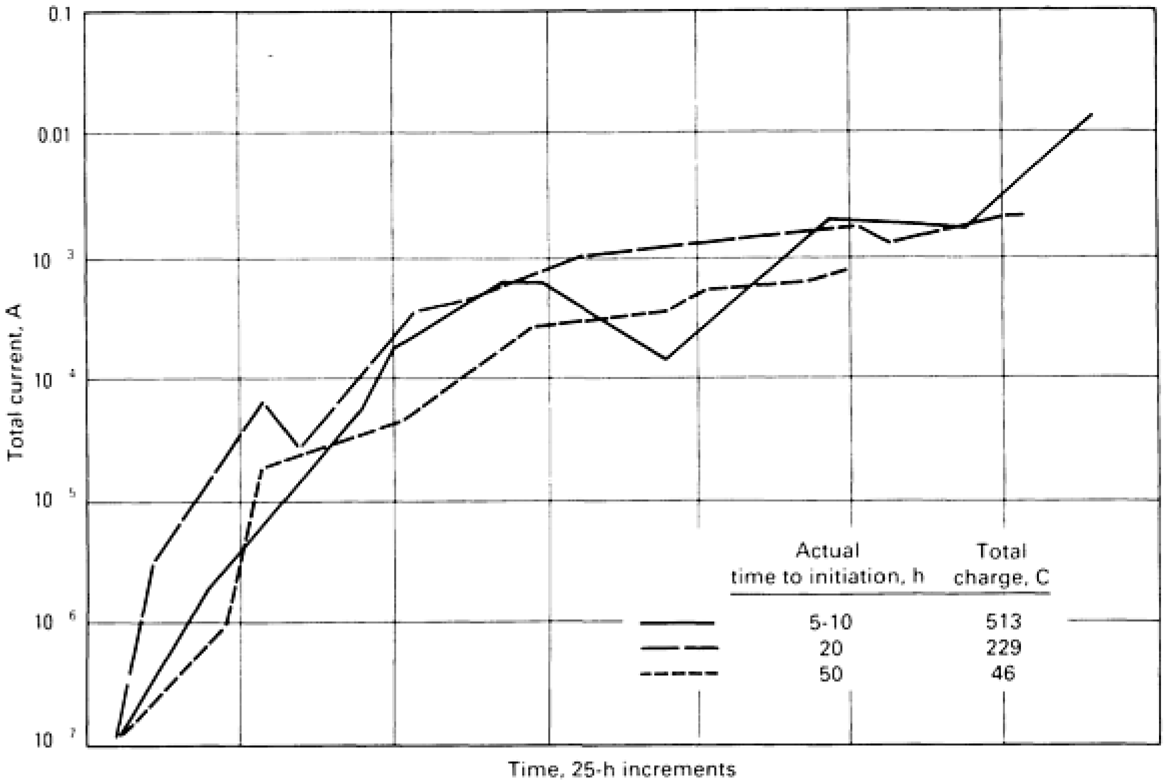

Fig. 12 Comparison of crevice corrosion propagation currents for type 316 stainless steel remote crevice assemblies after normalizing initiation times. Source: Ref 2

With larger crevice areas, such as the 15- × 15-mm (0.6- × 0.6-in.) electrodes used in these remote crevice assembly tests, crevice propagation may progress across the face of the electrode as well as penetrate it. A range of depths of attack is likely to be encountered within an apparent crevice area just as a range is encountered beneath the sites of a multiple-crevice assembly device.

Other Electrochemical Techniques. Other specialized tests are under investigation. One involves the use of compartmentalized cells with anode and cathode members exposed to their respective environments or simulations thereof (Ref 2, 6). Such tests have been used to describe the effects of changes in solution chemistry and surface area ratios. In addition, a vibrating electrode technique has been used to map variations in current density above a creviced stainless steel specimen of known crevice geometry (Ref 30). Necessarily, such tests are more expensive and perhaps more conducive to mechanistic studies rather than mass alloy characterizations. A number of electrochemical techniques that may be considered for crevice corrosion testing are reviewed in Ref 31 and 32. More information on electrochemical testing is available in the article "Laboratory Testing" in this Volume.

Evaluation of Erosion and Cavitation

Introduction

EROSION AND CAVITATION are mechanically assisted forms of material degradation. Erosion, in the context of this article, is defined as the progressive loss of material from a solid surface due to mechanical interaction between that surface and a fluid; therefore, any equipment that is exposed to moving fluids may be susceptible to erosion. Cavitation is caused by the formation and collapse of vapor bubbles in a liquid near a metal surface. More information on the mechanisms of these forms of attack is available in Ref 1 and in the article "Mechanically Assisted Degradation" in this Volume.

Laboratory tests used to evaluate erosion and cavitation damage in metals include the following (Ref 2):

- High-velocity flow tests, including venturi tubes, rotating disks, and ducts containing specimens in throat sections
- High-frequency vibratory tests using either magnetostriction devices or piezoelectric devices
- Impinging jet tests using either stationary or rotating specimens exposed to high-speed jet or droplet impact

These tests are generally designed to provide high erosion intensities on small specimens in relatively short times. These methods may not closely simulate service conditions, but they are useful for ranking candidate materials.

Standard Test Methods

There are two American Society for Testing and Materials (ASTM) standards for the evaluation of erosion and cavitation. These are designations G 32 (Ref 3), which is a vibratory test method using either a magnetostrictive or piezo-electric device that vibrates at a frequency of 20 kHz, and G 73 (Ref 4), which is much broader in scope than G 32. Both of these standards include definitions of terms related to cavitation and erosion as well as information on specimen preparation, test conditions and procedures, and data interpretation. In both cases, the test apparatus is calibrated, and comparisons of the relative resistances of materials are made by the use of reference materials.

ASTM Standard G 32 is based on the generation and collapse of cavitation bubbles on a specimen surface vibrating at high frequency (Ref 3). It is used to evaluate the relative resistances of different materials to cavitation erosion.

Test Specimen. Reference 3 specifies a test specimen measuring 15.9 mm ± 0.05 mm (0.625 ± 0.002 in.) in diameter and not less than 3.2 mm (0.125 in.) in thickness. More details on specimen requirements are provided in Ref 3.

The test apparatus (Fig. 1) produces axial oscillation of the test specimen, which is partially immersed in the test liquid. This is done by either a magnetostrictive or piezoelectric transducer driven by an electronic oscillator or amplifier. The transducer vibrates at a frequency of 20 kHz. The apparatus must include some method of measuring the displacement amplitude of the transducer as well as a means of maintaining the specified test temperature.

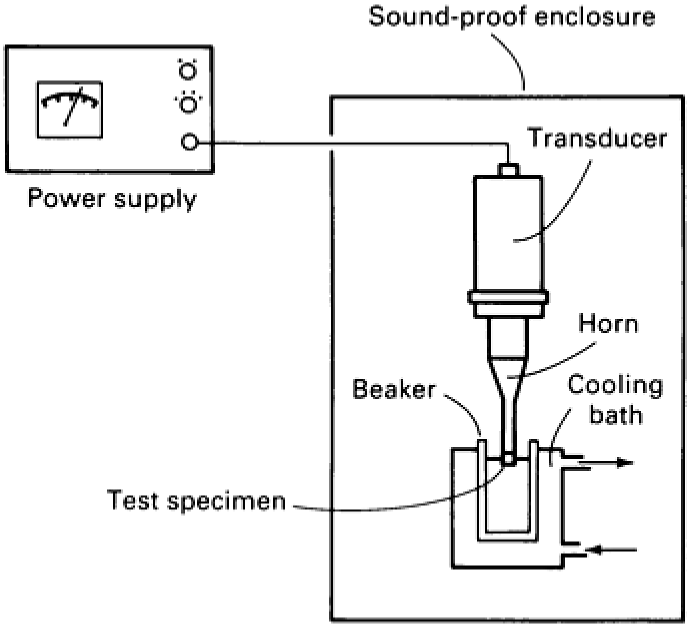

Fig. 1 Schematic of a typical vibratory erosion/cavitation test apparatus. Source: Ref 3

Test Conditions. The standard test liquid is distilled or other reagent water meeting the specifications of ASTM D 1193 ("Standard Specification for Reagent Water") maintained at a temperature of 22 ± 1 °C (72 ± 2 °F). Air is maintained over the test liquid at a pressure of 96 ± 12 kPa (28.4 ± 3.5 in. of mercury). A peak-to-peak displacement amplitude of 0.05 mm (0.002 in.) ± 5% is specified for the duration of the test.

Test conditions can be varied by using different test liquids, temperatures, and pressures. Any such variations must be noted when results are reported. Liquids other than reagent water that have been used include petroleum derivatives, glycerin, and liquid metals. Water has been used at temperatures other than 22 °C (72 °F), and these tests have shown that the erosion rate peaks strongly at a temperature about midway between the freezing point and the boiling point of the test liquid. Therefore, the erosion rate of a material in water at normal atmospheric pressure peaks at about 50 °C (122 °F) and falls off on either side of this value. The decrease in erosion rate is most dramatic as temperature rises above 50 °C (122 °F) (see the section "Effects of Test Parameters" in this article).

Test Procedure. The specimen must be cleaned and accurately weighed before testing, then immersed in the test liquid to a depth between 3.2 mm (0.125 in.) and 12.7 mm (0.5 in.). The peak-to-peak displacement amplitude should be monitored constantly. The test should be interrupted periodically to determine the mass loss of the specimen, which should be carefully cleaned and dried before reweighing. The time between measurements should be such that a plot of cumulative mass loss versus exposure time can be established. The time between measurements, therefore, depends on the specimen material; softer materials (for example, aluminum alloys) can be examined every 15 min, while the interval between measurements for a harder material, such as Satellite alloy 6B, may range from 8 to 10 h. Testing should be continued at least until the erosion rate reaches a maximum and begins to diminish. When several materials are being compared, all should be tested until they reach comparable mean depths of erosion.

Data Acquisition and Reporting. The mean depth of erosion of the specimen should be calculated based on the full area of the test surface of the specimen. The report should include the following information:

- Alloy type, metallurgical condition, composition, and mechanical properties (including hardness)
- Specimen preparation, preferably including initial surface roughness measurement
- The number of specimens tested
- Tabulation of cumulative mass losses and cumulative exposure time for each specimen
- Plots of cumulative mean depth versus cumulative exposure time for each specimen

To facilitate comparisons between different materials, results are often expressed in terms of a single number based on the erosion resistance of the test specimen relative to that of a standard reference material. These types of ratings are discussed more fully in Ref 4.

The report should also include information on any deviations from the standard test procedure (for example, test liquid, temperature, or pressure, as discussed earlier) as well as any unusual occurrences or observations. In addition, each test should include at least one of the standard reference materials to facilitate calculation of the normalized erosion resistance of the test materials. Reference materials include aluminum alloy 1100-0, commercially pure annealed nickel (for example, Nickel 270), and type 316 stainless steel with a hardness of 150 to 175 HV. As previously mentioned, these materials are also used to calibrate the testing apparatus.

ASTM Standard G 73 provides guidelines for liquid drop impingement testing that, in addition to evaluating the resistance of metals, can be used to evaluate the degradation of optical properties of window materials and the destruction of coatings by the impinging liquid (Ref 4). The standard does not outline a single test method or apparatus, but instead gives guidelines for setting up tests and specifies test and analysis procedures and the reporting of data.

Test Specimens. Metallic test specimens can be chosen to present a curved (airfoil or cylindrical) or flat surface to the impinging liquid. They can be machined from a solid bar or can be cut from sheet. If specimens are machined, care should be taken to avoid work hardening of the surface. Surface finish should range from 0.4 to 2.6 μm (16 to 63 μin.) rms (root mean square). If another surface finish is employed, it should be noted in the test report.

Test Apparatus. ASTM Standard G 73 mainly addresses erosion test devices of the rotating disk type. In these tests, the specimen or specimens are attached to a rotating disk or arm, and their circular path passes through one or more liquid jets or sprays, resulting in discrete impacts between the specimen and the droplets or the cylindrical surface of the jets. Peripheral velocities (and therefore impact velocities) ranging from about 50 m/s (165 ft/s) to as high as 1000 m/s (3280 ft/s) may be obtained, depending on the particular apparatus used. Figure 2 illustrates two examples of rotating disk test apparatuses.

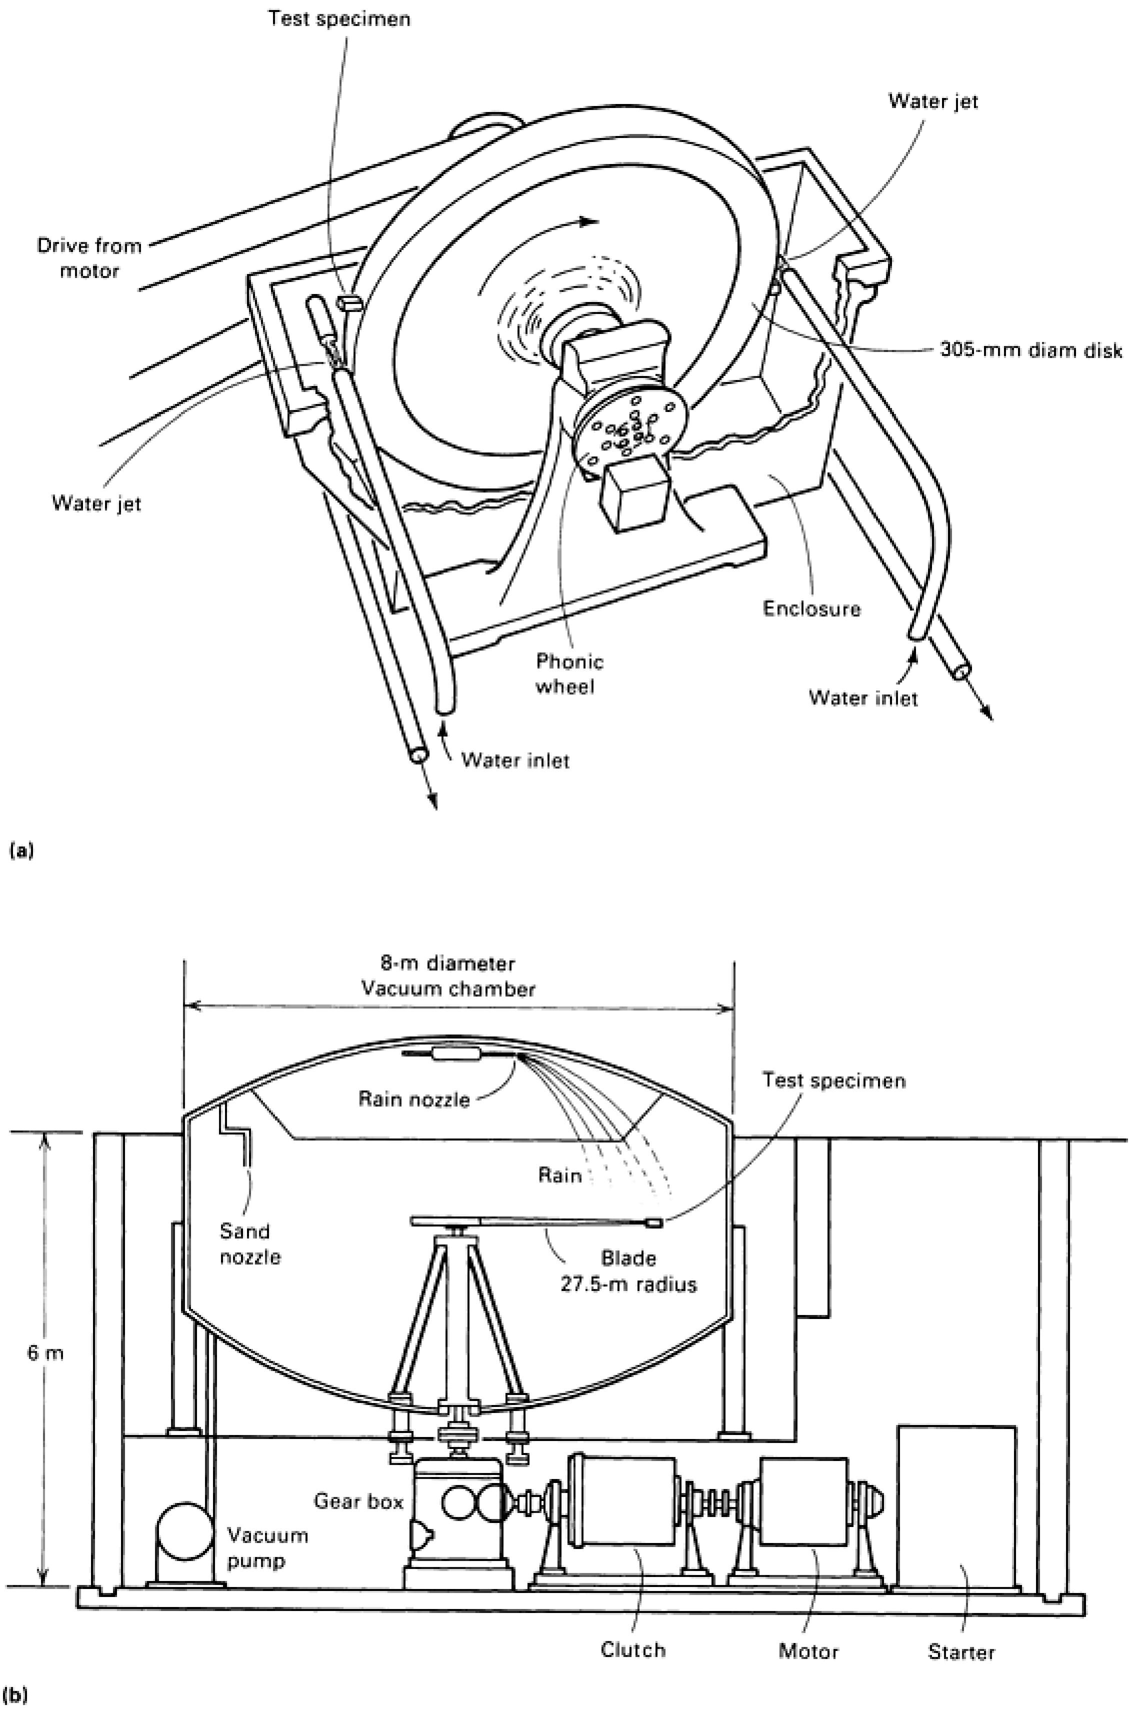

Fig. 2 Examples of rotating disk and rotating arm erosion/cavitation test apparatuses. (a) Small, relatively low-speed rotating disk and jet apparatus. (b) Large, high-speed rotating arm spray apparatus. Source: Ref 4

Droplet or jet diameters also vary from about 0.1 to 5 mm (0.004 to 0.2 in.). Droplets can be generated by spray nozzles, vibrating hollow needles, or rotating disks with water fed onto their surface. The typical droplet or jet diameter and the volume of liquid impacting the specimen per unit time should be determined within 10%. Jet diameter is usually assumed to be the same as the nozzle diameter. Other types of liquid impact erosion test devices are also briefly described in Ref 4.

Test procedures for various materials vary to some extent. The standard gives procedures for structural materials and coatings, including metals, structural plastics, composites, and metals with ceramic or metallic coatings; elastomeric coatings; window materials; and transparent thin-film coatings on window materials. Details on these procedures are outlined in the standard.

Calculation of Erosion Resistance. Because it is currently not possible to define "absolute" erosion resistance, most investigators use comparative evaluations of different materials to quantify relative erosion resistance. ASTM Standard G 73 details several approaches for calculating and presenting relative or normalized measures of erosion resistance for the various classes of materials considered. These include evaluation based on time to failure, total material loss, erosion rate-time patterns, incubation period and maximum erosion rate, and terminal erosion rate. Results for different materials can also be normalized by direct comparison to one of the designated reference materials (for metals, aluminum alloys 1100-0 or 6061-T6; annealed commercially pure nickel, such as Nickel 270; and type 316 stainless steel with a hardness between 155 and 170 HV) or by indirect comparison to a standardized reference scale. Details on these procedures, as well as on the calculation of an apparatus severity factor, are given in ASTM G 73.

Other Tests

Numerous other techniques are available for evaluating cavitation and erosion in the laboratory. Most of these are variations on the methods already described, employing rotating disks, vibrating devices, or venturi tubes to achieve the required fluid velocities (Ref 5). Another device used to produce cavitation and erosion is the liquid gun, which projects short, discrete slugs of liquid out of a nozzle onto the specimen (Ref 6). Details of other nonstandard test procedures are available in Ref 7, 8, and 9.

Effects of Test Parameters (Ref 5)

Test conditions--including the temperature, pressure, and flow velocity of the test liquid and the frequency, amplitude, and distance between the specimen and the vibrating surface in a vibrating fluid--all influence the incubation and intensity of cavitation. The effects of varying these test parameters are described below.

Variations in velocity and pressure should not be considered separately, because the intensity of erosion cavitation is a function of both parameters. Generally, erosion rates increase with velocity. A common technique used to evaluate the effect of velocity is to determine the number and size of pits produced in a soft material, such as aluminum, per unit time as velocity is varied (Ref 10). Although the number of pits observed increases over a wide range with velocity, the variation in pit size is relatively insignificant.

The influence of pressure has been investigated for both flow and vibratory cavitation (Ref 11, 12). In the former investigation, velocity was held constant and pressure was increased. Cavitation damage increased to a maximum and then decreased to zero at the pressure corresponding to cavitation inception (Ref 11). In vibratory testing, the erosion rate increased steadily with increasing pressure up to 4 atm, the maximum pressure obtainable in the device used (Ref 12). The authors noted, however, that at sufficient pressure the cavitation rate would in fact drop to zero.

Temperature. As mentioned earlier in this article, erosion rate increases with temperature to a maximum, then decreases near the boiling point of the test liquid. The decrease in erosion rate near the boiling point is attributed to the increase in vapor pressure of the test liquid (Ref 5). The effect of temperature on the erosion rate of plain carbon steel in three aqueous environments is shown in Fig. 3.

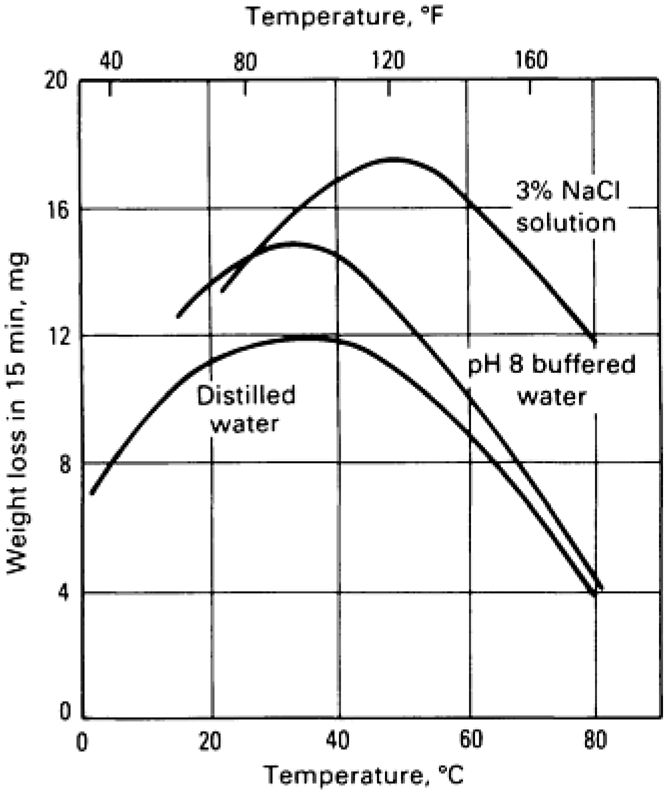

Fig. 3 Influence of temperature on the erosion rate of plain carbon steel in a vibratory cavitation device. Source: Ref 5

Amplitude and frequency in vibratory devices influence the degree of damage. In tests at constant frequency, erosion rate increased slightly with increasing amplitude (Ref 13). The incubation period for damage decreased with increasing amplitude.

Most vibratory devices operate at the the resonant frequency of a piezoelectric crystal. Therefore, frequency cannot be easily varied over a significant range. In one investigation, three different devices with frequencies of 10, 20, and 30 kHz were used to determine the effect of frequency on erosion rate (Ref 13). The stress produced by the cavitation increased as frequency decreased, but the effect was not as significant as that caused by changes in amplitude.

Distance Between Specimen and Vibrating Surface. The amount of erosion damage to a specimen rises to a maximum as the distance between the specimen and the vibrating surface decreases. At a frequency of 20 kHz, the position that results in maximum erosion rates is approximately 0.5 mm (0.02 in.) from the vibrating surface (Ref 5). The position of the maximum is independent of amplitude, but no data are available on the influence of frequency on this position.

The influence of fluid properties has been studied by several investigators. Unfortunately, most of them made little attempt to identify those properties of the fluid that affect erosion rates. One investigator, however, considered fluid viscosity, vapor pressure, surface tension, and specific gravity for water, gasoline, and the sodium-potassium eutectic (Ref 14). The temperature dependence of erosion rates was attributed to the effects of velocity and surface tension at low temperatures and to the increase in vapor pressure at high temperatures. By comparing the temperature dependence of properties of the different fluids, he was able to predict the variation in erosion damage in the three fluids. The resulting equation, however, cannot be used to predict erosion rates in other fluids.

Data Correlations

Correlations Among Test Methods (Ref 2). Investigations have indicated that there are considerable differences in the erosion intensities produced by different test techniques (that is, high-velocity flow, vibratory, and impingement) and

test parameters (vibratory frequency; specimen size and shape). There is, however, general agreement on the ranking of test materials. When the erosion resistance of a material is expressed as a normalized erosion resistance (NER), which is the ratio of the erosion rate of the test material to that of a standard material, results from different test methods and different laboratories can be directly compared and are reasonably consistent (Ref 15). Calculation of NER values and statistical analysis of erosion rate data are discussed in detail in Ref 4, which also reports on the results of interlaboratory testing using a liquid impingement testing method at three specified velocities.

Correlations Between Laboratory Results and Service (Ref 2). The erosion rates of materials that can be anticipated in service cannot be quantified at this time; however, methods have been developed to identify service erosion intensities under conditions of controlled operation. These include aluminum panels attached to hydraulic turbine vanes (Ref 16), a strain gage technique for measuring the relative intensities of laboratory and service devices (Ref 17), and the use of a radioactive paint to correlate the erosion intensity of an operating turbine with an erosion rate index (Ref 18). This latter investigation led to the establishment of relative resistance scales, in which laboratory exposures of 1 to 2 h in a vibratory apparatus can be compared with 16- to 100-h exposures in a venturi apparatus and with months of operation in full-scale turbines.

Evaluation of Microbiological Corrosion

John G. Stoecker II, Monsanto Company

Introduction

THE MANY CASE HISTORIES reported in the literature point out that microbiological corrosion can occur in any aqueous environment. An aqueous environment is defined as any environment that contains even a trace amount of water. For example, the small amount of water in aviation fuel qualifies that environment as aqueous. Therefore, microbiological corrosion is a potential problem. Because microorganisms are present in virtually all aqueous systems, they have the potential to influence corrosion in any aqueous system anywhere in the world.

An evaluation of the possibility for microbiological corrosion must be considered a part of good engineering practice when planning a new facility or process. This consideration must include water used for such processes as hydrostatic testing and water batching even though the final process environment may not contain water even in trace amounts. The water used by fabricators to hydrostatically test new equipment, along with the mud and soil in the construction area, must also be considered sources of microbes and associated corrosion problems. Microbiological corrosion should be avoided from all of these various sources, because the damage initiated by the microbes may continue as crevice or under-deposit attack after the organisms are killed in a nonaqueous process. There are currently no standard tests for determining whether or not the microbes present at a given site will be involved in initiating or accelerating corrosion. Nevertheless, several factors should be considered in identifying the potential for biological corrosion, as discussed below.

Use of Historical Data

The history of biological corrosion problems with the intended water source at the proposed site can provide a great deal of information regarding the potential for problems. An investigation at neighboring facilities can also yield valuable information, particularly when planning a new installation on an undeveloped site. Because many cases of microbiological corrosion have been misidentified as crevice or under-deposit corrosion, the investigation should center on the history of these problems. The investigation should include problems associated with microbes in the water and in the ground.

During the investigation, it is helpful to have several case histories with photographs of microbiologically influenced corrosion on hand. Some information of this type is available in this Volume in the articles "General Corrosion" (see the section "General Biological Corrosion") and "Localized Corrosion" (see the section "Localized Biological Corrosion") and in the Appendix to the article "Effects of Environmental Variables on Aqueous Corrosion." These articles also contain information on the mechanisms of microbiological corrosion and the environmental conditions under which it occurs. The section "Localized Biological Corrosion" mentioned above presents a table listing the industries known to be affected by microbiological corrosion and another table showing the microorganisms involved. Considerably more information is available in Ref 1 and in the references listed in the articles mentioned above.

The investigation of a water source can include many users if the source is a large municipal system. The list of users to be investigated can be reduced to a manageable number by selecting those that use the water in a manner similar to the intended use. Similar, in this context, means at the same temperature and pH, because the various microbes are generally active and troublesome only between specific temperatures and ranges of pH. Microbes seem to be the most troublesome at temperatures equivalent to the temperature of the human body and at pH 7, but there are cases in which they have created problems at extremes of both temperature and pH.

It should be noted that a filter-treated and/or chlorinated water source does not eliminate the potential for microbiologically influenced corrosion. Chlorination is not totally effective in eliminating all microbes from water, and it has been shown that several species use chlorides for metabolic purposes after the free chlorine has been reacted. In addition, microbiological activity is a persistent problem in ultrapure deionized water in which extremely fine filters are used; this proves that filtration will not remove all microbes or eliminate the problems they may cause. Additional information on the control or elimination of microbes in waters can be found in the article "Control of Environmental Variables in Water Recirculating Systems" in this Volume.

Testing for Microbiological Activity

The water source and soil at the proposed site should be tested for microbiological activity. These tests should be conducted under the direction of a microbiologist who has experience in microbiologically influenced corrosion. Field test kits are currently available that employ an antibody tagging technique to identify and facilitate the determination of the population or troublesome microbes, as described in Ref 2 and 3.

Chemical Analysis

Chemical analysis of the water source and the soil at the site is helpful in determining whether the critical nutrients and energy sources necessary to support microbiological activity are present. For example, the presence or absence in the environment of sulfur and its compounds to support the growth of sulfate-reducing or sulfur-oxidizing bacteria can be determined by chemical analysis. Chemical analysis should be used with caution, however, because the availability of nutrients is not a totally controlling factor in microbiological activity. Microbes are adaptable and can use both organic and inorganic sources for energy (Ref 4). Moreover, growth of a harmless bacterial species can sometimes result in production of a nutrient, not present in the ambient environment, that will allow the damaging species to flourish at a later time. In addition, microbiological activity is a major problem on filters in ultrapure deionized water, in which nutrients would seem to be rather scarce.

Corrosion Testing

The preceding discussion has dealt with determining the potential for microbiological corrosion problems at a new and undeveloped site where utility services are not available. At a developed site where energy sources such as electricity and steam are available, corrosion testing can be a valuable tool for assessing the potential for future problems or analyzing a present corrosion problem to determine if biological activity is involved (Ref 5, 6). Utilities are usually required to design tests so that the environmental conditions of the intended process can be reproduced as closely as possible.

There are no standard tests designed specifically for investigating susceptibility to microbiological corrosion. The presence of microorganisms in an environment, however, does not introduce some new type of corrosion, but rather influences the types of corrosion that are already known. Therefore, if the types of corrosion that a given material of construction is susceptible to are known, the standard test methods for those types (specified elsewhere in this Volume) can often be helpful--if supplemented with the proper biological techniques for the organisms involved.

As with most corrosion testing, the environmental conditions in the test vessels must match those in the proposed process in order to obtain valid results. Coupon and test probe procedures (described elsewhere in this Volume) should not be used to determine and/or confirm the potential for microbiological corrosion without the benefits of microbiological analysis. Laboratory testing is not recommended, because a population of mixed species is extremely difficult to maintain in this type of setting.

The corrosion tests will yield some very unusual results if the damage was microbiologically influenced. The damage will almost always be localized in the form of a pit (Fig. 1), whether under a deposit, tubercule, or scale; in a crevice; or nearly surrounded by a stain on the metal surface. In addition, there is usually a peculiar color associated with the damage.

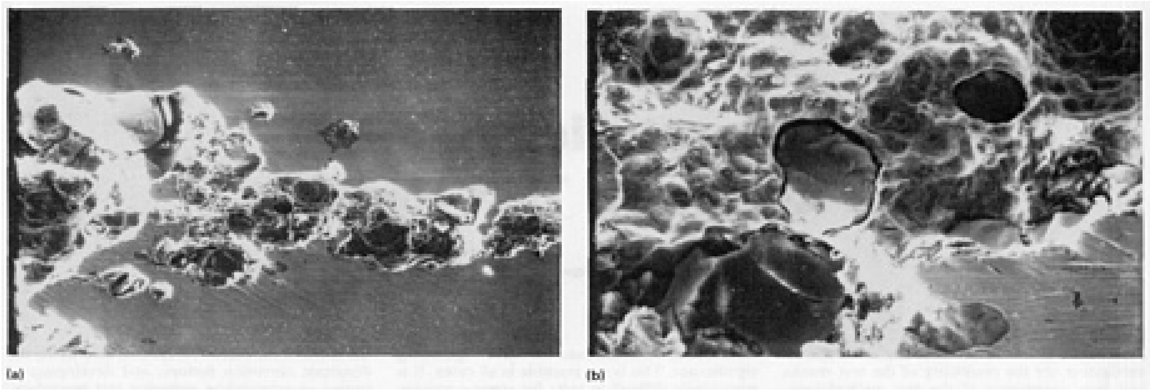

Fig. 1 Intergranular corrosion in a type 304 stainless steel associated with a typical pit and microbiological deposit. (a) View at 100×. (b) Higher-magnification view at 400×. Source: Ref 7

For example, the deposits, tubercules, and stains associated with the damage on carbon and stainless steel will usually be reddish brown. The pit in a copper alloy under scale will usually be vivid green. Black spots of iron sulfide will usually be present in association with the damage where sulfate-reducing bacteria are involved. A few drops of hydrochloric acid on these black spots will produce the pungent odor of hydrogen sulfide as a test for sulfur in this case.

Chemical analysis of the residue associated with the damage will usually show a depletion of iron and nickel and an increase in the concentration of chromium and copper as compared to the normal levels in the base material. Usual levels of chlorine, sulfur, manganese and other tramp elements may also be present in the residue.

Risk Analysis

A risk analysis should be performed based on the information collected according to the preceding outline. The information gathered from the case histories of the water and neighboring sites, along with the corrosion test results, should receive the heaviest weighting in this analysis. Much of the work that has been done to assess the risk of microbiological corrosion in soils and in North Sea oil pipeline environments is summarized in the article "Localized Corrosion" in this Volume.

Actual experiences are better suited to uncovering problems caused by dormant spores that have become active than are field microbiological and chemical tests. For example, spores that have been dormant for centuries have been found in the permafrost of Antarctica. These spores need only the proper environment to become active, as in the case with oil facilities in the North Sea and Arctic Ocean.

With this in mind, a safe, conservative approach during the risk analysis is a good policy. In this context, a safe, conservative approach involves the pessimistic view that microbiological corrosion will be a problem when definite facts and data are not available. Actual methods for reducing the potential for microbiological corrosion are covered in the articles "Localized Corrosion" and "Control of Environmental Variables in Water Recirculating Systems" in this Volume.

Summary

Several factors that should be considered in identifying the potential for biological corrosion have been presented. It should be noted that this is a relatively new and unexplored corrosion phenomenon for industry. Because it is a new field of study, the knowledge concerning it is expanding very rapidly; this makes the numbered references in this article extremely important as sources of detailed, current information.

Interpretation and Use of Corrosion Test Results

Donald O. Sprowls, Consultant

Introduction

IMPORTANT ASPECTS of any corrosion investigation are the credibility of the test results and user acceptance of the test methodology. When commercially competitive materials are evaluated or when corrosion tests are used for material acceptance, the testing techniques come under close scrutiny and quick criticism in the marketplace. Public safety and producer liability are potent considerations in decisions involving material selection and the determination of safe environments.

After the appropriate test (or tests) is completed, the data must be analyzed and presented in a manner that facilitates proper decision making. To be useful, an expression of the test results must have engineering significance, must be mechanistically sound, and must be comprehensible (Ref 1). Finally, there is the question of the amount of confidence that can be placed in the decision.

Credibility of Test Results

The question of the reliability of corrosion test results is discussed in the first article in this Section, "Planning and Preparation of Corrosion Testing." The following 13 articles are devoted to methods of generating reliable data. This article will consider the cost effectiveness of corrosion testing. One of the conclusions reached in Ref 2 is that perhaps the greatest problem is the misapplication of reliable laboratory corrosion data. An accelerated test can reliably indicate only how a given material will behave under the actual conditions of testing. Confidence should not be placed in accelerated corrosion test data when they are applied to other conditions, nor should a one-to-one correlation be expected. A significant degree of confidence is justified only after an accumulation of sufficient experience in correlating test data with actual performance behavior under known conditions (Ref 2).

Data that can be directly used in design or for control of operations will be obtained only in certain situations in which a corrosion test is required to provide an answer to a specific corrosion problem in a specific environment. Most often, the results must be interpreted in terms of comparisons or rankings. A criticism of such interpretations is that they are subjective; that is, they depend too much on the judgment of the investigator. Therefore, it is advisable when planning a corrosion-testing program to select techniques carefully in order to provide ranking parameters that are subject to minimal influence from testing conditions and that have engineering significance. This is not possible in all cases. It is particularly difficult in tests for stress-corrosion cracking (SCC) and corrosion fatigue cracking because there are so many confusing variables in these tests.

Interpretation of corrosion test results is also complicated by the time factor and by the consequences in the event of a corrosion failure. In addition, there are more difficult questions than ever before due to the increased use of toxic materials--questions such as:

- Can service life be predicted, and with what level of confidence?
- Will serious corrosion occur? In what form? Is there an incubation period?
- What is the corrosion rate, and will it change with time?
- What are the consequences of corrosion failure in terms of public safety and inconvenience, loss of life and property damage, and liability and cost?
- How can an acceptable degree of risk be defined in the selection of new, more corrosion-resistant materials?
- Is supplemental corrosion protection needed? If so, what type is best, and how long will it be effective?

Therefore, credible interpretation in many cases of material and environmental evaluation is ultimately a shared responsibility of the corrosion engineer, the material engineer/designer, and possibly a statistician. It should be recognized in the planning stage that the corrosion engineer needs input from the equipment designer to help identify the corrosion system correctly. A corrosion system consists of one or more metals and all parts of the environment that influence corrosion during the expected lifetime of a structure.

User Acceptance

Reference 1 contains a discussion of the user acceptance problem, with emphasis on the rank-ordering concept for interpreting material and environmental evaluation tests. A more critical approach to rank ordering is one way of improving user acceptance of laboratory test results. A preferred ranking parameter would be a dominant factor in the corrosion test and would be recognizable to the user/engineer as a type of data that would be useful.

Development of an appropriate corrosion-testing plan requires considerable research and engineering effort. Research aspects involve defining the limits of the corrosion system, identifying the dominant corrosion factors, and developing/selecting an appropriate corrosion test procedure. The engineering aspect involves collecting service experience data and correlating it with laboratory corrosion test data to permit establishment of acceptability criteria. An example of how this was done in the case of sulfide stress cracking is shown in Table 1. In this example, critical stress, S_c, for 50% probability of failure in a standard laboratory test was the rank-ordering parameter for materials considered for use in sour gas environments. Accumulated field experience with various materials was used to set an S_c acceptability limit. The validity of this limit was confirmed by showing that specimens cut from actual field service failures had S_c values below the acceptability criterion.

Table 1 Correlation of service sulfide stress cracking experience with typical laboratory test data that allowed establishment of the acceptability criterion of $S_c > 10$

Type of steel	Field experience failure frequency	Laboratory tests S_c (typical)[a]
API grade J-55	nil	11-17
API grade C-75	nil	10-17
API grade N-80	Moderate	5-14
API grades P-105, P-110	High	3-10

Source: Ref 3

(a) S_c is defined as the "critical stress" (ksi × 0.1) calculated from the deflection of a beam specimen (three-point loading), which corresponds to a 50% probability of failure in a standardized hydrogen sulfide solution as calculated from results obtained at varying beam deflections.

The lack of an acceptability limit for the rank-ordering parameter can delay engineering acceptance of a proposed standard corrosion test. A cooperative industry effort is usually required to obtain the necessary field experience information.

Statistical Planning and Analysis

Many investigators have traditionally avoided the use of statistical techniques because the added reliability did not seem to offset the effort and time required to become familiar with the methodology or to perform the calculations. Some individuals within larger organizations have access to company statisticians and to central computers, but because of lack of communication, these services have often not been used to advantage.

For example, the corrosion engineer performs the experiment and then turns over the data to a statistician for analysis. The statistician either does the best job that can be done with the available data or informs the engineer that the experiment was not properly designed. In the latter case, the engineer either decides to learn about statistical design or no longer seeks the services of a statistician.

Fortunately, personal computers have replaced the engineers' slide rule. The software that is available includes comprehensive statistical analysis programs. From these, methods can be selected to suit particular needs. Therefore, data can now be statistically analyzed almost as fat as the numbers can be punched on a keyboard. The engineer need only become familiar with statistical methods of experimental design and data analysis in order to take advantage of these expanded capabilities. With these techniques, the engineer can maximize both the amount of information obtained and the reliability of the results for any set amount of expended effort.

Reference 4 contains an introduction to the techniques of experiment design and data analysis. The specific application of statistics to corrosion problems often involves simplification and the use of a limited number of methods. Specification ASTM G 16 provides a set of sample procedures that is currently used in the statistical analysis of corrosion experiments (Ref 5). The examples included are intended to provide a method for planning corrosion experiments, analyzing data obtained, and establishing the degree of confidence that can be placed in the results of specific experimental or field applications data. Alternative methods or improved approaches are constantly being developed that may provide more complete analysis and understanding of specific experiments. More detailed information is given in Ref 6 and in the Section "Statistics and Data Analysis" in *Mechanical Testing,* Volume 8 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Computers and Data Utilization

With the advent of digital circuitry and the widespread use of microcomputers in the laboratory, new and extremely powerful techniques are now available for data acquisition, numerical processing, data management, and data communication. These techniques can provide higher resolution and can be less labor intensive, faster, and more interactive than conventional data recording (Ref 7, 8).

Corrosion will continue to be an important subject because it involves processes that cause serious deterioration of engineering structures. However, in the words of a British corrosion worker, "Existing technical data are not being properly used. The problem centers on how to translate the complexities of the corrosion processes into tabular form and simple equations that can be handled by artificial intelligence techniques. Since computer-aided systems have been developed for machine designs and chemical process flow sheets, it surely follows that this will be a major effort in the next few years. It will be necessary to look away from the laboratory bench and re-examine what the present needs of the user engineer community are" (Ref 9).

Materials Selection*

Gregory Kobrin, E.I. Du Pont de Nemours & Company, Inc.

Introduction

FACTORS THAT INFLUENCE the service life of equipment, for example, a chemical process heat exchanger or tank, a bridge, or an automobile chassis, from a corrosion standpoint include the following (Ref 1):

- Design
- Materials of construction
- Specification
- Fabrication and quality control
- Operation
- Maintenance
- Environmental conditions

In weighing the relative importance of these factors, design and materials are of major and equal importance in achieving the desired performance and life. The designer and materials engineer must work closely together to ensure that premature failure will not occur because of design defects or improper material selection. It is also inefficient and costly to use these elements of design and material selection in a compensatory manner.

This article will discuss the step-by-step process by which materials are selected in order to avoid or minimize corrosion and will include information on materials that are resistant to the various forms of corrosion. Subsequent articles in this Section will discuss design details that can be applied to minimize corrosion, the application of fracture mechanics to equipment design, corrosion of weldments, and the economics of corrosion.

Note

* The section "Hydrogen Damage" was written by George E. Kerns, E.I. Du Pont de Nemours & Company, Inc.; the section "Erosion-Corrosion" was written by J.Q. Lackey, E.I. Du Pont de Nemours & Company, Inc.

The Materials Selection Process

Review of Operating Conditions. The first step in the materials selection process is a thorough review of the corrosive environment and equipment operating conditions. This review requires input from knowledgeable process engineers. Precise definition of the chemical environment, including the presence of trace compounds, is vital. For example, the nickel-molybdenum alloy Hastelloy B-2 (UNS N10665) is highly resistant to hydrochloric acid (HCl) up to the atmospheric boiling point. However, the presence of small quantities of oxidizing metal ions, such as ferric ion (Fe^{3+}), will result in severe corrosion. Other operating conditions that require definition, especially for equipment used in the chemical-processing industry, include temperatures, pressures, flow rates, liquid versus gaseous phases, aqueous versus anhydrous phases, continuous versus intermittent operation, media used for cooling or heating, external versus internal environment, and product purity.

Abnormal or upset conditions are often overlooked during the selection process. For example, plain carbon steel may be the optimum choice for vessels and piping that must contain noncorrosive hydrocarbon gases, such as ethylene, under pressure at normal temperatures. However, the cooling effect that occurs during venting to the atmosphere, for whatever reason, may lower the temperature of vessels, piping, and relief valves to below the ductile-to-brittle transition point and

result in a catastrophic brittle fracture. Thus, the selection of special steels, qualified by impact testing at the lowest expected temperature, would be appropriate.

Review of Design. Next, the type and design of the equipment and its various components should be considered, along with size, complexity, and criticality in service. Selecting a material for a simple storage tank generally does not require the same attention and effort as choosing the material of construction for a highly sophisticated chemical process reactor. This is especially true when considering critical, unique pieces of equipment in large, single-train, continuous process plants in which a failure would shut down the entire operation. In this case, great effort is expended to select the optimum material for safe low-maintenance service.

The materials used to join the components into an assembly will require as much attention as the component materials themselves. Many bolted agitator assemblies in reactors, as well as riveted wheels in centrifugal compressors, have failed catastrophically because the bolts or rivets did not have adequate strength or corrosion resistance.

When welding is the joining method, the materials engineer is challenged to ensure that the welds are as corrosion resistant as the base metals. Generally, the weld metal must equal the base metal in chemical composition and must be virtually free of surface defects, such as porosity, slag inclusions, incomplete penetration or lack of fusion, for long maintenance-free service. The challenge is even greater when dissimilar-metal welds are required. Improper selection may allow local attack due to weld metal dilution or may allow hydrogen-assisted cracking due to hard heat-affected zones (HAZs). More information on preventing corrosion of welds is available in the article "Corrosion of Weldments" in this Volume.

Selection of Candidate Materials. Once the chemical environment, operating conditions, and type and design of the equipment have been defined, consideration of materials of construction is in order. Occasionally, the selection is based on reliable, pertinent past experience and, as such, is well defined. More often, however, selection is anything but straightforward for a number of reasons, such as complex chemical environments and stringent code requirements.

The list of materials to choose from is large and continues to increase. Ferrous and nonferrous metals and alloys, thermoplastics, reinforced thermosetting plastics (RTP), nonmetallic linings, glass, carbon and graphic, and catalyzed resin coatings are among the various materials available. Many materials will be immediately excluded because of service conditions, that is, pressures too high for RTP, temperatures too high for nonmetallic linings and coatings such as rubber or epoxy resins, environment too aggressive for carbon steel, and so on. Remaining choices may still be great in number.

It is always desirable to minimize the list of materials; this allows in-depth evaluation. In other cases, the initial list may be exceptionally small because of limited knowledge about the operating conditions or the complex chemical environment. A search of data sources should follow in either case.

Literature Survey. One might begin with a literature survey, using applicable sources such as *Corrosion Abstracts* (Ref 2), along with the *Corrosion Data Surveys* (Ref 3) published by the National Association of Corrosion Engineers (NACE). This technical society, in conjunction with the National Bureau of Standards, has initiated an on-going program to computerize reference data on the performance of materials in corrosive environments.

Other data sources include a wide variety of handbooks, conference proceedings, and literature compilations published by the American Society for Testing and Materials (ASTM), ASM INTERNATIONAL, and NACE. In addition, expert systems, which are computer programs containing methods and information developed by experts, are the latest tools available for materials selection (Ref 4, 5, 6, 7). Such systems are designed to solve problems, make predictions, suggest possible treatments, and offer materials and corrosion advice with a degree of accuracy equaling that of their human counterparts.

Experience and data generated in-house often serve as the most reliable bases for materials selection. Ideally, this is coupled with outside experience, when available, from materials vendors and equipment fabricators to complete this initial screening process. Contacts with clients referred by vendors should not be overlooked for added experience.

At this point, the list of candidate materials should be narrowed to a reasonable number for in-depth evaluation. Final selections should not be based solely on the above data sources, because in most cases the data provided are insufficient for the complete characterization of an environment or a set of conditions.

Evaluation of Materials. The in-depth evaluation of each candidate material should begin with a thorough understanding of the product forms available, along with the ease of fabrication by standard methods. For example, it would be wasteful of time and money to evaluate an Fe-14.5Si alloy for anything but a cast component such as a pump casing or valve body. The alloy is unavailable in any other form. Because of its poor weldability, this alloy should also be ruled out for applications involving welding.

Corrosion testing in representative environments is generally the next step. The extent of the investigation (and determination of test conditions) depends on such factors as (Ref 8):

- Degree of uncertainty after available information has been considered
- The consequences of making a less-than-optimum selection
- The time available for evaluation

Laboratory testing of candidate materials is common and in some cases may be the only means available for final determination. Wherever possible, the actual process fluids should be used. Otherwise, mixtures simulating the actual environment must be selected. There is considerable risk in using the latter, because undefined constituents can have a significant effect on the performance of a particular material.

Depending on the application, weighed and measured coupons of candidate materials are exposed to the corrosive fluids under a variety of conditions ranging from simple static immersion at a controlled temperature to complex testing under combined heat transfer and velocity conditions. Guidance for conducting laboratory corrosion tests is available in Ref 9 and 10. After exposure for a specified length of time (generally a minimum of 1 week), the coupons are, in the case of metals and alloys, cleaned and reweighed, and a corrosion rate is calculated based on weight loss and exposed surface area. The rate is commonly expressed in millimeters of penetration per year or inches or mils (1 mil = 0.001 in.) of penetration per year.

In addition, coupons are examined under a microscope for evidence of local attack, such as pitting, crevice corrosion, and exfoliation. Special coupons, such as galvanic couples, welded, and stressed coupons, are often exposed to determine if other forms of corrosion may occur on certain metals and alloys. These coupons may require metallographic examination for evidence of dealloying (parting), stress-corrosion cracking (SCC), intergranular corrosion, and other corrosion phenomena.

Nometallic materials, such as thermoplastics, coatings, reinforced thermosetting resins, elastomers, and ceramics, are also evaluated in laboratory test, but the criteria are different from those used for metals. First, exposure time must generally be longer (often a minimum of 1 to 3 months) before significant changes occur. Exposure times of 6 months to 1 year are common. Also, corrosion rate calculations based on weight loss and surface area are not applicable in most cases. Of more importance are changes in weight, volume, hardness, strength, and appearance before and after exposure. Corrosion testing and evaluation are covered in detail in the Section "Corrosion Testing and Evaluation" in this Volume.

If possible, candidate materials should be tested under conditions more like the final application rather than in laboratory glassware, that is, in a semi-works or pilot operation or in full-scale equipment. Generally, the results are more reliable because test coupons are integrated into the process and are exposed to the same conditions as the actual equipment. Because of nonuniform conditions (flows, composition) within process equipment, coupon locations should be carefully selected (see the article "In-Service Monitoring" in this Volume).

Reliability is further enhanced when it is possible to test full-size components fabricated from candidate materials (Ref 11). Examples include:

- Flanged sections of selected alloys and/or nonmetallics installed in a pipeline
- Experimental alloy impellers in pumps for corrosion and cavitation studies
- Tubing installed in a full-size operating or miniature test heat exchanger to evaluate materials with optimum resistance to corrosion under heat transfer conditions
- Paddles of candidate materials bolted to a reactor agitator for erosion-corrosion studies

The primary disadvantages of this method of testing are the cost of fabrication, installation, removal, and evaluation; the downtime resulting from equipment being taken out of service and dismantled for evaluation; and the fact that a test component could fail prematurely and cause a unit shutdown and/or equipment damage.

Specifications. At this point, all candidate materials have been thoroughly evaluated (along with the economics, to be discussed later), and the materials of construction have been selected for the particular application. Clear and concise specifications must now be prepared to ensure that the material is obtained as ordered and that it meets all the requirements of the application. Perhaps the best known and most widely used specifications are the standards of ASTM. Thousands of specifications for virtually all metal and nonmetal materials of construction are covered in 15 sections encompassing 65 volumes.

Similar standards in countries other than the United States include DIN (Germany), BS (Great Britain), AFNOR (France), UNI (Italy), NBN (Belgium), and JIS (Japan). Other materials specifications that are well known but are more limited in application are those of the Society of Automotive Engineers (SAE) and its Aerospace Materials Specifications (AMS), the American Welding Society (AWS), the American Petroleum Institute (API), and the American National Standards Institute (ANSI).

Fabrication requirements must also be spelled out in detail to avoid mistakes that could shorten the life of the equipment and to satisfy the requirements of state and federal regulatory agencies and insurance companies. The American Society for Mechanical Engineers (ASME) code governs the fabrication of equipment for the chemical, power, and nuclear industries, and the API code governs the fabrication of equipment for the refining industry. Piping for these industries is generally fabricated per applicable ANSI codes. In these codes, allowable stresses for design calculations have been determined for virtually all metals and alloys that might be selected for corrosive (and noncorrosive) service. Where welding is the primary joining method, welding procedures and welders must be qualified before fabrication begins. Testing and quality assurance requirements, such as radiography, hydrostatic testing, and ultrasonic inspection, are also covered in the codes and are specified where applicable to ensure compliance.

The fabricator is generally required to provide detailed drawings that list dimensions, tolerances, all pertinent materials specifications, fabrication and welding details, and testing and quality assurance requirements for review. Prefabrication meetings are held for final review of all drawings and details so that customer and vendor are in agreement. Thus, problems or errors that could lead to costly delays in fabrication or failures in service can be detected early and corrected.

Money spent on inspection and monitoring during equipment fabrication/erection to ensure compliance with specifications is repaid by trouble-free startup and operation of the fabricated assembly. In some cases, every component of an assembly must be tested to avoid excessive corrosion and/or premature failure. For example, an addition quality check of a vessel fabricated from AISI type 316L stainless steel for hot acetic acid service might be to test every plate, flange, nozzle, weld, and so on, for the presence of molybdenum by using a chemical spot test method (Ref 12). The absence of molybdenum, which might indicate the mistaken use of a different stainless steel, such as type 304L, would result in accelerated corrosion in this service. Another example is the testing of every component (including well metal) of a heat exchanger fabricated from chromium-molybdenum steels for hot high-pressure hydrogen service to avoid the possibility of catastrophic failure by hydrogen attack. The use of portable x-ray fluorescence analyzers for this type of quality assurance testing of critical service components has become quite popular in recent years (Ref 13).

Follow-Up Monitoring. Once built, installed, and commissioned in service, the equipment, piping, reactor, heat exchanger, and so on, should be monitored by the materials engineer to confirm the selection of materials of construction and all other requirements for the intended application. Frequent shutdowns for thorough inspections (visually and with the aid of applicable nondestructive examination methods) and periodic evaluation of corrosion coupons exposed at key locations in the equipment represent both the ideal and most difficult monitoring techniques to achieve. In actual practice, equipment is generally kept on-stream continuously for long periods of time between shutdowns, so on-stream monitoring techniques must also be used.

In the petroleum industry, the internal corrosion in oil and gas production operations is often monitored with hydrogen probes (Ref 14). These instruments measure hydrogen created by corrosion reactions. A portion of the hydrogen penetrates the vessel or pipeline wall, and the rest of the hydrogen is dissolved in the process fluid or released as gas bubbles. Hydrogen probes measure hydrogen permeation and provide information on the rate of corrosion.

Other on-stream corrosion-monitoring techniques that are used in petroleum and chemical industries include:

- The electrical resistance and linear polarization methods (Ref 15). The former determines corrosion trends with time, and the latter determines an instantaneous corrosion rate (see the article "In-Service Monitoring" in this Volume)
- Ultrasonic thickness measurement. This is a useful monitoring tool, especially when baseline readings are taken at selected locations before the equipment is placed in service. The inspection locations can be changed if erosion or corrosion areas are localized

With these methods, the materials engineer is able to determine the adequacy of the materials selection and to predict the remaining life so that replacements and/or repairs can be scheduled well in advance of failure. The corrosion test methods discussed above can also be used to evaluate alternate materials that might be more cost effective at the time of replacement of the vessel or a component.

Selecting Materials to Avoid or Minimize Corrosion

General Corrosion. Of the many forms of corrosion, general, or uniform, corrosion is the easiest to evaluate and monitor. Materials selection is usually straightforward. If a material shows only general attack, a low corrosion rate, and negligible contamination of the process fluid and if all other factors, such as cost, availability, and ease of fabrication, are favorable, then that is the material of choice. An acceptable corrosion rate for a relatively low-cost material such as plain carbon steel is about 0.25 mm/yr (10 mils/yr) or less. At this rate and with proper design and adequate corrosion allowance, a carbon steel vessel will provide many years of low-maintenance service.

For more costly materials, such as the austenitic (300-series) stainless steels and the copper- and nickel-base alloys, a maximum corrosion rate of 0.1 mm/yr (4 mils/yr) is generally acceptable. However, a word of caution is in order. One should never assume, without proper evaluation, that the higher the alloy, the better the corrosion resistance in a given environment. A good example is seawater, which corrodes plain carbon steel fairly uniformly at a rate of 0.1 to 0.2 mm/yr (4 to 8 mils/yr) but severely pits certain austenitic stainless steels.

At times, nonmetallic coatings and linings ranging in thickness from a few tenths to several millimeters are applied to prolong the life of low-cost alloys such as plain carbon steels in environments that cause general corrosion. The thin-film coatings that are widely used include baked phenolics, catalyzed cross-linked epoxy-phenolics, and catalyzed coal tar-epoxy resins (see the article "Organic Coatings and Linings" in this Volume). It is advisable not to use thin-film coatings in services where the base metal corrosion rate exceeds 0.5 mm/yr (20 mils/yr), because corrosion is often accelerated at holidays (for example, pinholes) in the coating. Thick-film linings include glass, fiber- or flake-reinforced furan, polyester and epoxy resins, hot-applied coal tar enamels, and various elastomers such as natural rubber.

A special case for materials selection under general corrosion conditions is that of contamination of the process fluid by even trace amounts of corrosion products. In this case, product purity, rather than corrosion rate, is the prime consideration. One example is storage of 93% sulfuric acid (H_2SO_4) in plain carbon steel at ambient temperature. The general corrosion rate is 0.25 mm/yr (10 mils/yr) or less, but traces of iron impart a color that is objectionable in many applications. Therefore, thin-film baked phenolic coatings are used on carbon steel to minimize or eliminate iron contamination. In the same way, thin-film epoxy coated carbon steel or solid or clad austenitic stainless steels are used to maintain the purity of adipic acid for various food and synthetic fiber applications. More information on this form of corrosion is available in the article "General Corrosion" in this Volume.

Localized Corrosion. Although general corrosion is relatively easy to evaluate and monitor, localized corrosion in such forms as pitting, crevice corrosion, and weld metal attack is at the opposite end of the scale, and materials selection is difficult. Localized corrosion is insidious and often results in failure or even total destruction of equipment without warning.

All metals and alloy systems are susceptible to most forms of localized corrosion by specific environments. For example, carbon or alloy steel pipelines will pit in aggressive soils because of local concentrations of corrosive compounds, differential aeration cells, corrosive bacteria, stray dc currents, or other conditions, and these pipelines generally require a combination of nonmetallic coatings and cathodic protection for long life. Also, holidays in mill scale left on plain carbon steels are sites for pitting because the mill scale is cathodic to the steel surface exposed at the holiday. For this reason, it is advisable to remove all mill scale by sand- or gritblasting before exposing plain carbon steels to corrosive environments.

Pitting. Aqueous solutions of chlorides, particularly oxidizing acid salts such as ferric and cupric chlorides, will cause pitting of a number of ferrous and nonferrous metals and alloys under a variety of conditions. The ferritic (400-series) and austenitic stainless steels are very susceptible to chloride pitting (as well as to crevice corrosion and SCC, which are discussed later in this section). Molybdenum as an alloying element is beneficial, so molybdenum-containing stainless steels, such as types 316 and 317, are more resistant than the nonmolybdenum alloys. However, most chloride environments require higher alloys containing greater amounts of chromium and molybdenum, such as Hastelloy alloy G-3 (UNS N06985), Inconel alloy 625 (UNS N06625), and Hastelloy alloy C-22 (UNS N06022), for optimum performance. Exceptions are titanium and its alloys, which show exceptional resistance to aqueous chloride environments (including the oxidizing acid chlorides), and copper, copper-nickel, and nickel-copper alloys, which are widely used in marine applications.

Other noteworthy combinations of metals and corrosive fluids to avoid when selecting materials because of pitting tendencies include:

- Aluminum and aluminum alloys in electrolytes containing ions of such heavy metals as lead, copper, iron, and mercury
- Plain carbon and low-alloy steels in waters containing dissolved oxygen or in waters and soils infected with surface-reducing bacteria
- Austenitic stainless steel weldments exposed to stagnant natural waters, particularly U.S. Gulf Coast well waters, which are infected with iron and/or manganese bacteria (Ref 16)

An unusual form of localized corrosion known as end-grain attack has occurred in chemical-processing plants with such specific metal/fluid combinations as austenitic stainless steels in hot nitric acid (HNO_3) and organic acids, and plain carbon steels in decanoic acid.

When certain forms of these metals (for example, plates, threaded rods, or pipe nozzle ends) are cut normal to the rolling direction, the ends of nonmetallic inclusions at the cut edges are attacked by the process fluid; this results in small-diameter but deep pits. The solution is to seal the cut edge with a layer of weld metal that is equal to the base metal in composition.

Crevice corrosion can occur not only at metal/metal crevices, such as weld backing rings, but also at metal/nonmetallic crevices, such as asbestos-gasketed pipe flanges or under deposits. In some fabricated assemblies, it is possible and cost effective to avoid crevices by careful design. For example, crevice corrosion occurred behind a weld backing strip at the closing seam in a type 304L stainless steel reactor handling hot HNO_3. A small amount of corrosion by stagnant acid in the crevice created hexavalent chromium ions (Cr^{6+}), which caused accelerated attack; other exposed surfaces in the vessel were unaffected. The closing seam could have been welded from both sides or from one side with a consumable insert ring, which would have avoided the problem. Similar attack has occurred in stainless shell and tube heat exchangers at the rolled tube-to-tubesheet joints and has been solved by seal welding the joints with appropriate weld filler metal and process.

However, in many cases, crevices are either too costly or impossible to design out of a system, so careful selection of materials is the answer. Titanium is susceptible to crevice corrosion in hot seawater and other hot aqueous chloride environments. Therefore, for a flanged and gasketed piping system in these fluids, commercially pure titanium grade 55 (UNS R50550) may be acceptable for piping, but flanges will require the more crevice attack resistant grade 7 (UNS R52400), which contains 0.15% (nominal) Pd, or grade 12 (UNS 53400), which contains small amounts of molybdenum and nickel. This is more cost effective than selecting the more expensive alloys for the piping as well. Another approach that has been successfully used in these fluids is installation of nickel-impregnated gaskets with grade 55 titanium flanges.

The austenitic stainless steels are susceptible to crevice corrosion in media other than HNO_3 solutions. For example, type 304L stainless steel exhibits borderline passivity in hot acetic acid solutions, particularly in crevices. Accordingly, the materials engineer will specify the more crevice corrosion resistant type 316L stainless steel where crevices cannot be avoided, such as piping and vessel flanges, or for the entire fabricated assembly because the cost differential between materials in this case may be negligible.

Preferential attack of weld metal is another form of localized corrosion that can be avoided by judicious selection of weld filler metal or weld process. Weld metal corrosion in high nickel-chromium-molybdenum Hastelloy alloy C-276

(UNS N10276) in a hot oxidizing H_2SO_4 process stream containing chlorides was eliminated by repair welding with Hastelloy alloy C-22 (UNS N06022). In applications in which type 304L stainless steel is selected for use in hot HNO_3 solutions, welds exposed to the process are frequently made by an inert gas process, such as gas tungsten arc or gas metal arc, rather than a flux-utilizing process, such as shielded metal arc. This prevents weld corrosion by eliminating the minute particles of trapped slag that are the sites for initiation of local corrosion. Many other examples of preferential weld metal attack and their solutions are discussed in the article "Corrosion of Weldments" in this Volume.

Nonmetallic materials of construction are widely used where temperatures, pressures, and stresses are not limiting and in such media as aqueous chloride solutions, which cause localized corrosion of metals and alloys. Examples in which lower-cost nonmetallic constructions are selected over expensive high alloys include the following:

- Rubber-lined steel for water treatment ion exchange resin beds, which must be periodically regenerated with salt brine or dilute mineral acids or caustic solutions
- Glass-lined steel for reaction vessels in chlorinated hydrocarbon service
- Acid-proof brick and membrane lined steel for higher temperature, and solid RTP polyester and vinyl-ester construction for lower temperature, flue gas and chlorine neutralization scrubbers

It should be apparent that an in-depth evaluation of candidate materials for environments that can cause localized corrosion is imperative in order to select the optimum material of construction. In particular, corrosion test coupons should reflect the final fabricated component--that is, include crevices and weldments where applicable--and should be examined critically under the microscope for evidence of local attack. In cases in which the more common 300- and 400-series stainless steels fall short, the newer ferritics, such as 26Cr-1Mo (UNS S44627) and 27Cr-3Mo-2Ni (UNS S44660), and the duplex ferritic-austenitic alloys, such as 26Cr-1.5Ni-4.5Mo (UNS S32900) AND 26Cr-5Ni-2Cu-3.3Mo (UNS S32550), should be evaluated as potentially lower-cost alternatives to higher alloys. Finally, proven nonmetallic materials (for example, the RTPs), used either as linings for lower-cost metals (such as plain carbon steel) or for solid construction, should not be overlooked. More information on the mechanisms of pitting, crevice corrosion, and other forms of localized attack is available in the article "Localized Corrosion" in this Volume: the articles "Corrosion of Weldments" and "Metallurgically Influenced Corrosion" contain information on the preferential corrosion of weld metal.

Galvanic corrosion is quite possibly the only form of corrosion that can be beneficial as well as harmful. The materials engineer will frequently select galvanic corrosion--that is, cathodic protection using sacrificial metal anodes or coatings of magnesium, zinc, or aluminum--to stifle existing, or prevent new, corrosion of structures fabricated primarily from plain carbon or low-alloy steels--for example, bridges, underground and underwater pipelines, auto frames, off-shore drilling rigs, and well casings. All too often, however, galvanic corrosion caused by contact between dissimilar metals in the same environment is harmful. Examples are:

- Unprotected underground plain carbon steel pipelines connected to above-ground tanks and other structures that are electrically grounded with buried copper rods or cables
- Stainless steel shafts in "canned" pumps rotating in carbon or graphite bushings in a strong electrolyte
- Copper-nickel or stainless steel heat exchanger tubes rolled in plain carbon steel tubesheets exposed to river water for cooling
- Aluminum thermostat housings on cast iron auto engine blocks in contact with glycol-water mixtures

Newer designs that require several different metals for various reasons such as cost and physical, mechanical, and/or electrical properties present a challenge to the materials engineer with regard to selection for the avoidance of galvanic corrosion. Knowledge of the galvanic series of metals based on the electrochemical potential between a metal and a reference electrode in a given environment is essential. A practical galvanic series for metals and alloys in seawater is given in Table 1.

Table 1 Practical galvanic series of metals and alloys in seawater

Least noble; most anodic; most susceptible to corrosion
Magnesium and its alloys
Zinc
Aluminum and its alloys
Cadmium
Plain carbon and low-alloy steels
Gray and ductile cast irons
Nickel cast irons
Type 410 stainless steel (active)
50Pb-50Sn solder
Type 304 and 316 stainless steels (active)
Lead
Tin
Muntz metal, manganese bronze, naval brass
Nickel (active)
Inconel 600 (active)
Yellow and red brasses, aluminum and silicon bronzes
Copper and copper-nickel alloys
Nickel (passive)
Inconel 600 (passive)

Monel 400
Titanium
Type 304 and 316 stainless steels (passive)
Silver, gold, platinum
Most noble; most cathodic; least susceptible to corrosion

Source: Ref 17 (condensed and modified from the original to include the precious metals)

A word of caution: Metals behave differently in different environments; that is, the relative positions of metals and alloys in the galvanic series can vary significantly from one environment to another. In fact, variations within the same environment can occur with changes in such factors as temperature, solution concentration, degree of agitation or aeration, and metal surface condition. Thus, galvanic series that are based on seawater or other standard electrolytes are worthwhile for initial materials selection for multiple metal/alloy systems in a given environment. However, additional tests should be carried out in the stated environment by using the anodic polarization measurements described in ASTM G 5 (Ref 10). Suitable metal combinations can be determined by examining and superimposing polarization curves of candidate metals and by estimating the mixed potential values (Ref 18).

In conclusion, the selection of dissimilar metals that are far apart on any galvanic series should be avoided unless provisions are made for sacrificial corrosion of one for another, as in cathodic protection. Otherwise, dissimilar-metal applications in corrosive environments should be approached with extreme caution and should be thoroughly investigated before making the final selections. The section "Galvanic Corrosion" of the article "General Corrosion" in this Volume contains more information on galvanic attack.

Intergranular corrosion is a selective form of corrosion that proceeds along individual grain boundaries, with the majority of the grain being unaffected. Intergranular corrosion can affect certain alloys that are highly resistant to general and localized attack: noteworthy are several of the 300- and 400-series stainless steels and austenitic higher-nickel alloys. These alloys are made susceptible to intergranular corrosion by sensitization--that is, the precipitation of chromium carbides and/or nitrides at grain boundaries during exposure to temperatures from 450 °C (840 °F) to 870 °C (1600 °F), with the maximum effect occurring near 675 °C (1250 °F). Exposure to such temperatures can occur during processing at the mill, welding and other fabrication operations, or by plant service conditions. The resulting depletion in chromium adjacent to the chromium-rich carbides/nitrides provides a selective path for intergranular corrosion by specific media, such as hot oxidizing (nitric, chromic) and hot organic (acetic, formic) acids.

Susceptible stainless steels are those that have normal carbon contents (generally >0.04%) and do not contain carbide-stabilizing elements (titanium and niobium). Examples are AISI types 302, 304, 309, 310, 316, 317, 430, and 446. Susceptible higher-nickel alloys include Inconel alloys 600 (UNS N06600) and 601 (UNS N06601). Incoloy alloy 800 (UNS N08800) despite the presence of titanium. Incoloy 800H (UNS N08810), Nickel 200 (UNS N02200), and Hastelloy alloys B (UNS N10001) and C (UNS N10002). Intergranular corrosion in these alloys is avoided by one or a combination of the following:

- Keep the alloy in the solution heat-treated condition at all times
- Limit interstitial elements, primarily carbon and nitrogen, to the lowest practical levels
- Add carbide-stabilizing elements, such as titanium, niobium, and tantalum, along with a stabilizing heat treatment where necessary

In general, these alloys are purchased from the mill in the solution heat-treated condition, a requirement of most specifications. With regard to the austenitic stainless steels, solution heat treating consists of heating to a minimum

temperature of 1040 °C (1905 °F) to dissolve all the carbides, followed by rapid cooling in water or air to prevent sensitization.

Preserving the solution-treated condition is difficult, except for certain applications in which reheating is not a requirement of fabrication. One example is a pump shaft machined from forged or rolled and solution heat-treated bar stock. However, most applications for these alloys, such as piping components and pressure vessels, require hot rolling (for example, of plate) or hot bending (for example, of pipe) and welding; these practices, as discussed earlier, can cause sensitization. Solution heat treating after fabrication is generally impractical, because of the possibility of irreparable damage due to distortion or excessive scaling or because of the inability to cool rapidly enough through the critical sensitization temperature range.

Therefore, in most applications involving exposure to environments that cause intergranular corrosion, the low-carbon/nitrogen or stabilized alloy grades are specified. The new ferritic stainless steel UNS S44800 with 0.025% C (maximum) plus nitrogen is replacing the higher-carbon 446 grade in applications in which resistance to intergranular corrosion is a requirement. Types 304L, 316L, and 317L, with carbon and nitrogen contents limited to 0.03% (maximum) and 0.10% (maximum), respectively, are used instead of their higher-carbon counterparts. The newer nickel-chromium alloy 904L (UNS N08904), with 0.02% maximum carbon, and the high-nickel Hastelloy alloys C-22 (UNS N06022) and B-2 (UNS N10665), which have maximum carbon contents of 0.015% and 0.01%, respectively, are now being used almost exclusively in the aswelded condition without intergranular corrosion problems.

These low carbon levels are readily and economically achieved with the advent of the argon oxygen decarburization (AOD) refining process used by most alloy producers. By limiting the interstitial element content, sensitization is limited or avoided entirely during subsequent welding and other reheating operations. However, designers should be aware of the fact that lowering the carbon/nitrogen content also lowers the maximum allowable design stresses, as noted in appropriate sections of applicable fabrication codes, such as ASME Section 8, Division 1 for unfired pressure vessels and ANSI B31.3 for process piping.

Commercially pure Nickel 200 is a special case. With a maximum carbon content of 0.15%, Nickel 200 will precipitate elemental carbon or graphite in the grain boundaries when heated in the range of 315 to 760 °C (600 to 1400 °F). This results in embrittlement and susceptibility to intergranular corrosion in certain environments, such as high-temperature caustic. Where embrittlement and intergranular corrosion must be avoided. Nickel 201 (UNS N02201) with a maximum carbon content of 0.02% is specified.

Titanium as a carbide-stabilizing clement is used in several ferritic and austenitic stainless steels, including types 409, 439, 316Ti, and 321, as well as the higher-nickel Incoloy alloy 825 (UNS N08825), at a minimum concentration of about five times the carbon plus nitrogen content. In the same way, niobium, generally with tantalum, is used in types 309Cb, 310Cb, and 347 austenitic stainless steels at a minimum combined concentration of about ten times the carbon content.

The higher-nickel alloys 20Cb-3, Inconel 625, and Hastelloy G contain even higher concentrations of niobium--up to a maximum of about 4% in the case of alloy 625. In general, when stabilized alloys are heated in the sensitizing temperature range, chromium depletion at the grain boundaries does not occur, because the stabilizing elements have a greater affinity for carbon than does chromium.

Under certain conditions, however, stabilized alloys will sensitize, especially during multipass welding or cross welding. They are also susceptible to a highly localized form of intergranular corrosion known as knife-line attack, which occurs in base metal at the weld fusion line. In some cases, these alloys are given stabilizing heat treatments after solution heat treatment for maximum resistance to intergranular corrosion in the as-welded condition. For example, type 321 stainless steel is stabilize annealed at 900 °C (1650 °F) for 2 h, and alloys 825 and 20Cb-3 at 940 °C (1725 °F) for 1 h, before fabrication to avoid sensitization and knife-line attack. So treated, type 321 may still be susceptible because titanium has a tendency to form an oxide during welding: therefore, its role as a carbide stabilizer may be diminished. For this reason, type 321 is always welded with a niobium-stabilized weld filler metal, such as type 347 stainless.

Some specialty alloys have low interstitial element content plus the addition of stabilizing elements for resistance to intergranular corrosion. These alloys include the higher-nickel Hastelloy alloy G-3 (UNS N06985), which contains 0.015% C (maximum) and niobium plus tantalum up to 0.5%, and the newer ferritic stainless steels (Ref 19) listed below:

- UNS S44627: 26% Cr, 1% Mo, 0.01% C (max), 0.015% N (max), 0.2% Nb (max)
- UNS S44635: 25% Cr, 4% Ni, 4% Mo, 0.025% C (max), 0.035% N (max), 0.80% Ti + Nb (max)

- UNS S44660: 26% Cr, 2% Ni, 3% Mo, 0.03% C (max), 0.04% N (max), 1.0% Ti + Nb (max)
- UNS S44735: 29% Cr, 0.5% Ni, 4% Mo, 0.03% C (max), 0.045% N (max), 1.0% Ti + Nb (max)

The new ferritic stainless steels were developed primarily for heat exchanger tubing applications for use in place of the higher-carbon unstabilized type 446 stainless steel. These ferritic stainless steels have many useful properties.

As discussed previously, specific corrosion environments cause intergranular corrosion in specific metal and alloy systems. A wealth of information, both published (Ref 20) and unpublished, has been developed on corrodents that cause intergranular corrosion in sensitized austenitic stainless steels; a partial listing appears in Table 2. The low-carbon/nitrogen or stabilized grades are specified for applications in which the austenitics have satisfactory general and localized corrosion resistance in these environments and in which sensitization by such operations as welding and hot forming will undoubtedly occur.

Table 2 Partial listing of environments known to cause intergranular corrosion in sensitized austenitic stainless steels

Environment	**Concentration, %**	Temperature, °C (°F)
Nitric acid	1	**Boiling**
	10	**Boiling**
	30	**Boiling**
	65	**60 (140) to boiling**
	90	**Room to boiling**
	98	**Room to boiling**
Lactic acid	50-85	**Boiling**
Sulfuric acid	30	**Room**
	95	**Room**
Acetic acid	99.5	**Boiling**
Formic acid	90	**Boiling**
	10 (plus Fe^{3+})	**Boiling**
Chromic acid	10	**Boiling**

Oxalic acid	10 (plus Fe^{3+})	**Boiling**
Phosphoric acid	60-85	**Boiling**
Hydrofluoric acid	2 (plus Fe^{3+})	**77 (170)**
Ferric chloride	5	**Boiling**
	25	**Room**
Acetic acid anhydride mixture	Unknown	**100-110 (212-230)**
Maleic anhydride	Unknown	**60 (140)**
Cornstarch slurry, pH 1.5	Unknown	**49 (120)**
Seawater	. . .	**Room**
Sugar liquor, pH 7	66-67	**75 (167)**
Phthalic anhydride (crude)	**Unknown**	**232 (450)**

Evaluation tests for intergranular corrosion are conducted to determine if purchased materials have the correct chemical composition and are in the properly heat-treated condition to resist intergranular corrosion in service (Ref 21). Evaluation testing is imperative for a number of reasons:

- The stainless steels and nickel-base alloys to which these test are applied are relatively expensive
- These materials are frequently specified for critical applications in the petrochemical, process, and power industries
- The principal cost associated with a corrosion failure is generally that of production loss, not replacement
- For maximum cost effectiveness, these materials should be used in their best possible metallurgical and corrosion-resistant conditions

Most of the evaluation tests are described in detail in ASTM standards. Appropriate evaluation tests and acceptance criteria for wrought alloys are listed in Table 1 in the article "Evaluation of Intergranular Corrosion" in this Volume.

Intergranular corrosion is rare in nonsensitized ferritic and austenitic stainless steels and nickel-base alloys, but one environment known to be an exception is boiling HNO_3 containing an oxidizing ion such as dichromate (Ref 22), vanadate, and/or cupric. Intergranular corrosion has also occured in low-carbon, stabilized and/or property solution heat-treated alloys cast in resin sand molds (Ref 23). Carbon pickup on the surface of the castings from metal-resin reactions has resulted in severe intergranular corrosion in certain environments. Susceptibility goes undetected in the evaluation tests mentioned above because test samples obtained from castings generally have the carbon-rich layers removed. This problem is avoided by casting these alloys in ceramic noncarbonaceous molds.

Other metals, such as magnesium, aluminum, lead, zinc, copper, and certain alloys, are susceptible to intergranular corrosion under very specific conditions. Very few case histories are reported in the literature. An unusual form of intergranular corrosion known as exfoliation, which occurs in aluminum-copper alloys, is discussed in the section "Other Forms of Corrosion" in this article. Intergranular SCC is discussed in the following section. More information on intergranular corrosion is available in the article "Metallurgically Influenced Corrosion" in this Volume.

Stress-corrosion cracking is a type of environmental cracking caused by the simultaneous action of a corrodent and sustained tensile stress. The following discussion deals primarily with anodic SCC. Anodic SCC is believed to be a delayed cracking phenomenon that occurs in normally ductile materials under the stress resulting from accelerated electrochemical corrosion at anodic sites of the material as well as at the crack tip. Other types of environmental cracking, such as hydrogen stress cracking and liquid-metal embrittlement, are discussed later in this article (see also the article "Environmentally Induced Cracking" in this Volume).

The National Association of Corrosion Engineers, the Materials Technology Institute of the Chemical Process Industries, and others have published tables of corrodents known to cause SCC of various metal alloy systems (Ref 24, 25, 26). Table 3 lists these data in condensed form and covers the SCC environments of major importance to the materials engineer. This table, as well as those published in the Literature, should be used only as a guide for screening candidate materials for further in-depth investigation, testing, and evaluation.

Table 3 Some environment-alloy combinations known to result in SCC

Environment	Alloy system								
	Aluminum alloy	**Carbon Steels**	**Copper alloys**	**Nickel alloys**	**Stainless steels**			**Titanium alloy**	Zirconium alloys

Stress-corrosion cracking is not a certainty in the listed environments under all conditions. Metals and alloys that are indicated as being susceptible can give good service under specific conditions. For example, referring to Table 3:

- Anhydrous ammonia will cause SCC in carbon steels, but rarely at temperatures below 0 °C (32 °F) and only when such impurities as air or oxygen are present; addition of a minimum of 0.2% H_2O will inhibit SCC

- Aqueous fluorides and hydrofluoric acid (HF) primarily affect Monel alloy 400 (UNS N04400) in the nickel alloys system; others are resistant
- Steam is known to cause SCC only in aluminum bronzes and silicon bronzes in the copper alloys system
- Polythionic acid only cracks sensitized austenitic stainless steels and nickel alloys; SCC is avoided by solution annealing heat treatments or selection of stabilized or low-carbon alloys

Stress-corrosion cracking is often sudden and unpredictable, occurring after as little as a few hours exposure or after months or even years of satisfactory service. Cracking occurs frequently in the absence of other forms of corrosion, such as general attack or crevice attack. Virtually all alloy systems are susceptible to SCC by a specific corrodent under a specific set of conditions, that is, concentration, temperature, stress level, and so on. Only the ferritic stainless steels as a class are resistant to many of the environments that cause SCC in other alloy systems, but they are susceptible to other forms of corrosion by some of these environments.

The combination of aqueous chlorides and austenitic stainless steels is probably the most important from the standpoints of occurrence, economics, and investigation. Although the mechanism and boundary conditions for chloride SCC are still not fully defined, it is reasonably safe to state that chloride SCC of austenitic stainless steels:

- Seldom occurs at metal temperatures below 60 °C (140 °F) and above 200 °C (390 °F)
- Requires an aqueous environment containing dissolved air or oxygen or other oxidizing agent
- Occurs at very low tensile stress levels such that stress-relieving heat treatments are seldom effective as a preventive measure
- Affects all the austenitic stainless steels about equally with regard to susceptibility, time to failure, and so on
- Is characterized by transgranular branchlike cracking as seen under a metallurgical microscope

So many materials and environments are sources of chlorides that they are hard to avoid (Ref 27). Significant costs for repairs and replacements, as well as lost utility, have occurred through the years in the petrochemical industry as a result of chloride SCC:

- In water-cooled heat exchangers from chlorides in the cooling water
- Under thermal insulation allowed to deteriorate and become soaked with water that leached chlorides from the insulation
- Under chloride-bearing plastics, elastomers, and adhesives on tapes

In the case of shell and tube heat exchangers, in which chloride-bearing waters are used for cooling, a number of preventive measures are available. In vertical units with water on the shell side, cracking occurs most often at the external surfaces of the tubes under the top tubesheet (Ref 28). This is a dead space (air pocket) at which chlorides are allowed to concentrate by alternate wetting and drying of tubing surfaces. Adding vents to the top tubesheet sometimes alleviates this problem by eliminating the dead space and allowing complete water flooding of all tubing surfaces (Ref 29).

However, in many cases, this approach results in only a nominal increase in time to failure or no benefit whatsoever, because of other inherent deficiencies, such as low water flows or throttling water flow to control process temperatures. Thus, a material more resistant to chloride SCC is required, such as the austenitic higher-nickel Incoloy alloys 800 (UNS N08800) and 825 (UNS N08825); Inconel 600 (UNS N06600); ferritic stainless steels such as type 430 (UNS S43000), 26Cr-1Mo (UNS S44627), and SC-1 (UNS S44660); duplex stainless steels such as Ferralium 255 (UNS S32550) and AISI type 329 (UNS S32900); or titanium. In this case, selection depends primarily on economics, that is, the least expensive material that will resist process-side corrosion as well as water-side SCC.

Alloys are said to be either resistant or immune to chloride SCC, depending on how they perform in accelerated laboratory tests. In general, an alloy is immune if it passes the boiling 42% magnesium chloride test conducted according to ASTM G 36. Examples are Inconel alloy 600, 26Cr-1Mo, and grade 3 commercially pure titanium (UNS R50550). Industry has recognized the severity of this test and has devised other accelerated laboratory tests, such as boiling 25% sodium chloride and the Wick Test (ASTM C 692), that are more representative of actual conditions in the field (Ref 30).

Thus, alloys that fail the G 36 test but pass the C 692 test, such as Incoloy 800, alloy 2205 (UNS S31803), and 20 Mo6 (UNS N08026), typically provide many years of service as tubes in water-cooled heat exchangers. (The austenitic 300-series stainless steels, as a class, fail all of the accelerated laboratory chloride SCC tests mentioned above.)

Unfortunately, all of the immune and resistant alloys are more expensive than most of the austenitic stainless steels. A more cost-effective application of some of these alloys involves a procedure known as safe ending, in which short lengths, (for example, 0.3 to 0.6 m, or 12 to 24 in.) are butt welded to the austenitic stainless steel tubes. The SCC-resistant ends are positioned in the exchanger at the point of greatest exposure to SCC conditions, that is, under the top tubesheet. Safe-ended tubes have extended the life of austenitic stainless steel tubing several-fold, with only a nominal increase in cost. Of course, the dissimilar metals must be weld compatible; this eliminates the use of titanium for safe ending.

Another cost-effective answer to chloride SCC in heat exchangers is bimetallic tubing, in which the austenitic stainless steel required for process-side corrosion resistance is clad with a water-side SCC- and corrosion-resistant material such as 90Cu-10Ni (UNS C70600) (Ref 31). Still another answer is cathodic protection with a sacrificial metal coating such as lead containing 2% Sn and 2% Sb applied by hot dipping or flame spraying (Ref 32).

Chloride SCC under insulation can be prevented by keeping it dry, but this is easier said than done in many cases. It is particularly difficult in humid, high annual rainfall climates, such as the Gulf Coast area of the United States, and where insulated equipment must be washed down periodically or is exposed to fire control deluge systems that are periodically activated (Ref 33). Under these conditions, three preventive measures are applied, as follows.

The first preventive measure is the addition of sodium metasilicate as an SCC inhibitor to the insulation at a minimum concentration of ten times the chloride content. The inhibitor is activated when the insulation becomes wet and is effective only when it wets the stainless steel surface. For maximum protection, metasilicate is painted on the vessel or piping before the installation of inhibited insulation. However, SCC has occurred after many years of service under inhibited insulation that was allowed to become so wet that the water-soluble inhibitor was leached out to a point below the minimum concentration required for prevention of SCC.

Second is protective coating of the vessel or piping before insulation. Catalyzed high build epoxy paints are effective to about 100 °C (212 °F), catalyzed coal tar-epoxy enamels to about 150 °C (300 °F), and silicone-base coatings to about 200 °C (390 °F). These coatings are even more effective if the stainless steel surfaces are heavily sandblasted before coating. Sandblasting peens the surface to a depth of 0.01 to 0.1 mm (0.4 to 4 mils), and this results in a layer under compressive stresses that counteract the tensile stresses required for SCC (peening will be discussed later in this article).

The third preventive measure is cathodic protection of the vessel or piping with aluminum foil under insulation (Ref 34). This method is claimed to provide both a physical barrier to chloride migration to stainless steel surfaces as well as cathodic protection when the insulation becomes wet, and it is effective at vessel temperatures between 60 and 500 °C (140 to 930 °F). However, the foil is attacked by the alkaline (generally) leachates from the insulation and must be renewed periodically.

Other important environments that cause SCC of stainless steels are hydroxide (caustic) solutions, sulfurous acid, and polythionic acids. Caustic SCC of austenitic stainless steels can be both transgranular and intergranular and is a function of solution concentration and temperature. It seldom occurs at temperatures below 120 °C (250 °F). At higher temperatures, the newer ferritic stainless steels, nickel, and high-nickel alloys provide outstanding service; 26Cr-1Mo stainless steel has found widespread application in heat-exchanger tube bundles serving caustic evaporators at 170 to 200 °C (340 to 390 °F). Nickel 200 and 201 as well as Inconel alloy 600 are resistant to 300 °C (570 °F) in caustic concentrations to 70%.

Polythionic acid and sulfurous acid will cause SCC in sensitized nonstabilized austenitic stainless steels and nickel-base alloys. Cracking is always intergranular and requires relatively low tensile stresses for initiation and propagation. As-welded, normal carbon grades, such as types 304 and 316 and Incoloy alloy 800, are particularly susceptible to SCC in weld HAZs. Low-carbon (<0.03% C) and stabilized grades, such as types 321 and 347, are resistant, especially after receiving a stabilizing heat treatment. The normal carbon grades in the solution heat-treated condition are also resistant. Susceptibility to polythionic acid SCC can be determined by laboratory corrosion testing according to ASTM G 35.

Polythionic acid and sulfurous acid SCC are major considerations in the petroleum-refining industry, especially in desulfurizer, hydrocracker, and reformer processes (Ref 35, 36). These acids form in process units during shutdowns

when equipment and piping containing sulfide deposits and scales are opened and exposed to air and moisture. Preventive measures include flushing with alkaline solutions to neutralize sulfides before shutdown and purging with dry nitrogen during shutdown according to recommended practices established by NACE (Ref 37).

Cast austenitic stainless steels such as Alloy Casting Institute (ACI) types CF-8 (UNS J92600) and CF-8M (UNS J92900) are inherently more resistant (but not immune) to chloride SCC than their wrought counterparts (types 304 and 316, respectively) for several reasons. Castings generally have lower residual stresses than wrought alloys after solution-annealing heat treatments, and service-applied stresses are often lower because of heavy section thicknesses. However, the principal reason for improved SCC resistance is the presence of varying amounts of free ferrite, resulting in a duplex austenitic-ferritic microstructure. Free ferrite is primarily attributed to additions of 1 to 2% Si to improve fluidity during pouring and to resist hot cracking during cooling of the casting.

During work conducted some years ago on the development of the duplex cast ACI alloy CD-4MCu (UNS J93370), researchers noted improved resistance to chloride SCC in cast alloys containing high ferrite; this confirmed observations in the field by materials engineers (Ref 38). A significant improvement in SCC resistance occurred with ferrite contents in the range 13 to 20 vol% and greater. This led to the development of alloys with controlled ferrite content by balancing chemical composition. Ferrite formation is promoted by chromium and by elements that act like chromium, such as silicon, niobium, and molybdenum. Nickel and elements that act like nickel (carbon, manganese, nitrogen) retard ferrite formation. When specified, ferrite is typically controlled at the foundry by adjusting chromium toward the upper end of the specification range, and nickel toward the lower end, along with the silicon addition.

Resistance to SCC in these alloys is believed to be a result of the keying action of ferrite particles (Ref 39). This action blocks direct propagation of SCC through the austenitic matrix. Along with this benefit, however, are improvements in strength, weldability, and resistance to general corrosion, particularly in hot concentrated nitric, acetic, phosphoric, and sulfuric acids and mixed nitric-hydrofluoric acid (Ref 40). The American Society for Testing and Materials has recognized alloys produced with controlled ferrite content in specification A 351. However, users are cautioned to limit applications to a maximum temperature of 425 °C (800 °F) because of the thermal instability of these grades.

A number of measures for preventing SCC of austenitic stainless steels have already been discussed. Two additional measures worthy of consideration are stress-relieving heat treatments and shot peening. The typical stress-relieving temperature for plain carbon steels--595 °C (1100 °F)--is only slightly effective for the austenitics, which require slow cooling from about 900 °C (1650 °F) for effective relief of residual stresses from such operations as welding. However, such treatments may not prevent, but only prolong, the time to failure; chloride SCC of austenitic stainless steels can occur at very low stress levels. Also, these elevated temperatures may cause unwanted distortion of complex and/or highly stressed structures and will sensitize susceptible alloys. This sensitization will result in intergranular corrosion or intergranular SCC.

Shot peening is the controlled bombardment of a metal surface with round, hard steel shot for the purpose of introducing compressive stresses in surface layers. These compressive stresses counteract the tensile stresses required for SCC. The depth of the resultant cold-worked layers is generally in the range 0.1 to 0.5 mm (4 to 20 mils): 100% coverage is required. In laboratory tests in boiling 42% magnesium chloride, shot-peened type 304 stainless steel U-bend samples showed no SCC after more than 1000 h of exposure, but nonpeened control samples all cracked in approximately 1 h (Ref 41). Successful applications in the chemical-processing industries include a type 316 stainless steel centrifuge exposed to an organic chloride process stream (Ref 42) and numerous storage tanks exposed to a variety of SCC conditions (Ref 43).

The exposure of shot-peened surfaces to excessive temperatures or to environments that cause excessive general or pitting corrosion should be avoided. Temperatures above 565 °C (1050 °F) will relieve the beneficial compressive stresses and reduce the overall benefits of shot peening. Once the relatively thin layers of residual compressive stress are penetrated by general corrosion or pitting, SCC can occur.

Plain carbon steels are susceptible to SCC by several corrodents of economic importance, including aqueous solutions of amines, carbonates, acidified cyanides, hydroxides, nitrates, and anhydrous ammonia. Susceptible steels in common use throughout the petrochemical-processing industry include ASTM A106 grade B for piping, A285 grade C for tanks, and A 515 grade 70 for pressure vessels. Cracking is both intergranular and transgranular; the former occurs in hot hydroxides and nitrates, and the latter in warm acidified cyanide solutions.

The temperature and concentration limits for the SCC susceptibility of carbon steels in caustic soda (sodium hydroxide) are fairly well defined; they have been derived from field experience and reproduced in chart form (Fig. 1). These limits

for the other aqueous SCC environments mentioned above are not nearly as well defined. For example, SCC was not considered to be a problem at temperatures below 88 °C (190 °F) in aqueous monoethanolamine and diethanolamine solutions used for scrubbing carbon dioxide and hydrogen sulfide out of natural gas and hydrogen-rich synthesis gas streams. However, recent experience in petroleum refineries has resulted in general agreement that SCC preventive measures, such as thermal stress relief, must be applied to plain carbon steels in aqueous amines at all temperatures and concentrations.

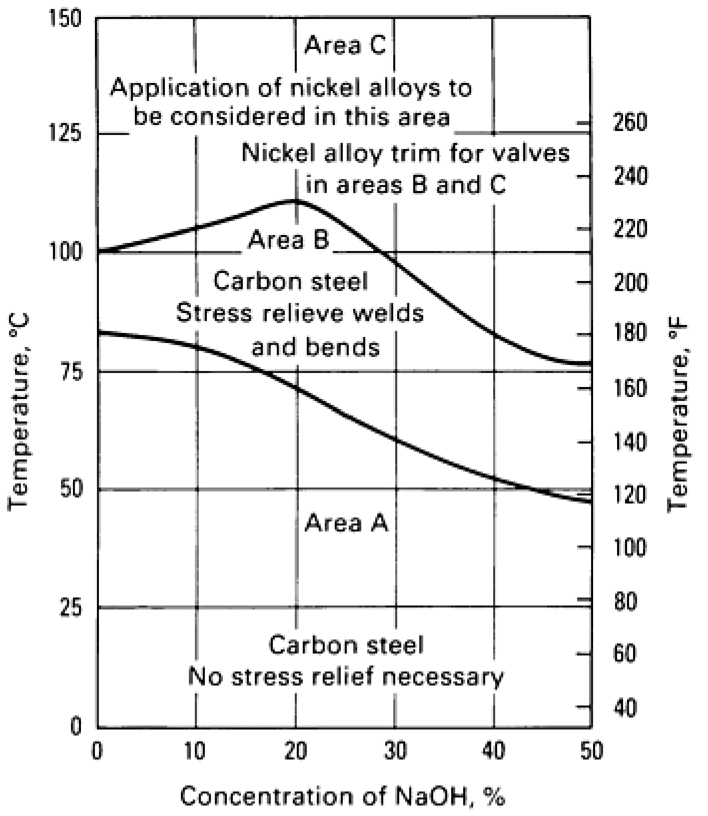

Fig. 1 Temperature and concentration limits for SCC susceptibility of carbon steels in caustic soda. Source: Ref 44

With regard to anhydrous ammonia, the SCC of plain carbon and low-alloy steels occurs at ambient temperatures when air or oxygen is present as a contaminant at concentrations of only a few parts per million (Ref 45). Most of the adverse experience has been with the nonstress-relieved higher-strength quenched-and-tempered steels, such as the grades covered in ASTM A 517. Cracking seldom occurs at temperatures below 0 °C (32 °F) and is virtually nonexistent at or below -33 °C (-28 °F), a common temperature for storage at atmospheric pressure. Water is an effective SCC inhibitor at a minimum concentration of 0.2% by weight.

Thermal stress relief is perhaps the single most effective measure for preventing, or at least greatly prolonging, the time to SCC of plain carbon and low-alloy steels in all of the environments mentioned above. However, temperature is a more important factor than time at temperature. There is general agreement that stress-relieving temperatures below 595 °C (1100 °F), regardless of the hold time, are not effective for preventing SCC. In fact, the recommended minimum temperature for some environments, such as aqueous acidified cyanides, is 650 °C (1200 °F). As with any thermal treatment, special precautions must be observed, such as adequate support to avoid distortion and the removal of dirt, grease, and other foreign material that might react with the structure at elevated temperatures.

The above comments on thermal stress relief apply to new carbon steel piping and vessels. Stress-corrosion cracking has been found in such vessels as horizontal pressure storage tanks ("bullets") that were stress relieved after SCC was found in the original as-welded vessels and were repaired by grinding and welding (Ref 45). Undoubtedly, the stress-relieving temperatures propagated tiny cracks that were not detected during repairs.

Just as aqueous chloride is a potent SCC environment for austenitic stainless steels, aqueous ammonia causes extensive cracking in copper-base alloys. Virtually all copper alloys, as well as pure copper itself, can be made to crack in this environment. The most susceptible alloys are the brasses containing more than 15% Zn, such as admiralty brass (UNS C44300, 28% Zn), yellow brass (UNS C27000, 34% Zn), and Muntz metal (UNS C28000, 40% Zn), followed by red brass (UNS C23000, 15% ZN) and several bronzes. The least susceptible alloys are 90Cu-10Ni (UNS C70600), 70Cu-30Ni (UNS C71500), and unalloyed copper.

The conditions that are conducive to SCC by aqueous ammonia are water, ammonia, air or oxygen, and tensile stress in the metal. Cracking is always intergranular, requires only trace quantities of ammonia in many cases, and occurs at ambient temperature. For example, U-bends in admiralty brass condenser tubes cracked in warm water from a cooling tower that contained 15 to 25 ppm ammonia because of close proximity to an ammonia plant. Other sources of ammonia include the decomposition of amines and the microbiological breakdown of organic matter.

Thermal stress relief is generally not one of the better preventive measures, because ammoniacal SCC occurs at relatively low stress levels. In fairly mild ammoniacal environments, such as the cooling tower water system mentioned above, the copper-nickel alloys, particularly 90Cu-10Ni, give good service. Small quantities of hydrogen sulfide have been found to inhibit SCC of brasses in petroleum refinery process streams, probably by reducing the dissolved oxygen content (Ref 46).

Another potent SCC great for copper alloys is steam, but susceptibility is limited primarily to the higher-strength bronzes alloyed with aluminum (for example, UNS C61400) or silicon (for example, UNS C65500). In this regard, one noteworthy design to avoid is dimpled jacket construction. Severe SCC occurred at plug welds in a silicon bronze steam jacket on a similar alloy vessel used for heating a waste H_2SO_4 stream.

Stress-corrosion cracking of aluminum and its alloys in the chemical-processing industries is rare, because the lower-strength alloys in predominant use are resistant. These include the commercially pure alloy 1100, manganese alloy 3003, and magnesium alloys 5052 and 5083. Susceptible alloys are the high-strength grades of economic importance in the aircraft and aerospace industries, such as the copper alloys 2014 (UNS A92014) and 2024 (UNS A92024) and the copper-zinc-magnesium alloys 7075 (UNS A97075) and 7178 (UNS A97178). These alloys, heat treated to maximum strength levels, are susceptible to SCC in humid air containing traces of chlorides (Ref 47).

Titanium (UNS R50550 and other unalloyed grades) has found increasing application in the chemical-processing industries, primarily as a replacement for autenitic stainless steels, because of outstanding resistance to corrosion by hot, concentrated oxidizing acids, such as HNO_3, and virtual immunity to pitting and SCC by hot aqueous chloride solutions. However, titanium and, to a greater extent, its higher-strength alloys (for example, UNS R56400) are susceptible to SCC in a variety of environments, including anhydrous alcohols (methanol, ethanol) containing traces of halides, anhydrous red fuming HNO_3, anhydrous hot chlorides, some important industrial organic solvents (carbon tetrachloride, trichloroethane, and so on), anhydrous nitrogen tetroxide, and HCl.

In general, SCC preventive measures, such as thermal stress relief, cathodic protection, or inhibition, have not been used to any great extent with titanium and its alloys, although water additions are reported to inhibit cracking in anhydrous red fuming HNO_3 and anhydrous nitrogen tetroxide (Ref 48). Rather, SCC is prevented by avoiding contact with specific cracking agents.

Zirconium (UNS R60702) and, to a greater extent, its alloys (for example, UNS R60705) exhibit SCC behavior similar to that of titanium and its alloys in anhydrous alcohols containing traces of halides and in chlorinated organic solvents. Stress-corrosion cracking also occurs in aqueous ferric and cupric chloride solutions and hot concentrated HNO_3, especially when sustained tensile stresses are high. Because threshold stresses for SCC are high in comparison to yield strengths, thermal stress relief is a practical preventive measure. Holding temperatures between 650 and 850 °C (1200 and 1560 °F) are reported to be effective (Ref 49).

As a class, nickel-base alloys are susceptible to SCC by a wide variety of corrodents. However, in most cases, the corrodents are specific to a few, but not all, of the alloys in this class. For example, sensitized alloys 800 and 600 crack in thiosulfate solutions and polythionic acids, but the stabilized alloys Incoloy 825 and Inconel 625 are resistant. The latter alloys are particularly applicable in petrochemical process streams containing chlorides along with polythionic acids. In the nuclear power industry, Inconel 600 and weld metal alloys 82 (UNS N06082) and 182 (UNS W86182) crack intergranularly in crevices in high-purity water containing oxygen at elevated temperatures and pressures (Ref 50). In the absence of crevices, these alloys are resistant. Inconel alloy 690 (UNS N06690) is resistant under all conditions.

Nickel 200 and 201, Monel 400, Inconel 600 and 690, and Incoloy 800 are susceptible to SCC in caustic solutions over a wide range of concentrations and at temperatures above 290 °C (550 °F). Cracking is predominantly intergranular. The presence of oxygen and chlorides, which are common contaminants, tends to accelerate cracking, especially in Inconel alloy 600. Fairly high stress levels are generally required. Failures have occurred in steam generator tubes serving nuclear power plants from caustic concentrated on tube surfaces in crevices or as a result of a hot wall effect and/or poor water circulation. This experience prompted considerable research (Ref 51, 52, 53, 54, 55, 56, 57). In general, Nickel 200 and 201 and the nickel-chromium-iron-Inconel alloys 690 and 600 appear to be the most resistant under the various conditions tested, although they are not immune to caustic SCC.

Other SCC environments of importance with regard to nickel-base alloys, especially Monel 400, are acidic fluoride solutions and HF. Monel 400 is susceptible to SCC in cold-worked or as-welded conditions, but is resistant in annealed or thermally stress-relieved conditions (Ref 58). Free air or oxygen accelerates corrosion rates and SCC tendency. However, Monel 400 has excellent general corrosion resistance over a broad range of temperatures and concentrations, so its use in HF alkylation units and other process streams containing HF or fluorides is widespread (Ref 59). Thermal stress relief at a minimum temperature of 540 °C (1000 °F), followed by slow cooling, will prevent SCC or will greatly prolong time to failure.

Corrosion-resistant polymers, such as thermoplastic and thermosetting resins, that are of interest to the materials engineer are susceptible to two forms of cracking in specific environments (Ref 60):

- Environmental stress cracking, which occurs when the polymer is stressed (residual or applied) and exposed to an organic solvent or aqueous solution of a wetting agent
- Craze cracking, which consists of a multitude of fine cracks that develop in contact with organic liquids or vapors, with or without the presence of mechanical stresses

For example, high-density polyethylene may crack in the presence of benzene or ethylene dichloride, and polystyrene may crack in the presence of aliphatic hydrocarbons (Ref 61). The mechanisms for these phenomena are not completely understood. Cracking may initiate at minute particles of low molecular weight polymers in the higher molecular weight polymer matrix. Thus, when evaluating polymers for corrosive service, test specimens should be stressed before exposure and should be carefully examined after exposure for evidence of environmental stress cracking and craze cracking. For guidance, the Non-Metals Section of Ref 3 uses the footnote "May Stress Crack" to indicate potential problems with a specific polymer in a specific environment. Additional information on SCC is available in the article "Environmentally Induced Cracking" in this Volume.

Hydrogen Damage. The entry of hydrogen into metals and alloys can result in several forms of damage:

- Loss of ductility and/or fracture strength
- Internal damage due to defect formation
- Sustained propagation of defects at stresses well below those required for mechanical fracture
- Macroscopic damage due to entrapment at mechanical interfaces

Although atomic, rather than molecular, hydrogen is the detrimental species within metals, it may be absorbed from a molecular hydrogen gas atmosphere. Hydrogen itself may be introduced during several stages of equipment or component manufacture (before any period of service). Heat treating of the metal (or alloy) in a hydrogen-containing furnace atmosphere, such as cracked ammonia, can result in absorption. Acid pickling, plating, or welding operations can each introduce hydrogen into the lattice of the metal.

Subsequent chemical service involving aqueous corrosion or high-temperature, hydrogen-containing environments may also introduce hydrogen. It is important to realize that many ductile metals and alloys, such as copper or austenitic stainless steels, will show a definite loss in ductility when exposed to environments that strongly promote the entry of nascent hydrogen (Ref 62).

Because iron-base alloys are principal materials of construction, these alloys have been the focus of most of the studies relating to hydrogen effects. In addition, ferritic (body-centered cubic, or bcc) steels have a particular sensitivity to

hydrogen. For these reasons, this discussion will focus on hydrogen effects on steel. Such hydrogen effects have been thoroughly described in a recent review of hydrogen damage (Ref 63).

In ferrous alloys, embrittlement by hydrogen is generally restricted to those alloys having a hardness of 22 HRC or greater. However, other forms of hydrogen damage, such as hydrogen attack or hydrogen blistering, are associated with unhardened low-alloy or carbon steels.

As the result of hydrogen absorption, embrittlement of a metal or alloy may influence subsequent mechanical behavior without producing immediate and resolvable damage within the metal structure. In this respect, it is an insidious and somewhat reversible process, unlike hydrogen attack or blistering.

Hydrogen embrittlement may occur as a result of acid pickling, electroplating, and aqueous corrosion, which are electrochemical processes involving the discharge of hydrogen ions. The resulting nascent hydrogen is a chemisorbed species on the metal surface and, if not evolved as a molecular product, can enter the metal. This entry (or charging) of hydrogen has been described in detail (Ref 64). For the case of pure iron, introduction of hydrogen into the metal at high rates can produce irreversible effects (Ref 64). The solubility of hydrogen in the lattice is known to increase with applied tensile stress (Ref 65). Its solubility in metals obeys Sievert's law, with the concentration being directly proportional to the square root of the pressure (or fugacity). Within the lattice, hydrogen has been shown to interact with dislocations in iron (Ref 66, 67, 68, 69) and can thus affect subsequent plastic deformation.

In the case of pure titanium, as well as in alloys of titanium or zirconium, the entry of hydrogen can result in the formation of a hydride phase, thus reducing the ductility (Ref 62). A surface hydride phase has also been produced by hydrogen charging of nickel (Ref 70). An iron-chromium-nickel hydride has been proposed for austenitic stainless steel (Ref 71). Hydrogen charging of austenitic stainless steels is known to produce a martensite phase responsible for microcracking (Ref 72). Similar microcracks have been reported for cold-worked Inconel 600 (Ref 73). Studies of hydrogen effects on aluminum alloys have not been conclusive (Ref 74).

It is known for the case of low-carbon steel that hydrogen absorption is enhanced by plastic deformation (Ref 75). This occurs up to 76% cold reduction, as shown in Fig. 2. However, the hydrogen permeation rate is increased by reduction up to only 15% and is decreased by further plastic deformation (Ref 63). In the presence of an applied stress, the deleterious effect of hydrogen on delayed failure is increased by the triaxiality of the stress state, as shown in Fig. 3.

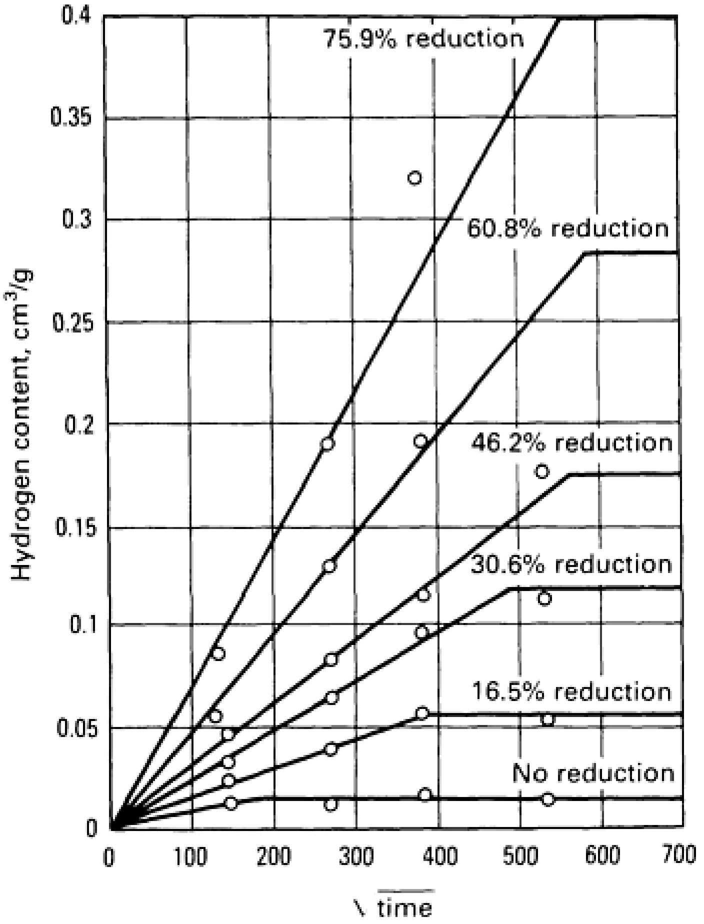

Fig. 2 Effect of cold reduction on rate of hydrogen absorption in carbon steel. Test performed on wire stock in 1 *N*H_2SO_4 at 35 °C (95 °F); original rod diameter was 13 mm ($\frac{1}{2}$ in.). Source: Ref 75

For heat-treated steels, sensitivity to hydrogen is a strong function of strength level. Figure 4 shows substantial embrittlement in a quenched-and-tempered steel with a tensile strength of 1860 MPa (270 ksi). The deleterious hydrogen content of 0.5 cm^3/100 g corresponds to approximately 1 hydrogen atom per 40,000 metal atoms (Ref 77). Other studies have shown substantial embrittlement of high-strength steels at a hydrogen contents of 2 to 3 ppm (Ref 78, 79).

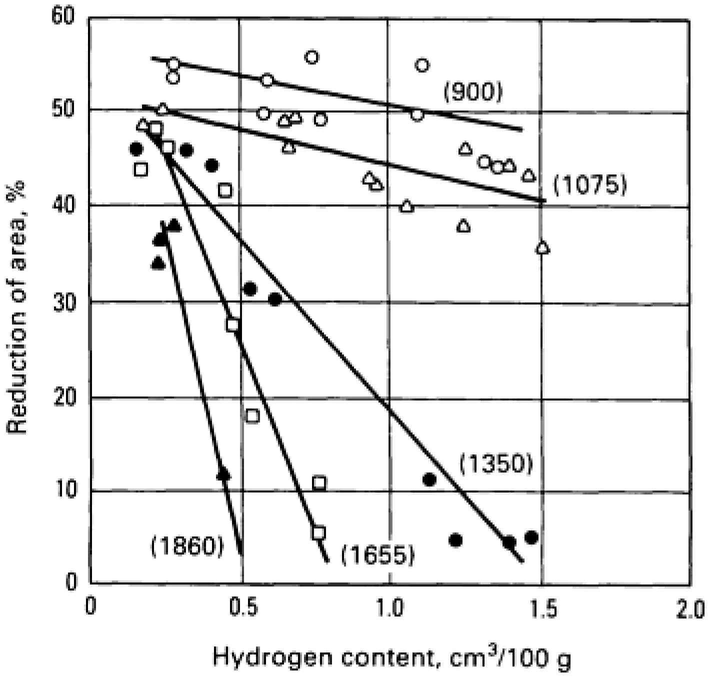

Fig. 4 Ductility (measured as percent reduction of area) versus hydrogen content for quenched-and-tempered steel at various strength levels. Ultimate tensile strength in megapascals is indicated in parentheses beside the curves. Source: Ref 77

The effects of temperature and strain rate on the embrittlement of carbon steel have been carefully studied (Ref 80). For a spheroidized AlSl 1020 steel charged with hydrogen, the maximum embrittling effect appears to occur in the temperature range of -31 to 24 °C (-25 to 75 °F). Embrittlement is also enhanced by lower strain rates (5×10^{-2} in./in./min) and is insignificant at higher strain rates of the order of 2×10^4 in./in./min. Figure 5 shows such an effect of strain rate. A similar effect of strain rate has been shown for nickel and an iron-nickel alloy charged with hydrogen (Ref 81).

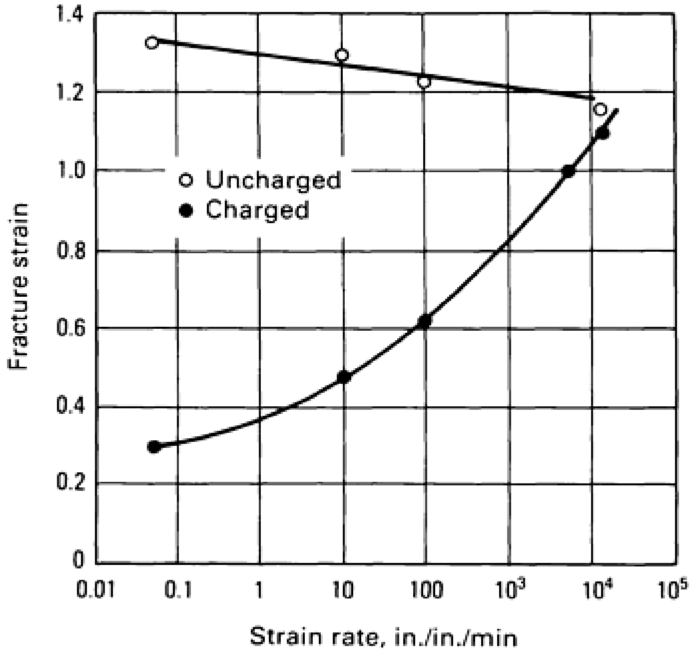

Fig. 5 Fracture strain as a function of strain rate in hydrogen-charged and uncharged 1020 steel at room

temperature. Source: Ref 80

In aqueous systems, the entry of hydrogen is promoted by cathodic poisons that inhibit the recombination od adsorbed, discharged nascent hydrogen on the surface of the corroding metal. These poisons include cyanide and ionic species of sulfur, arsenic, selenium, bismuth, tellurium, phosphorus, iodine, and antimony.

Embrittlement by hydrogen-containing gas species may manifest itself in the stress-assisted propagation by preexisting surface defects (cracks). In the case of high-strength steels, such a phenomenon has been observed in H_2, H_2S, HCl, and HBr gas environments (Ref 82, 83, 84, 85). A hydrogen sulfide (versus H_2) environment will result in a much higher crack velocity for the same steel, applied mechanical stress, and gas pressure (Ref 84).

One key to removing detrimental atomic hydrogen derives from its mobility at higher temperatures. A bake-out cycle, involving temperatures of 175 to 205 °C (350 to 400 °F), allows the diffusion and escape of hydrogen from the metal or alloy. If the hydrogen charging conditions were not severe enough to cause internal damage, the bake-out cycle (described in Federal Specification QQC-320) will restore full ductility.

In aqueous systems, the entry of hydrogen can be promoted by galvanic coupling to a more active metal. Therefore, cadmium or zinc platings containing defects or holidays can promote the hydrogen charging and embrittlement of susceptible metals or alloys. Such platings, or hot-dip galvanizing, should be avoided in the case of low-alloy high-strength steels. As another example, titanium has been found to embrittle by hydriding when it is coupled with carbon steel in acidic environments or when it is exposed to moist environments after the application of a zinc chromate paint primer.

Susceptibility to hydrogen embrittlement is strongly influenced by the strength level of the metal or alloy. Wet hydrogen sulfide environments are considered to be among the most aggressive in promoting hydrogen entry. In such environments, common metals and alloys are qualified according to strength level and/or heat treatment in terms of their resistance to hydrogen-induced failure. These qualifications are summarized in NACE standards MR-01-75, MR-01-76, and RP-04-75. In general, iron-base alloys with a ferritic or martensitic structure are restricted to a maximum hardness of 22 HRC. Most other alloys are restricted to a maximum hardness of 35 HRC. There are exceptions in both cases. The procedure for materials testing in a wet hydrogen sulfide environment are discussed in NACE TM-01-77.

Face-centered cubic (fcc) metals or alloys generally have more resistance to hydrogen embrittlement than those having a bcc lattice structure. However, cold work can increase the susceptibility of either structure. As a more direct effect of hydrogen entry, formation of a hydride phase can be expected to reduce the ductility of any metal or alloy.

In the pickling of steel, the level of hydrogen absorption is strongly affected by both the bath temperature and the nature of the acid (Fig. 6). Cathodic poisons have been ranked according to their effectiveness in increasing the permeation rate of hydrogen through low-carbon steel, as follows (Ref 87):

$$As > Se > Te > S > Bi$$

The role of sulfur as a poison is particularly important because sulfur is commonly encountered and because the chemical form of the sulfur greatly influences its effectiveness as a hydrogen entry promoter. The susceptibility to embrittlement by hydrogen can be demonstrated by the relative resistance to cracking in such environments as wet hydrogen sulfide. In such tests, microstructure has a definite effect on susceptibility. In steels, untempered martensite is the most susceptible phase. Lamellar carbide structures are less desirable than those with spheroidized structures. Quenched-and-tempered microstructures are more resistant than those that have been normalized and tempered (Ref 88). For the same strength level in low-alloy steel, it has been shown that a bainitic structure is more resistant to hydrogen-assisted cracking than a quenched-and-tempered martensitic structure (Ref 89).

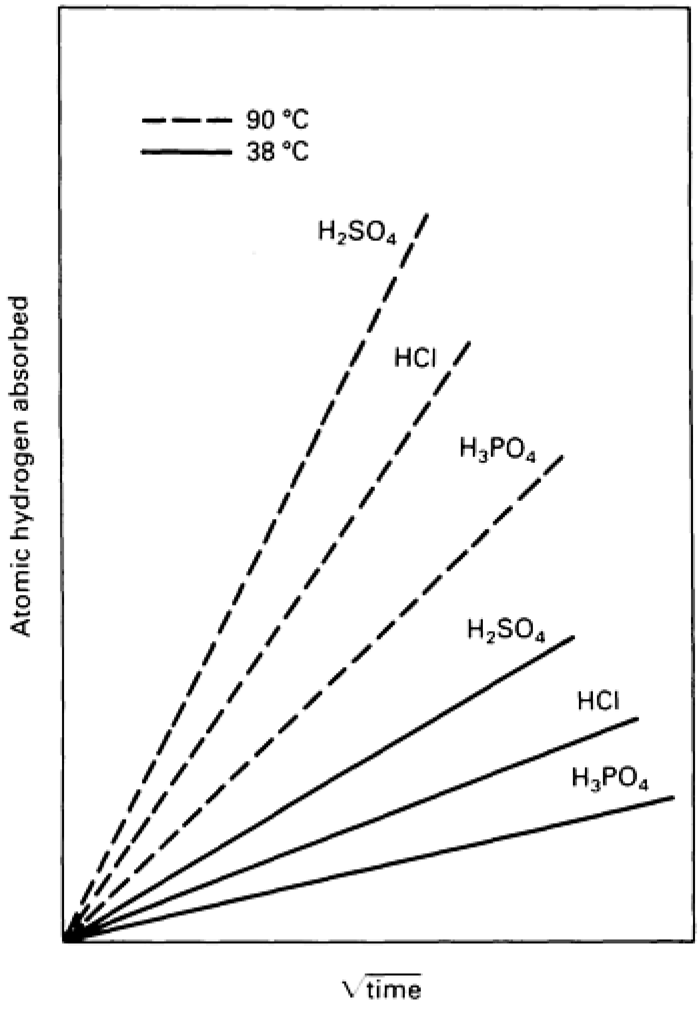

Fig. 6 Effect of anion and temperature on hydrogen absorption in a low-carbon steel. All acid concentrations were 2 *N*. Source: Ref 86

Embrittlement by gaseous hydrogen environments at ambient temperature has been effectively inhibited by the addition of 0.4 to 0.7 vol% oxygen (Ref 82, 90, 91). However, similar additions to a hydrogen sulfide gas environment did not halt the growth of cracks (Ref 91, 92).

Because of the higher hydrogen solubility in the high-temperature fcc structure of iron (versus the low-temperature bcc structure), cooling of steel in hydrogen atmospheres from temperatures of the order of 1100 °C (2010 °F) can result in internal damage. Exceeding the solubility limit for hydrogen will result in the embrittlement of hydrogen-sensitive microstructures, such as martensite, formed by rapid cooling of some ferritic alloys. The internal precipitation of hydrogen is believed to be responsible for the generation of fissures, delaminations, or other defects. Such defects have been termed flakes, shatter-cracks, fisheyes, or snowflakes. The defects are generally associated with hydrogen precipitation at voids, laminations, or inclusion/matrix interfaces already present in the steel. A reduced cooling rate, which allows hydrogen to be slowly released from the steel, is a general solution to the problem. Slower cooling will also inhibit the formation of hydrogen-sensitive microstructures.

Underbead cracking is an embrittlement phenomenon that is associated with absorption of hydrogen by molten metal during the welding process. Sources of hydrogen include moisture or organic contaminants on the surface of the prepared joint, moisture in low-hydrogen coated electrodes (such as E7018), moisture in fluxcored wire (such as M16), or a high-humidity environment. Upon rapid cooling of the weld, entrapped hydrogen can produce internal fissuring or other damage, as described earlier. In addition, the weld HAZ may contain the martensite phase in quench-hardenable alloys. The HAZ is then embrittled by high levels of entrapped hydrogen. Several steels have exhibited susceptibility to such embrittlement--for example, carbon steels containing 0.25 to 0.35 wt% C, low-alloy steels (such as AISI 4140 to 4340), and martensitic or precipitation-hardening stainless steels. Solutions to the hydrogen damage problems associated with

welding include the use of dry welding electrodes, proper cleaning and degreasing procedures for prepared weld joints, the use of an appropriate preheat before welding, and an adequate postweld heat treatment.

Welding electrodes should be kept dry by using a heated rod box. The electrodes should be removed only as needed. If they are moistened or exposed in the ambient atmosphere for prolonged periods, low-hydrogen coated electrodes must be heated at 370 to 425 °C (700 to 800 °F) to remove moisture (Ref 63). Recommended preheat temperatures for steels, as a function of steel composition, section thickness, and electrode type, have been published (Ref 93). Welding procedures for the avoidance of hydrogen cracking in carbon-manganese steels have also been published (Ref 94). Appropriate postweld heat treatments for steels can range from a hydrogen bake-out at 175 °C (350 °F) to a martensite tempering treatment at temperatures as high as 705 °C (1300 °F) (Ref 63).

Hydrogen attack is a damage mechanism that is associated with unhardened carbon and low-alloy steels exposed to hydrogen-containing environments at temperatures above 220 °C (430 °F) (Ref 63). Exposure to the environment is known to result in a direct chemical reaction with the carbon in the steel. The reaction occurs between absorbed hydrogen and the iron carbide phase, resulting in the formation of methane:

$$2H_2 + Fe_3C \rightarrow CH_4 + 3Fe$$

Unlike nascent hydrogen, the resulting methane gas does not dissolve in the iron lattice. Internal gas pressures develop, leading to the formation of voids, blisters, or cracks. The generated defects lower the strength and ductility of the steel. Because the carbide phase is a reactant in the mechanism, its absence in the vicinity of generated defects serves as direct evidence of the mechanism itself. The recommended service conditions (temperature, hydrogen pressure) for carbon and low-alloy steels are shown by the respective Nelson curves in Fig. 7. Chromium and molybdenum are beneficial alloying elements. This is most likely the result of their high affinity for carbon as well as the stability of their carbides. Hydrogen attack does not occur in austenitic stainless steels (Ref 63). In carbon or low-alloy steels, the extent of hydrogen attack is a function of exposure time.

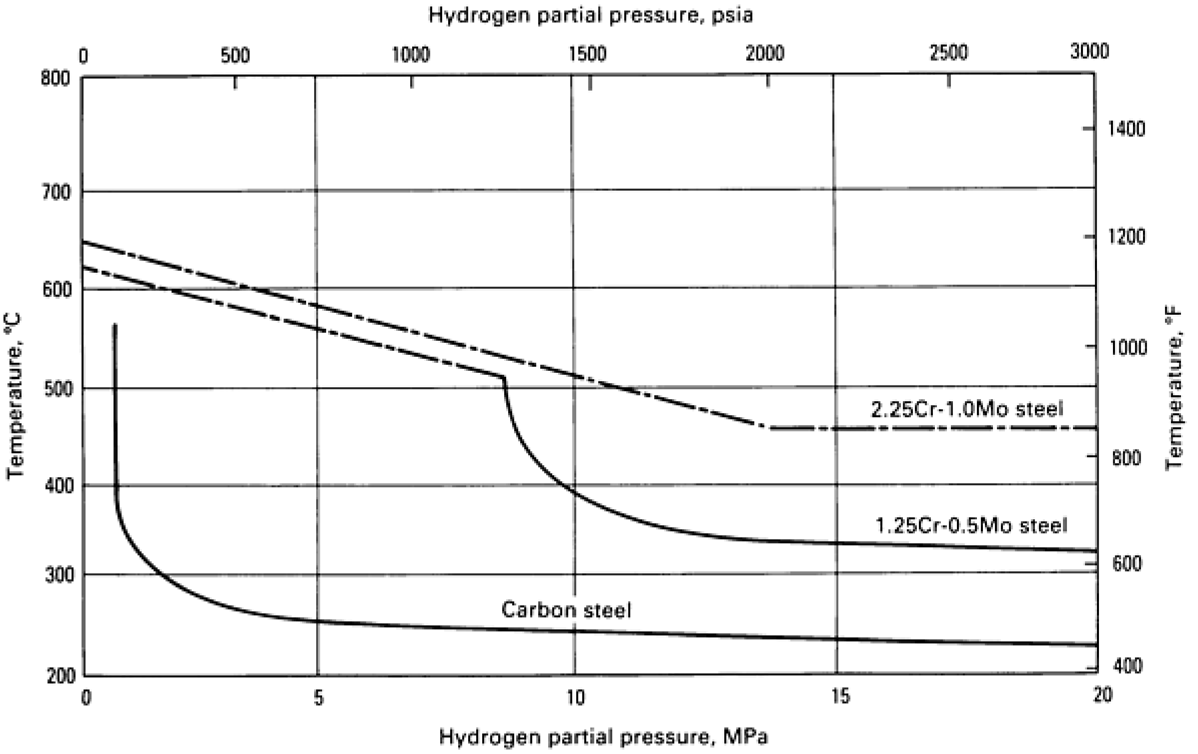

Fig. 7 Operating limits for three steels in hydrogen service to avoid hydrogen attack. Dashed lines show limits for decarburization, not hydrogen attack. Source: Ref 63

Hydrogen blistering is a mechanism that involves hydrogen damage of unhardened steels near ambient temperature. It is known that the entry of atomic hydrogen into steel can result in its collection, as the molecular species, at internal defects or interfaces. If the entry kinetics are substantial (promoted by an acidic environment, high corrosion rates, and cathodic poisons), the resulting internal pressure will cause internal separation (fissuring or blistering) of the steel. Such damage typically occurs at large, elongated inclusions and results in delaminations known as hydrogen blisters. Field experience indicates that fully killed steels are more susceptible than semikilled steels (Ref 95), but the nature and size of the original inclusions appear to be the key factors with regard to susceptibility. Rimmed steels or free-machining grades with high levels of sulfur or selenium would most likely show a high susceptibility to blistering. Stepwise cracking at the ends of blisters indicates an effect of elongated inclusions in the delamination process (Ref 63, 95). Similar stepwise cracking occurs in the hydrogen-induced failure of low-alloy pipeline steels (Ref 96). Both stepwise cracking and blistering appear to be limited to environments in which acidic corrosion occurs and in which cathodic poisons, such as sulfide, are present to promote hydrogen entry.

Solutions to the blistering problem include the use of low-sulfur calcium-treated argon-blown steels. Hot-rolled or annealed (as opposed to cold-rolled) steel is preferred (Ref 63). Silicon-killed steels are preferable to aluminum-killed steels. Also, treatment with synthetic slag or the addition of rare-earth metals can favor the formation of less detrimental globular sulfides (Ref 97). Ultrasonic inspection of the steel (according to ASTM E 114 and A 578) should be done before fabrication to detect laminations and other discontinuities that will promote blister formation. Equipment inspection and blister-venting procedures require unusual care (Ref 63). In services in which blistering can be expected, external support pads should not be continuously welded to the vessel itself. This will prevent hydrogen entrapment at the interface.

The permeation of hydrogen through ferritic steels can produce physical separation at mechanical joints. For example, bimetallic tubes, with a carbon steel inner liner, exhibited collapse of the liner due to its exposure to HF. Acid corrosion of the inside surface allowed nascent hydrogen to permeate the steel. Molecular hydrogen gas was formed, and trapped, at the interface with the outer tube section (brass). The accumulation of pressure was found to collapse the inner steel liners (Ref 63).

In high-temperature H_2/H_2S service, weld overlaid 2.25Cr-1Mo steel was found to disbond at the weld interface (Ref 98). In this case, a weld overlay of type 309 stainless steel, followed by type 347 stainless steel, was applied. Hydrogen-induced cracking was found to occur in the transition zone below the weld metal after approximately $3\frac{1}{2}$ years of service. The disbonding was found to be more severe with higher cooling rates after hydrogen absorption. Out-gassing treatments during the cool down were found to prevent disbonding (Ref 99).

Figure 8 shows an example of hydrogen-assisted SCC failure of four AISI 4137 steel bolts having a hardness of 42 HRC. Although the normal service temperature (400 °C, or 750 °F) was too high for hydrogen embrittlement, the bolts were also subjected to extended shutdown periods at ambient temperatures. The corrosive environment contained trace hydrogen chloride and acetic acid vapors as well as calcium chloride if leaks occurred. The exact service life was unknown. The bolt surfaces showed extensive corrosion deposits. Cracks had initiated at both the thread roots and the fillet under the bolt head. Figure 8(b) shows a longitudinal section through the failed end of one bolt. Multiple, branched cracking was present, typical of hydrogen-assisted SCC in hardened steels. Chlorides were detected within the cracks and on the fracture surface. The failed bolts were replaced with 17.4 PH stainless steel bolts (Condition H1150M) having a hardness of 22 HRC (Ref 63).

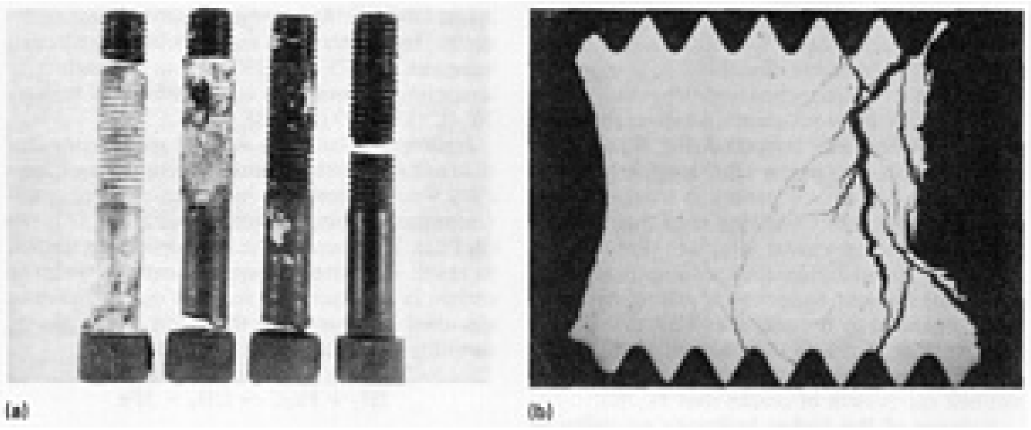

Fig. 8 4137 steel bolts (hardness: 42 HRC) that failed by hydrogen-assisted SCC caused by acidic chlorides from a leaking polymer solution. (a) Overall view of failed bolts. (b) Longitudinal section through one of the failed bolts in (a) showing multiple, branched hydrogen-assisted stress-corrosion cracks initiating from the thread roots. Source: Ref 63

As an example of hydrogen attack, a section of plain carbon steel (0.22% C and 0.31% Si) had been mistakenly included as a part of a type 304 stainless steel hot-gas bypass line used to handle hydrogen-rich gas at 34 MPa (5000 psi) and 320 °C (610 °F). After 15 months of service, the steel pipe section ruptured, causing a serious fire. Figure 9 shows a section of the 44-mm ($1\frac{3}{4}$-in.) OD pipe near the fracture. The pipe had been weakened by hydrogen attack through all but 0.8 mm of the 8-mm ($\frac{5}{16}$-in.) thick wall. As a result of the hydrogen attack and the internal methane formation, the microstructural damage consisted of holes or voids near the outer surface as well as interconnected grain-boundary fissures in a radial alignment near the inner surface (Fig. 9b). The radially aligned voids preceded both the circumferential crack and pipe rupture (Ref 63).

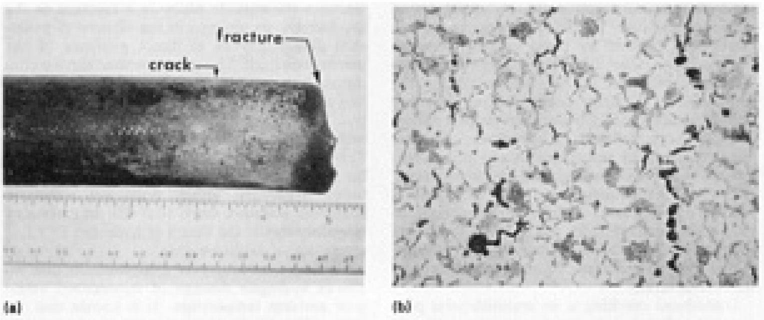

Fig. 9 Section of ASTM A 106 carbon steel pipe with wall severely damaged by hydrogen attack. The pipe failed after 15 months of service in hydrogen-rich gas at 34.5 MPa (5000 psig) and 320 °C (610 °F). (a) Overall view of failed pipe section. (b) Microstructure of hydrogen-attacked pipe near the midwall. Hydrogen attack produced grain-boundary fissures that are radially aligned. Source: Ref 63

Hydrogen blistering is illustrated in Fig. 10, which shows a cross section of a 152-mm (6-in.) diam blister that formed in the wall of a steel sphere. The sphere had been used to store anhydrous HF for 13.5 years at ambient temperatures. The source of nascent hydrogen gas was the cathodic hydrogen generated by the corrosion reaction between the acid and the steel. The corrosion rate was less than 0.05 mm/yr (2 mils/yr). Figure 10(b) shows the propagation of the blister, with the stepwise cracking (arrow) at its edge caused by the buildup of hydrogen pressure within the blister itself (Ref 63). More information on hydrogen attack is available in the article "Environmentally Induced Cracking" in this Volume.

Erosion-corrosion is a frequently misinterpreted type of metal deterioration that results from the combined action of erosion and corrosion. This section will be limited to a discussion of three types--liquid erosion-corrosion, cavitation, and fretting. Abrasive wear, which is erosion without corrosion, will also be discussed for comparison purposes.

Liquid erosion-corrosion is the accelerated wastage of a metal or material attributed to the flow of a liquid (Ref 100, 101, 102). Liquid erosion-corrosion damage is characterized by grooves, waves, gullies, rounded holes, and/or horseshoe-shaped grooves. Analysis of these marks can help determine the direction of flow. Most metals are susceptible to liquid erosion-corrosion under specific conditions. Carbon steels, for example, can be severely damaged by steam containing entrained water droplets. By contrast, the 300-series stainless steels at about the same hardness and strength level are very resistant to flowing wet steam. Virtually anything that is exposed to a moving liquid is susceptible to liquid erosion-corrosion. Examples include piping systems, particularly at bends, elbows, or wherever there is a change in flow direction or increase in turbulence; pumps; valves, especially flow control and pressure let-down valves; centrifuges; tubular heat exchangers; impellers; and turbine blades.

Surface films that form on some metals and alloys are very important in their ability to enhance resistance to liquid erosion-corrosion. Titanium is a reactive metal, but is resistant to liquid erosion-corrosion in many environments because of its very stable titanium dioxide surface film. The 300-series stainless steels, as mentioned above, are also resistant because of their stable passive surface films.

Both carbon steel and lead have relatively good resistance to certain concentrations of H_2SO_4 under low-to-moderate flow conditions. Both depend on a metal sulfate corrosion product film for resistance; however, both will fail fairly rapidly after removal of the sulfate film, even at low velocities.

Another example is the carbon steel and some low-alloy steels used to handle petroleum refinery fluids that contain hydrogen sulfide. At low velocities or under stagnant conditions, these materials are normally satisfactory because of formation of a tenacious protective iron sulfide film. However, with increased velocity, the film is eroded away, and very rapid attack occurs.

Velocity often increases attack, but it may also decrease attack, depending on the material of construction and the corrosive environment. For example, increasing the velocity causes accelerated attack of carbon steel in steam condensate by increasing the supply of dissolved oxygen and/or carbon dioxide to the steel surface. In cooling water, however, increased velocity often reduces the attack of carbon steel by improving the effectiveness of inhibitors and by reducing deposits and pitting in stagnant areas.

Many 300-series stainless steels are subject to pitting and crevice corrosion in seawater. However, they may exhibit good resistance if the seawater is kept flowing at a minimum critical velocity. This prevents the formation of deposits and retards general corrosion, pitting, and crevice attack. Table 4 shows the effects different seawater velocities have on the liquid erosion-corrosion of various metals.

Table 4 Corrosion of metals and alloys in seawater as a function of velocity

Material	Typical corrosion rate, $mg/dm^2/d$

Cavitation is a form of erosion-corrosion that is caused by the formation and collapse of vapor bubbles in a liquid against a metal surface (Ref 102, 103, 104, 105, 106). Cavitation occurs in hydraulic turbines, on pump impellers, on ship propellers, and on many surfaces in contact with high-velocity liquids subject to changes in pressure. Cavitation can occur if the pressure on a liquid is reduced sufficiently to cause boiling even at room temperature. Boiling produces bubbles that collapse on the high-pressure cycle. Rapidly collapsing vapor bubbles produce shock waves that have developed pressures as high as 414 MPa (60 ksi).

The appearance of cavitation (Fig. 11) is similar to pitting except that surfaces in the pits are usually much rougher. Most investigators believe that cavitation damage is caused by a combination of corrosion and mechanical effects. Apparently, the collapsing vapor bubbles mechanically destroy the protective surface films. Thus, fresh surfaces are exposed to corrosion and the reestablishment of protective films, which is followed by more cavitation, and so on. Damage occurs when the cycle is allowed to repeat over and over again, for example, when a pump is operated "dead headed" against a closed valve. Table 5 shows the relative cavitation resistance of a variety of metals and alloys in water and seawater.

Table 5 Resistance of metals and alloys to cavitation damage in vibratory testing at 25 °C (75 °F)

Fretting is erosion-corrosion that occurs at the contact area between two metals under load and subject to slight relative movement by vibration or some other force (Ref 108, 109, 110). Damage begins with local adhesion between mating surfaces and progresses when adhered particles are ripped from a surface and react with air or other corrosive environment. Affected surfaces show pits or grooves with surrounding corrosion products. On ferrous metals, corrosion product is usually a very fine, reddish iron oxide; on aluminum, it is usually black.

Fretting is detrimental not only because of the destruction of metallic surfaces but also because of a severe effect on the fatigue life. It has been shown that fretting can reduce the endurance limit of a metal by 50 to 70% (Ref 109).

The relative motion necessary to produce fretting is very small. Displacements as small as 10^{-8} cm have produced fretting. Fretting generally does not occur on contacting surfaces in continuous motion, such as ball or sleeve bearings.

Fretting can be minimized or eliminated in many cases by one or more of the following:

- Increasing the hardness of contacting surfaces. This may mean increasing the hardness of bother just one of the components. Surface-hardening treatments such as shot peening, nitriding, chrome plating, and carburizing are beneficial
- Increasing the friction between the mating members by roughening or by plating (lead, copper, nickel, silver, gold)
- Applying phosphate coatings to exclude air or applying anaerobic sealants or adhesives to increase the tightness of the fit
- Increasing the fit interference, which reduces slippage by increasing the force on mating components
- Switching to materials with more fretting resistance, as shown in Table 6

Table 6 Relative fretting resistance of various material combinations

Combination	Fretting resistance
Aluminum on cast iron	**Poor**
Aluminum on stainless steel	**Poor**

Abrasive wear is damage that results from the action of hard particles on a surface under the influence of a force that is oblique to the surface (Ref 112, 113, 114, 115, 116, 117). This is not, strictly speaking, a form of erosion-corrosion, but will be briefly discussed for comparison with the forms of erosion-corrosion mentioned above.

Three common forms of abrasive wear are erosion abrasion, grinding abrasion, and gouging abrasion. Erosion abrasion usually involves low velocities and weak support of the abrasive material. Examples are wear on a plowshare in sandy soil and polishing of a metal surface with an abrasive held in a soft cloth. Thus, the energy of the abrasive is quite low, and impact is absent.

Grinding abrasion is the fragmentation of the abrasive, usually between two strong surfaces. Examples are a lapping operation in a machine shop and ball/rod mill grinding. Thus, impact is low to moderate, but the gross stress may be quite high, at least on a microscopic scale.

Gouging abrasion is recognized by the prominent grooves or gouges that are present on the wearing surfaces. Examples are abrasive disk grinding, machine tool cutting, and wear of power shovel bucket teeth. Heavy impact is generally associated with this type of abrasion, along with gross stress.

To alleviate these forms of abrasion, a careful study of the type of abrasion and an understanding of the service conditions are required. The material selection should be based on the known properties of materials versus service requirements. More information on metal wear and corrosion is available in the article "Mechanically Assisted Degradation" in this Volume; the article "Wear Failures" in *Failure Analysis and Prevention,* Volume 11 of *ASM Handbook,* formerly 9th Edition *Metals Handbook* contains information on abrasion and wear.

Other Forms of Corrosion. Selective leaching, also known as dealloying or parting corrosion, occurs when one element is preferentially removed from an alloy, leaving an often porous residue of an element that is more resistant to the environment. It is a problem of commercial significance in copper alloy systems (Ref 118), primarily copper-zinc and copper-aluminum and, to a lesser extent, copper-nickel. The terms dezincification, dealuminization, and denickelification describe the selective leaching of zinc, aluminum, and nickel, respectively, from the alloys. In these cases, a porous residue of copper remains, either as a fairly uniform layer or in plugs. The latter is more damaging in that the effect is similar to pitting corrosion.

Selective leaching in copper alloy systems occurs primarily in certain waters, especially under deposits in stagnant areas in heat exchangers. Alloy additions of arsenic, antimony, or phosphorus are effective in inhibiting this attack, but only in copper-zinc alloys. Thus, arsenical or antimonial admiralty brass (UNS C44300 and C44400, respectively) is specified, for example, where this alloy is required for water service.

Graphitic corrosion of cast iron is another commercially important form of selective leaching. In this case, the iron matrix corrodes, leaving behind a porous graphite mass that can be carved with a pocket knife. Cast iron underground municipal

watermains (Ref 119) and fire watermains at petrochemical plant sites are affected by graphitic corrosion from both the soil and water sides. Internal cement linings and external protective coatings, with cathodic protection in severely corrosive soils, are relatively low-cost solutions to watermain corrosion problems. The section "Dealloying Corrosion" of the article "Metallurgically Influenced Corrosion" in this Volume contains more information on the phenomenon of dealloying.

Exfoliation is a form of localized corrosion that primarily affects aluminum alloys. Corrosion proceeds laterally from initiation sites on the surface and generally proceeds intergranularly along planes parallel to the surface. The corrosion products that form in the grain boundaries force metal away from the underlying base material, resulting in a layered or flakelike appearance. Extruded products from the 2000-series copper-magnesium alloys, the 7000-series zinc-copper-magnesium alloys, and, to a lesser extent, the 5000-series alloys are particularly susceptible to exfoliation in both marine and industrial environments. Also, at least one case affecting 6000-series magnesium-silicon alloys in freshwater service has been reported (Ref 120).

This attack is generally associated with the alloy fabrication method and temper, impurities in the alloy matrix, and the distribution of intermetallic compounds at the surface and in grain boundaries. Aluminum alloys 1100, 3003, and 5052 are resistant. Standard test methods for determining susceptibility to exfoliation corrosion in aluminum alloys are covered in ASTM standards G 34 and G 66.

Liquid-metal embrittlement (LME), also known as liquid metal assisted cracking, is not considered to be a corrosion phenomenon, except in cases involving aqueous mercury compounds (Ref 121). However, LME is discussed here because it is a problem frequently encountered by materials engineers. Liquid-metal embrittlement is the penetration, usually along grain boundaries, of metals and alloys by such metals as mercury, which are liquid at room temperature, and metals that have relatively low melting points, such as bismuth, tin, lead, cadmium, zinc, aluminum, and copper. Stress, temperature, and time are the factors that facilitate and accelerate LME. Virtually all metal and alloy systems are subject to LME by one or more of these metals at or above their melting points.

Zinc is a prime offender because of widespread use throughout industry in the form of corrosion-resistant coatings applied to carbon steels by hot-dip galvanizing, electroplating, tumbling, and spray painting. Plain carbon steels are embrittled by zinc at temperatures above 370 °C (700 °F) for long periods of time, especially when the steel is heavily stressed or cold worked.

Austenitic stainless steels and nickel-base alloys will also crack in the presence of molten zinc. These alloys usually crack instantly when welded to galvanized steel, a fairly common occurrence in the chemical-processing industry. In addition, austenitic alloy failures have occurred:

- In high-temperature bolting fastened with galvanized steel nuts
- During welding or heat treating of components contaminated by grinding with zinc-loaded grinding wheels, contact with zinc-coated structurals or slings, or exposure to zinc paint overspray
- During process industry plant fires involving piping and vessels (thin-wall expansion joint bellows are especially susceptible) sprayed with molten zinc from coated steel structures

Thus, it is imperative that all traces of zinc be removed from coated steel members before welding to austenitic alloys and before intimate contact with these alloys at temperatures above 370 °C (700 °F). Also, austenitic stainless steels and nickel-base alloys should be handled with non-coated steel hoist chains, cables, and structurals; they should be dressed and cleaned with new grinding wheels and stainless steel brushes, and they should be marked with materials (paints, crayons, and so on) free from zinc and other low-melting metals.

Cadmium is probably second to zinc in importance as an agent of liquid-metal embrittlement, because of its application as a corrosion-resistant coating to a variety of hardware, particularly fasteners. Failures by cadmium LME of bolting operating at temperatures above 300 °C (570 °F) and fabricated from such high-strength alloy steels as AISI 4140 and 4340 and austenitic stainless steels are fairly common. In fact, some high-strength steels and high-strength titanium alloys are embrittled by cadmium at temperatures below its melting point by mechanisms not yet understood. The solution to LME by cadmium is similar to that of zinc, that is, avoidance of contact with, and contamination of, susceptible metal and alloy systems at temperatures above the 321 °C (610 °F) melting point of cadmium (and at all temperatures at which high-strength steels and titanium alloys are involved).

Metal systems that are embrittled by contact with mercury include copper and its alloys, aluminum and its alloys, Nickel 200 (at elevated temperatures) and Monel alloy 400, and titanium and zirconium and their alloys. Cracking is intergranular except in zirconium alloys; in these alloys, cracking is transgranular. Mercury LME of aluminum and copper alloys was more common years ago in the petrochemical industry when mercury-filled manometers and thermometers were extensively used. Failures or upsets would release mercury into process or service (steam, cooling water, and so on) streams, causing widespread cracking of piping, heat exchanger tube bundles, and other equipment. Under these conditions, even pure aluminum and pure copper are susceptible. With regard to the titanium system, the commercially pure grades used in the chemical-processing industry are less sensitive than the alloys. In addition, LME in aqueous solutions of mercurous salts, such as mercurous nitrate, is possible because the mercurous ion can be reduced to its elemental form at local cathodic sites.

Although not a metal, sulfur will penetrate the grain boundaries of nickel and nickel alloys at elevated temperatures in much the same way as in the low-melting metals mentioned above. Sulfur forms a very aggressive nickel-nickel sulfide eutectic alloy that metals at about 625 °C (1157 °F). Sources other than elemental sulfur include organic compounds (greases, oils, cutting fluids) and sulfates. Thus, contamination from these sources before welding, hot forming, annealing, and other heating operations must be avoided (see the section "Liquid-Metal Embrittlement" of the article "Environmentally Induced Cracking" in this Volume).

Economics

Cost-Effective Materials Selection. The two extremes for selecting materials on an economic basis without consideration of other factors are (Ref 122):

- *Minimum cost:* Selection of the least expensive material, followed by scheduled periodic replacements or correction of problems as they arise
- *Minimum corrosion:* Selection of the most corrosion-resistant material regardless of installed cost or life of the equipment

Cost-effective selection generally falls somewhere between these extremes and includes consideration of other factors, such as availability and safety. For example, critical components in a large single-train chemical-processing plant should be fabricated from materials that tend toward the minimum corrosion extreme because failure could shut down the entire operation. However, component materials for a multitrain or batch operation, especially one that processes a relatively short-lived product, might tend toward the minimum cost extreme, even to the point of purchasing used equipment at a fraction of the cost of new fabrication. Thus, different strategies are appropriate for different situations. Additional information is available in the article "Corrosion Economic Calculations" in this Volume.
